Family health history. It is customary to start with the siblings of the patient (**the proband**), proceed to the parents and the parents' siblings and their children, and then consider the 4 grandparents and their siblings. This approach is more helpful than the generic question, "Does anyone in the family have anything like this?" Many parents may be unaware of neonatal deaths in older relatives (the proband's grandparents or uncles and aunts). Most people are unfamiliar with the term *consanguinity,* but the examiner can ask whether there are ancestors in common or inquire about the place of origin and the size of the community from which the families derive. Maiden names of women should always be noted. Self-identified, remote ancestry may help identify a fruitful area to investigate because certain conditions may be more common in certain ethnic population groups. Consanguinity refers to couples who have ancestors in common within 2 or 3 generations, whereas group identity is not consanguinity.

Pregnancy and birth history. Maternal health and concurrent illness with treatment is a critical part of the evaluation. Details of participation in prenatal screening programs and prenatal evaluations can help resolve uncertainties that arise during the evaluation. On occasion, a discrepancy is discovered between an ultrasound report and a neonatal clinical finding: for example, a "normal" cerebellum reported at 17 weeks of gestation and absence of the cerebellum at term. Before concluding that some process happened between 17 and 40 weeks of gestation, it is important to review the actual studies done at 17 weeks. This type of investigation can help pinpoint the timing of in utero problems or can eliminate erroneous hypotheses if the study of the fetus at 17 weeks was actually incomplete or inconclusive. Viral and other infectious illnesses and rashes are germane to note, as are times of exposure during the pregnancy. Parvovirus B19, rubella virus, cytomegalovirus, *Toxoplasma* species, herpes simplex virus, varicella virus, and *Treponema pallidum* (syphilis) are microorganisms that can

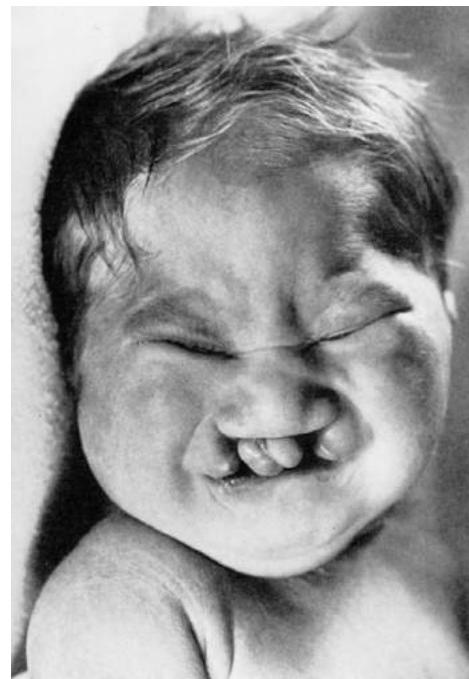

FIGURE 25.10 Facial appearance of a child with trisomy 13. (From Wiedemann HR, Kunze J, Dibbern H. *Atlas of Clinical Syndromes: A Visual Guide to Diagnosis*. 3rd ed. St. Louis: Mosby; 1989.)

TABLE 25.4 Clinical Findings That May Be Present with Trisomy 21*	
Stature smaller than that of peer age group	Lax joints, including laxity of the atlantoaxial articulation (the latter predisposing the patient to C1–C2 dislocation)
Developmental delays	Short, broad hands, feet, and digits; single palmar crease, clinodactyly
Congenital heart disease (e.g., endocardial cushion defect and ventricular septal defect)	Exaggerated space between 1st and 2nd toes
Structural abnormalities of the bowel (e.g., tracheoesophageal atresia, duodenal atresia, annular pancreas, duodenal web, and Hirschsprung disease)	Velvety, loosely adhering mottled skin (cutis marmorata) in infancy; coarse, dry skin in adolescence
Central hypotonia	Statistically increased risk for leukemia, Alzheimer disease, hypothyroidism
Brachycephaly	
Delayed closure of fontanels	
Small midface, hypoplastic frontal sinuses, myopia, and small (short) ears	

*An individual may exhibit any combination of these findings. There is no correlation between the number of physical findings and eventual level of mental performance. The increased risk for leukemia is significant, but probably no >1% for any individual. Alzheimer disease is relatively common in persons with trisomy 21 who die in middle adult life, but its frequency in all adults with Down syndrome is not known.
From Behrman RE, Kliegman RM. *Nelson Essentials of Pediatrics*. 4th ed. Philadelphia: Saunders; 2002:142.

be teratogenic or affect organ function. Fetal exposure to these organisms at a vulnerable time can be critical; conversely, exposures after formation of an organ are not expected to have a morphologic effect on the organ. Perinatal anoxia is often blamed for infants' problems, but infants with a syndrome or genetic condition may be predisposed to perinatal problems, including fetal distress or neonatal adaptive difficulties.

Developmental history. A developmental history establishes the pattern for acquisition of developmental milestones. A screening tool such as the Denver Developmental Assessment Test can assist in the evaluation of younger children. It is important to establish whether a child is making progress, remaining static, or showing signs of

developmental regression by losing landmarks of development. The last possibility is the most ominous for prognosis and warrants aggressive evaluation for diagnosis and possible treatment.

Prior medical concerns including all evaluations and investigations to date should be reviewed. It is often necessary to delay the initial consult so that past medical records can be made available for thorough review.

Examination

The details of morphology are documented in much more detail than is ordinarily the case in a general physical examination. Diagnosis is often based on the language used in the description. Even if a diagnosis

is not clear, the description is the starting point of the evaluation. It is helpful to have an anatomic outline for assessing morphology in an orderly and systematic manner.

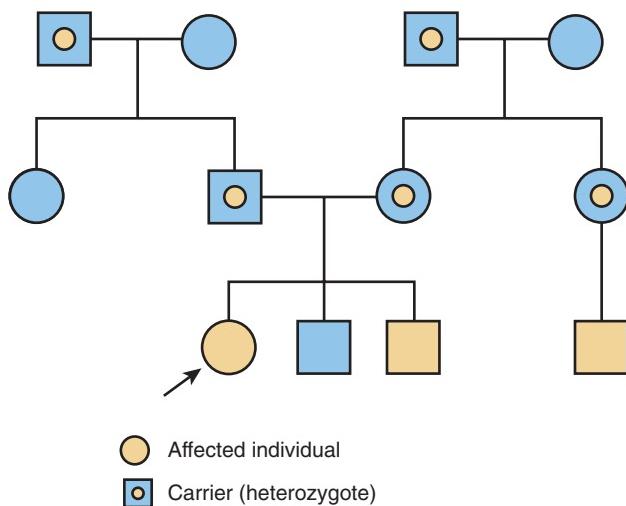
There are few opportunities to follow a predetermined flow for the examination in most young children, but it is important to maintain a level of structure to the data collection process so as not to overlook a critical finding. It is also good practice to obtain photographs of the face with frontal and side profiles for later reflection and utilization of newer facial recognition tools.

FIGURE 25.11 Pedigree showing affected individuals and carriers. (From Marcdante KJ, Kliegman RM. *Nelson Essentials of Pediatrics*. 7th ed. Philadelphia: Elsevier; 2015:147; Figure 47-1.)

Initial Inspection

General observation of the patient is important. The office visit is a small snapshot in the life of the person being evaluated. Subtle movements, behaviors, and social interactions may be key to the underlying diagnosis. Children with Williams syndrome are exceptionally sociable with verbose language skills and frequently have a coarse character to their voice, whereas on the opposing end, children with autism may not permit you to perform a complete physical examination and the greatest opportunity to evaluate movements and physical traits is while you are initially interviewing the parents or caregivers.

Anthropometrics

The Centers for Disease Control and Prevention has published growth curves for children and adolescents that are based upon a heterogeneous U.S. population more representative of various ethnic and ancestral groups than were previous charts. There are separate curves for height, weight, head circumference, and stature for boys and girls aged 0-36 months, and there are corresponding curves for boys and girls aged 2-18 years, in addition to curves for body mass index, but without curves for head circumference. There are also references for anthropometric measurements of various body parts from the fetus to adult age. If a child's measurements are discrepant from the norms— that is, *over the 97th percentile* or *under the 3rd percentile*—it is possible to transpose the actual measurement up or down to the 50th percentile on the same line to determine the height age or weight age equivalent. Height can be plotted versus weight on the stature curve to determine whether these parameters are proportional. Thus, a child can be identified as small or tall for age and appropriate or inappropriate in weight (either too heavy or too thin) for height. A child with short stature and proportionate weight has proportionate short stature. Head growth is an important factor in assessing brain growth as well as skull growth


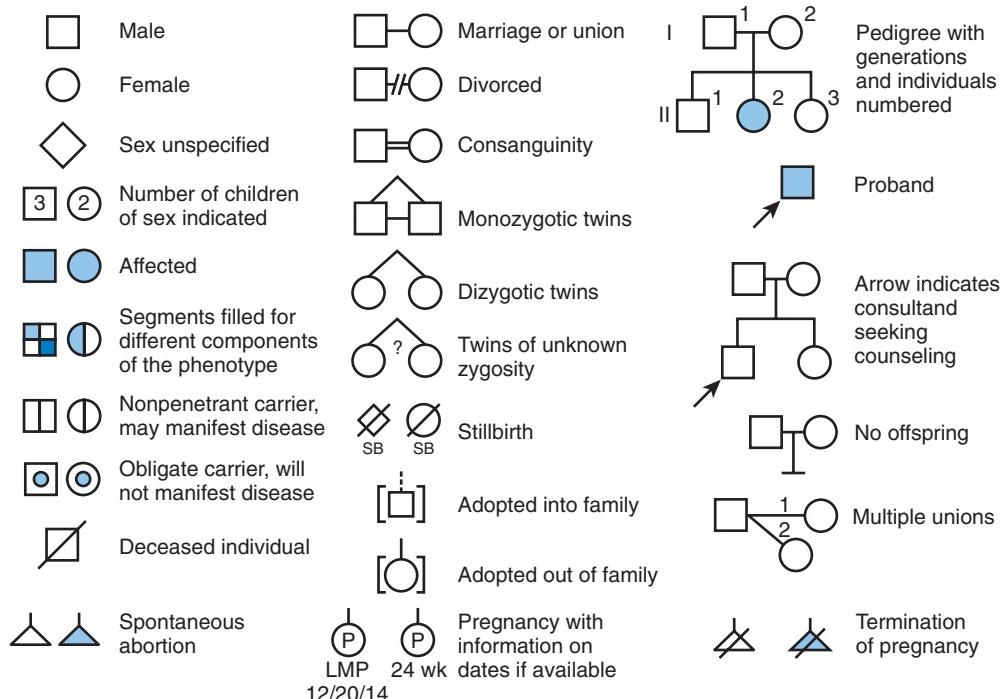


FIGURE 25.12 Symbols commonly used in pedigree charts. Although there is no uniform system of pedigree notation, the symbols used here are according to recent recommendations made by professionals in the field of genetic counseling. (From Nussbaum RL, McInnes RR, Willard HF, eds. *Thompson and Thompson Genetics in Medicine*. 8th ed. Philadelphia: Elsevier; 2016:109.)

and suture closure. Abnormally small head size (**microcephaly**) and abnormally large head size (**macrocephaly**) are considered in proportion to stature with consideration for chronologic age. A child 7 years of age but with a height age of 4 years and proportionate weight and head circumference does not truly have microcephaly but proportionate short stature. Standardized tables exist in various reference resources for several ethnic groups that allow for assessment across racial barriers. Additionally standardized charts exist for known syndromes so that normal growth can be appropriately evaluated in a child with a known diagnosis.

A helpful diagnostic assessment for children of discrepant size is the **bone age**, determined by radiograph: generally of the left hand and wrist, according to the standards of Gruleich and Pyle, but occasionally, for infants, by radiograph of the hemiskeleton.

The data collection should include the following highlights with more detail completed as needed.

Head and Neck

- Hair: distribution, texture, pigmentation, low posterior hairline (Fig. 25.13)
- Skull: shape, fontanel
- Neck: mobility, adenopathy, thyroid, embryonic remnants (branchial arch)

FIGURE 25.13 Turner syndrome. *A–C,* Note prominent ears, loose folds of skin in posterior neck with low hairline, broad chest with widely spaced nipples. (Courtesy Dr. Lynne M. Bird, Children's Hospital, San Diego; From Jones KL, Jones MC, Del Campo M, eds. *Smith's Recognizable Patterns of Human Malformation.* 7th ed. Philadelphia: Elsevier; 2013:81.)

Face

- Forms the largest and most important aspect of the dysmorphic evaluation.

General "Rules"

- 1/3s = forehead-nasion : nasion-subnasale : subnasale-chin = 1 : 1 : 1
- Perpendicular from pupils should meet corners of mouth
- Inner canthal distance should allow space for an additional eye (on magnetic resonance imaging [MRI] space between globes should allow an additional globe)
- Top of ear should align with eyebrow/line through pupils should align with root of outer helix.
- Forehead: slope, breadth, height, prominence
- Eyebrows: thickness/fullness, arch
- Eye: distance (hyper- or hypotelorism), color, pupil shape, presence of epicanthus or telecanthus, alignment (up- or down-slanting)
- Ears: overall shape/architecture, position, rotation, pits, creases, hearing
- Nose: root, bridge, tip, columella, nasolabial fold, alae nasi, philtrum
- Mouth: lips thickness and shape, lip pits, mucosal lesions, dental alignment, dentition, palate, uvula
- Chest: shape, pectus, nipples, breathing
- Abdomen: organomegaly, masses, hernia
- Genitalia: structure, size, Tanner stage, anus, and perineum
- Musculoskeletal: spine alignment, joint mobility (Fig. 25.14 and Table 25.7), proportions, finger length, palmar surfaces, nail health.
- Neurologic evaluation: complete including development, behavior and modified mini-mental examination, and observation for unique movements or behaviors.

If a child has an unusual appearance and the differences do not seem to be familial variations as judged by observing the parents, it is necessary to describe how the child appears different. When the variation is a discontinuous variable—that is, a birth defect (e.g., there is an extra digit on the ulnar side of each hand; there is a cleft of the lip on the left that extends into the left nostril, and there is a notch in the gum behind the cleft)—the task is easier. Such birth defects may be considered major abnormalities. The subtle malformations are often minor abnormalities, but both major and minor findings are relevant to diagnosis. Some conditions may be obvious on inspection alone, especially to an experienced observer. Typical manifestations of Down syndrome (Figs. 25.15 and 25.16; see also Tables 25.4 and 25.5 and Fig. 25.9), trisomy 13 or 18 (Figs. 25.17 and 25.18; see also Table 25.6 and Fig. 25.10), severe manifestations of Cornelia de Lange syndrome, and those of Williams syndrome may represent a quick diagnosis; however, even these classical syndromes may manifest in atypical and subtle ways, and careful assessment is necessary to identify them. The expectation that, with enough experience, a physician, even a geneticist or a dysmorphologist, can unerringly identify every case of a common syndrome (even one so common and well known as trisomy 21) is not true. Human diversity is so great that even the most experienced clinicians are glad for confirmatory tests. Most cases of trisomy 21 can be identified by inspection, but there is not the same degree of certainty about every dysmorphic patient.

ASSEMBLING THE DATA

After the history and examination are complete, the abnormal findings are listed. In general, the order is in a sequence ranked by perceived importance. In determining the order, the clinician may consider the magnitude of the deviation, but uniqueness is important in

differentiating conditions. Subtleties can be significant; for example, **inverted nipples** (common in carbohydrate-deficient glycoprotein syndrome) or **redundant umbilical skin** (in company with abnormal anterior chamber of the eye and abnormally shaped teeth in Rieger syndrome) can be very helpful in identifying a condition.

The description of history and morphology becomes the working diagnosis. Even if the clinician cannot find a match in the standard references concerning the syndrome identification, a descriptive diagnosis is invaluable for providing the constellation of findings that delineate the problems.

MINIMAL DIAGNOSTIC CRITERIA

The key phenotypic elements of a syndrome, which unquestionably identify it and differentiate it from all other similar conditions, have been termed the *minimal diagnostic criteria*. In the absence of a definitive laboratory test, establishing the diagnostic criteria is a logical and ideal goal for achieving uniformity of diagnosis.

Unfortunately, minimal diagnostic criteria are difficult to decide upon and are enumerated for only a few conditions. Reasonably successful efforts for identifying diagnostic criteria for 2 relatively common conditions, **neurofibromatosis type 1 (NF1)** (Table 25.8) and **Marfan syndrome** (Table 25.9), have been achieved and updated through consensus conferences. The molecular abnormalities for each condition have been identified, but the absence of a molecular result does not exclude the diagnosis, and in the case of Marfan syndrome, the molecular finding itself is not sufficient for a diagnosis.

In NF1, a family history that includes an affected parent is a major help (and major criterion) for diagnosis. When there is no positive family history, an index case requires additional criteria. The criteria are quite specific and include easily documented findings. However, criteria do not include learning disabilities, intellectual disability, scoliosis, short stature, asymmetric limb growth, endocrine and neuroendocrine tumors, hypertension, or epilepsy, any of which may be present in NF1. These conditions are germane but not unique to NF1.

The concept of minimal diagnostic criteria is laudable but difficult to achieve. When available, the minimal diagnostic criterion is the confirmatory laboratory test; however, the confirmatory laboratory test does not necessarily define the parameters of the phenotype of the syndrome as is noted in the example of Marfan syndrome and *FBN1* gene variants.

TOOLS TO ASSIST THE DIAGNOSTIC ODYSSEY

Reference books on syndromology, human malformations, and deformations are excellent resources for assistance with diagnosis; however, most illustrations in texts focus on individuals with the most exaggerated findings to illustrate the condition. Birth defects are discrete (discontinuous) variables, but human features occur in a continuum. Diagnosis becomes a process of identifying the variables by a systematic evaluation of the entire individual.

Technology has eliminated some of the art forms once common practice (e.g., dermatoglyphics or the analysis of finger and palm ridge patterns).

The advent of broader molecular screening tools for diagnosis has limited the initial quest for a clinical diagnosis as the relatively high prevalence of copy number variations (microdeletion/duplication disorders) has established chromosome microarrays as the first-line standard of care in the evaluation of a child with multiple congenital anomalies, developmental delays, or autism spectrum behaviors. This is supported by the American College of Medical Genetics as well as the U.S. Food and Drug Administration (FDA). Common

FIGURE 25.14 Beighton Hypermobility Score. *A,* Passive dorsiflexion of the fifth metacarpophalangeal joint. Score is positive if ≥90 degrees (bilateral testing). *B,* Passive hyperextension of the elbow. Score is positive if ≥10 degrees (bilateral testing). *C,* Passive hyperextension of the knee. Score is positive if ≥10 degrees (bilateral testing). *D,* Passive apposition of the thumb to the flexor side of the forearm, while the shoulder is 90 degrees flexed, elbow extended, and hand pronated. Score is positive if the whole thumb touches the flexor side of the forearm (bilateral testing). *E,* Forward flexion of the trunk with the knees straight. Score is positive if the hand palms rest easily on the floor. (From Smits-Engelsman B, Klerks M, Kirby A. Beighton score: a valid measure for generalized hypermobility in children. *J Pediatr*. 2010;158:119-123.)

TABLE 25.7 9-Point Beighton Score of Hypermobility

Description	Bilateral Testing	Scoring (Max. Points)
Passive dorsiflexion of the 5th metacarpophalangeal joint to ≥90 degrees	Yes	2
Passive hyperextension of the elbow >190 deg in females and >180 deg in males	Yes	2
Passive hyperextension of the knee >190 deg in females and >180 deg in males	Yes	2
Passive apposition of the thumb to the flexor side of the forearm, while the shoulder is flexed 90 degrees, elbow is extended, and hand is pronated	Yes	2
Forward flexion of the trunk, with the knees straight, so that the hand palms rest easily on the floor	No	1
Total		**9**

FIGURE 25.15 Characteristic dermal patterns of the palm of a child with Down syndrome: a single flexion crease (simian crease), axial tri-radius *(arrowhead)* in distal position, a pattern area on the palm between the third and fourth digits, and ulnar loops on all 10 digits. (From Nussbaum RL, McInnes RR, Willard HF. *Thompson and Thompson Genetics in Medicine*. 6th ed. Philadelphia: Saunders; 2001:160.)

TABLE 25.8 Diagnostic Criteria for Neurofibromatosis Type 1*

1. Family history (an affected parent)
2. 6 or more café-au-lait spots
   >0.5 cm in prepubertal children
   >1.5 cm in postpubertal children
3. 1 or more plexiform neurofibromas
4. 2 or more neurofibromas
5. Freckling of the armpits or in skin folds
6. 2 or more Lisch modules of the iris
7. Optic glioma
8. Osseous dysplasia of the sphenoid bone and/or long bones

*There must be positive findings in 2 or more categories.
From National Institutes of Health Consensus Developmental Conference. Neurofibromatosis conference statement. *Arch Neurol.* 1988;45:575.

chromosomal deletion and duplication disorders can be identified in this way (Table 25.10).

Utilization of specific genetic databases such as POSSUM (Pictures of Standard Syndromes and Undiagnosed Malformations) or LMD (London Medical Databases) relies on cross-referencing the presence of specific dysmorphologic features to create differential diagnoses. These resources, however, require an annual subscription and are curated by affiliated academic programs. Free resources that use the standardized ontologic nosology include OMIM (Online Mendelian Inheritance in Man; http://www.omim.org/) and Phenomizer (http://compbio.charite.de/phenomizer/), which similarly allow the end user to generate lists of potential diagnoses.

Novel technologic approaches such as utilization of facial recognition software in order to generate possible differential diagnoses are being developed and are playing an increasingly important role as experienced dysmorphologists become an endangered species. The most successful implementation of a mobile application called Face2Gene (http://www.fdna.com/face2gene/). This software is compliant with the Health Insurance Portability and Accountability Act (HIPAA) and gaining more acceptance as a powerful clinical tool in the dysmorphic evaluation as it utilizes facial heat mapping signatures to generate visual differential diagnoses that allow complex database analysis using standardized ontology to search clinical findings in OMIM, LMD, and POSSUM.

Genetic Testing

The catalog of available tests has expanded exponentially over the past decade, and as large-scale sequencing becomes more accessible and affordable, genomic analysis is not far away from becoming standard of care. The primary limitation of this testing is our current ability to interpret all the variation and to connect relevance of this variation to the clinical phenotype being evaluated. It thus remains important to collect and identify crucial/significant data elements that assist in the interpretation of the tests ordered. Broad panels encompassing common phenotypes are available for complex heterogeneic disorders such as epilepsy or cardiomyopathy. To assist in the identification of laboratories offering specific testing, a company offering global laboratory listing was established (https://www.genetests.org/).

Testing itself should be judiciously selected to confirm a diagnosis or gather more information to enable a diagnosis to be formulated. Before any laboratory or imaging testing is done, the examiner should address the question "Does the description correlate with a described condition or syndrome?" Often, the working diagnosis is the succinct and relevant description of the child, which amounts to a list of

TABLE 25.9 Revised Ghent Criteria for the Diagnosis of Marfan Syndrome

The revised criterion place more emphasis on aortic root dilatation/dissection and ectopia lentis

I: In the **absence of family history**: MFS DX if:
   (1) Aortic root dilated/dissected (Z ≥2) AND Ectopia Lentis (EL)*
   (2) Aortic root dilated/dissected (Z ≥2) AND FBN1
   (3) Aortic root dilated/dissected (Z ≥2) AND Syst (≥7 points)*
   (4) Ectopia Lentis with normal aortic root AND FBN1 mutation associated with Aortic root dilated/dissection

II: In the **presence of family history**: MFS DX if:
   (5) EL AND FH of MFS
   (6) Systemic feature score (≥7 points) AND FH of MFS*
   (7) Ao (Z ≥2 above 20 years old, ≥3 below 20 years) + FH of MFS*

***Caveat**: without discriminating features of Shprintzen–Goldberg syndrome, Loeys–Dietz syndrome, or Vascular EDS **AND** after TGFBR1/2, collagen biochemistry, COL3A1 testing if indicated.
(Other conditions/genes will emerge with time.)

Scoring of systemic features: Max total: 20 points; score ≥7 points indicates systemic involvement
- Wrist AND thumb sign **[3]** (wrist OR thumb sign **[1]**)
- Pectus carinatum deformity **[2]** (pectus excavatum or chest asymmetry **[1]**)
- Hindfoot deformity **[2]** (plain pes planus **[1]**)
- Pneumothorax **[2]**
- Dural ectasia **[2]** *(sensitive, but not specific; not considered equal to lens dislocation or aortic root enlargement)*
- Protrusio acetabuli **[2]** *AP Pelvis:* medial protrusion of the acetabulum at least 3-mm beyond the ilioischial line
- ↓US/LS** **AND** ↑arm span/height (>1.05) AND no severe scoliosis **[1]**
- Scoliosis (≥2 degrees) or thoracolumbar kyphosis **[1]**
- Reduced elbow extension **[1]** 170 degrees or less upon full extension
- Facial features (3/5) **[1]** (dolichocephaly, enophthalmos, downslanting palpebral fissures, malar hypoplasia, retrognathia)
- Skin striae **[1]** *(abnormal position or excessive)*
- Myopia > 3 diopters **[1]**
- Mitral valve prolapse (all types) **[1]**

US/LS** (normal upper to lower segment ratios)
   White adults, 0.85; black adults, <0.78
   Children 0–5 yo <1; 6–7 yo <0.95; 8-9 yo <0.9

Major Differential Diagnoses
Ectopia Lentis syndrome: EL with or without Syst AND with an FBN1 not known with Ao or no FBN1
MASS phenotype: Ao (Z < 2) AND Syst (≥5 with at least 1 skeletal feature) without EL
Mitral Valve Prolapse syndrome: MVP AND Ao (Z <2) AND Syst (<5) without EL
Differential expanded, conditions with:
aortic aneurysms: LDS, bicuspid aortic valve, familial thoracic aortic aneurysm, vEDS, arterial tortuosity
ectopia lentis: ectopia lentis syndrome, Weill–Marchesani syndrome, homocystinuria, Stickler syndrome systemic features: Shprintzen–Goldberg syndrome, CCA, LDS, MASS phenotype and MVPS

Ao, aortic root dilatation/dissection; AP, anteroposterior; CCA, Congenital Contractural Arachnodactyly; DX, diagnosis; EDS, Ehlers-Danlos syndrome; FH, family history; LDS, Loeys-Dietz syndrome; LS, lower segment; MASS, Mitral valve, myopia, Aorta, Skin and Skeletal features; MVPS, Mitral Valve Prolapse syndrome; Syst, systemic feature score; US, upper segment; vEDS, Vascular type of Ehlers-Danlos syndrome; yo, years old.
From Loeys BL, Dietz HC, Braverman AC, et al. The revised Ghent nosology for the Marfan syndrome. *J Med Genet.* 2010;47:476-485.

TABLE 25.10   Some Chromosomal Deletion Syndromes for Which There Is a Commercially Available DNA Probe for Fluorescent In Situ Hybridization Analysis

Condition	Brief Description	Probe
Williams syndrome	Proportionate short stature, mild–moderate to severe intellectual disability, cocktail patter for conversation, stellate pattern of iris pigmentation, supravalvular aortic stenosis, recessed nasal bridge, and wide mouth with full lips	7q11
WAGR syndrome	Wilms tumor, aniridia, growth delay, intellectual disability, and genitourinary anomalies	11p13
Prader–Willi syndrome Angelman syndrome	Distinct syndromes with common or overlapping areas of deletion; phenotype depends on gender of the parent of origin of the deletion. *Prader–Willi syndrome:* hypotonia in infancy, short stature, obesity, mild–moderate and occasionally, severe intellectual disability, small hands and feet (caused by paternal deletion of 15q11-13 or maternal uniparental disomy for chromosome 15). *Angelman syndrome:* severe intellectual disability, absence of speech, ataxia, tremulous movements, large mouth, frequent drooling (caused by maternal deletion of chromosome 15q11-13 or paternal uniparental disomy)	15q11
Smith–Magenis syndrome	Brachycephaly, prognathism, self-destructive behavior, wrist biting, pulling out nails, head banging, indifference to pain, severe intellectual disability, hyperactivity, social behavior problems	17p11.2
Miller–Dieker syndrome	Microcephaly, narrow temples, hypotonia/hypertonia, abnormal posturing, seizures, severe to profound intellectual disability, poor growth, lissencephaly and other brain abnormalities on CT or MRI	17p13
Velocardiofacial (VCF) syndrome (overlaps with DiGeorge syndrome)	*VCF:* cleft palate, congenital heart disease, learning and/or behavior problems, long face, prominent nose, limb hypotonia, slender hands with tapering fingers. *DiGeorge syndrome:* T cell deficiency, immunoglobulin deficiency	22q11

CT, computed tomography; MRI, magnetic resonance imaging; WAGR, Wilms tumor, aniridia, genitourinary anomalies, and mental retardation.

TABLE 25.12   Genetic Testing in Congenital Heart Disease

Patient Features	What to Order
CHD with features suggestive of trisomy 21 or 45X	Karyotype
CHD with features of trisomy 13 or 18	STAT chromosome FISH 21/18/13
Conotruncal congenital heart lesion • Interrupted aortic arch • Pulmonary atresia with ventricular septal defect • Tetralogy of Fallot • Truncus arteriosus • Malaligned ventricular septal defect and/or features typical of 22q11.2 deletion syndrome	DNA microarray
Heterotaxy	DNA microarray Next generation sequencing heterotaxy panel
CHD with or without dysmorphic features/multiple anomalies	DNA microarray

CHD, congenital heart disease; FISH, fluorescent in situ hybridization.

findings arranged in order of importance or significance from the perspective of the examiner.

A further advance in molecular understanding is the identification of metabolic disorders that are associated with intellectual disability but have proven treatments. The publication by Dr. van Karnebeel: *The Treatable Intellectual Disability* (www.treatable-id.org) digital tool to enhance diagnosis and care for rare diseases impacted the initial testing recommendations for children with intellectual disability, and recommendations for initial evaluations as listed in Tables 25.11 and 25.12

have become more broadly implemented. Thus metabolic screening for disorders that would not have been detected through national newborn screening programs is routinely used in the evaluation of children with intellectual disability.

Diagnostic imaging is invaluable in assessing CNS malformations, cardiac structure and function, skeletal deformity, and abdominal organs. The rapid advances in imaging technology and resolution are additionally enabling functional studies as well as real-time metabolic analysis with spectroscopy when using MRI to study the brain.

Bone age testing is indicated with short stature, growth delay, or large stature. Complete skeletal surveys are one of the only ways to help delineate skeletal dysplasias but require expert interpretation.

Specialized laboratory testing is reserved to aid specific diagnostic investigation (e.g., muscle biopsy, fibroblast culture for enzyme analysis, electron microscopy of arterial walls or blood buffy coat). These specialized tests are performed by a small number of laboratories to aid the diagnosis of rare disorders and should ideally be left to the expert physician.

Irritable Infant

Angela L. Rabbitt

An irritable infant is a challenge to the caregiver and medical provider and is a common presenting complaint in early infancy. An irritable infant is defined here as a patient younger than 1 year of age who according to the caregiver, cries excessively or is excessively fussy. There are many causes, but most irritable infants do not have significant underlying pathologic processes. However, there are serious entities that must not be missed (Table 26.1).

Medical providers should also recognize the profound anxiety and stress that infant crying may place on families and other caregivers. Although excessive crying generally resolves with time, the family's beliefs about the cause of the crying can have a lasting effect on the way they interact with the child and their beliefs about the infant's health. Caregivers who perceived their infant's crying as excessive or inconsolable described higher rates of depression, strained family relationships, and guilt about their inability to calm the infant. Excessive crying may even trigger thoughts of harming the infant and is reported as a common trigger for child physical abuse. Additionally, infants with early cry-fuss problems in combination with family dysfunction are at higher risk for ongoing behavioral problems, highlighting the need for early identification and intervention in this population. Therefore, the provider's response when evaluating an irritable infant should be focused on diagnosing potentially treatable medical conditions and on addressing the caregiver's understanding and response to the crying.

DIAGNOSTIC APPROACH

Less than 5-10% of infants who present for medical care due to excessive crying will have a serious underlying etiology. However, a thorough medical evaluation is needed to identify the minority of infants with treatable issues, and in healthy infants a thorough evaluation may reassure caregivers.

The initial evaluation of an irritable infant starts with a careful history and physical examination with the intent of ruling out potentially emergent conditions and stabilizing the patient if indicated (Fig. 26.1). The physical examination should include a complete examination of all body systems with the clothing removed. Table 26.2 lists elements of the history and physical examination suggestive of emergent and common diagnoses that may present with a chief complaint of crying. The history should be comprehensive, given the wide array of possible diagnoses to consider. The history should include questions about the characteristics of the cry (the time of day, duration, whether it is associated with feeds) and any changes to the infant's typical crying pattern. Infants with a sudden increase in the frequency and duration of inconsolable crying compared to normal are more likely to have an underlying medical condition. Clinicians should also ask caregivers why they think the infant is crying in order to specifically address any fears about the infant's health.

In the majority of cases, the history and/or physical examination will suggest the diagnosis, which can be confirmed with the judicious use of laboratory and imaging studies. However, providers should be aware of potentially serious diagnoses that may present with vague symptoms of fussiness and few other signs or symptoms on physical examination, including neurologic conditions and certain fractures. In very young infants, the neurologic exam is a poor screening tool to detect subtle neuropathology, and intracranial injury may not be accompanied by external evidence of trauma. An accurate history of injury may be concealed or unknown to the presenting caregiver in cases of physical abuse, and the child may present for medical care after the symptoms of acute injury have resolved. In addition to questions about recent symptoms, medical providers should ask about any remote history of suspicious bruising or other injury. A history of previous neurologic symptoms, such as episodes of unexplained seizures, apnea, altered mental status, developmental delay, or periods of extreme lethargy, may suggest an occult head injury or other non-traumatic neuropathology. Consider a skeletal survey and/or head imaging in infants with this history.

Growth parameters, including head circumference, should be obtained. Increasing head circumference percentile may point to increased intracranial pressure in infants with otherwise vague symptoms. Though conditions such as constipation, gastroenteritis, and gastroesophageal reflux are most often benign, poor growth or developmental delay may indicate more severe disease or that another medical condition is causing the symptoms.

A urinary tract infection (UTI) may also present with vague symptoms of irritability in infants. This may be one of the few conditions in which laboratory or imaging leads to a diagnosis in the absence of a suggestive clinical picture. Some suggest that a urinalysis and culture should be a standard screening test in infants who present with crying.

When the history and physical examination do not suggest a diagnosis, additional laboratory or radiographic evaluation may be needed. In particular, if the infant is ill-appearing, has evidence of poor growth or developmental delay, or is persistently inconsolable beyond the initial assessment, laboratory and radiographic studies should be done (Table 26.3). Patients may need to be monitored in the hospital until a diagnosis can be established. Some tests to consider include:

- A complete blood cell count with differential, erythrocyte sedimentation rate, and/or C-reactive protein measurement (for infection or inflammation, sickle cell disease)
- Analysis of cerebrospinal fluid (for meningitis or encephalitis)
- Blood culture
- Serum pH and complete metabolic panel, amylase, and lipase (for Electrolyte abnormalities, metabolic diseases, abdominal trauma)
- Urinalysis and culture
- Stool guaiac (for intussusception, gastroenteritis, cow's milk allergy)
- A skeletal survey

TABLE 26.1   **Differential Diagnosis in the Irritable Infant**

Emergent/Urgent Diagnoses	Nonemergent/Urgent Diagnoses
Eyes, Ears, Nose, Throat	
Choanal atresia	Otitis externa
Corneal abrasion	Teething
Foreign body	
Glaucoma	
Otitis media	
Respiratory	
Airway obstruction (croup, foreign body)	Upper respiratory tract infection
Lower respiratory tract infection (pneumonia, bronchiolitis)	
Cardiovascular	
Congestive heart failure	
Supraventricular tachycardia	
Anomalous coronary artery

TABLE 26.2	**Clinical Presentation of Selected Diagnoses in Infants Presenting with Crying**	
Review of Systems	**Possible Physical Exam Findings**	**Diagnoses to Consider**
Eyes, Ears, Nose, Throat • Pain or irritation of 1 eye • Chronic or intermittent tearing	• Photophobia • Tearing • Foreign body seen on lid inversion • Corneal enlargement or clouding • Ocular enlargement • Optic nerve cupping • Photophobia	• Foreign body • Corneal abrasion • Glaucoma
• Difficulty breathing and cyanosis during feeds; symptoms improve with crying	• Inability to pass a nasogastric tube • Decreased air movement through nares	• Choanal atresia
• Otorrhea • Fever • Ear tugging • Decreased appetite	• Bulging or immobile tympanic membrane • Abnormal color or perforated tympanic membrane • Otorrhea	• Otitis media • Otitis externa
• Excessive drooling • Decreased appetite	• Inflamed gums • Tooth eruption • Erythema over frenulum	• Teething • Lacerated frenulum
Respiratory • Trouble breathing, cough, congestion	• Abnormal breath sounds • Respiratory distress	• Airway obstruction (foreign body, croup) • Pneumonia • Bronchiolitis
Cardiovascular • Tachypnea and diaphoresis with feeds • Trouble breathing • Easy fatigability • Pallor, cyanosis	• Tachycardia • Respiratory distress • Poor perfusion • Abnormal heart sounds • Abnormal breath sounds • Hepatomegaly • Cardiomegaly	• Congestive heart failure • Supraventricular tachycardia • Anomalous coronary artery • Myocarditis
Gastrointestinal System • Constipation (hard stools, <2 per wk)	• Nonspecific exam • Stool mass in left lower quadrant • Anal fissure	• Constipation
• Delayed passage of meconium, poor growth, vomiting	• Abdominal distention • Tight anal canal with empty ampulla	• Hirschsprung disease
• Vomiting • Poor feeding with or without poor weight gain • Crying associated with feeds • Diarrhea	• Nonspecific exam • Hematochezia	• Milk and/or soy protein allergy • Gastroesophageal reflux disease • Gastroenteritis
• Vomiting • Poor feeding • Abdominal pain	• Abdominal distention • Abdominal tenderness, guarding • Abdominal or pelvic mass	• Intestinal obstruction (volvulus, intussusception) • Peritonitis
• History of injury • No history or history of prior suspicious injury in abusive trauma	• With or without evidence of injury on exam • Nonspecific abdominal exam	• Abdominal trauma
• Forceful vomiting • Hungry between episodes of emesis	• Dehydrated • Palpable pyloric sphincter	• Pyloric stenosis
• Improper formula volume or mixing • Frustration with feeds • Poor latch • Feeding aversion • Poor growth • Vomiting • Excess gas	• Nonspecific exam	• Inappropriate feeding volume or technique

TABLE 26.2 Clinical Presentation of Selected Diagnoses in Infants Presenting with Crying—cont'd

Review of Systems	Possible Physical Exam Findings	Diagnoses to Consider
Genitourinary System		
• Testicular swelling	• Testicular swelling, tenderness	• Testicular torsion
• Previous urinary tract infection	• Suprapubic tenderness • Nonspecific exam	• Urinary tract infection
Musculoskeletal System		
• Decreased movement of an extremity • Increased crying with movement	• Swelling, tenderness, warmth, erythema, pain or crepitus with palpation or movement • Nonspecific exam	• Fractures • Soft tissue injury • Osteomyelitis • Septic arthritis • Diskitis
Skin		
• Rash • Purulent drainage • Itching	• Swelling, tenderness, warmth, erythema, rash	• Infection • Dermatitis • Insect bites
• Swollen appendage	• Well-demarcated line separating normal tissue from a distal dusky edematous appendage • Ligature deeply imbedded in a groove covered by edematous tissue	• Tourniquet syndrome
• Sudden onset of irritability • History of injury • No history of injury or prior suspicious injury in abusive trauma	• Bruising, laceration, burns	• Abusive or nonabusive trauma
• Hernia	• Dusky or nonreducible umbilical or inguinal bulge	• Incarcerated hernia
Central Nervous System		
• Lethargy • Vomiting • Seizures • With or without fever	• Abnormal neurologic exam • Ill-appearing • Papilledema • Enlarged head circumference	• Meningitis • Encephalitis • Increased intracranial pressure (hydrocephalus, intracranial hemorrhage) • Intracranial mass
• No history, or history of prior suspicious injury • Prior history of symptoms of increased intracranial pressure	• Nonspecific exam • Retinal hemorrhages (present in 85% of patients with abusive head trauma) • With or without other injuries	• Abusive or nonabusive head trauma
Miscellaneous		
• Medication administration • Illicit drug use by caregivers	• Nonspecific exam • Altered mental status • Tachycardia • Respiratory or cardiac compromise • Seizures	• Drug ingestion
• Maternal drug use in a newborn • Poor feeding • Vomiting • Sneezing, hiccups, diarrhea • Poor sleep • Tremors • Seizures	• Nonspecific exam	• Neonatal abstinence syndrome
• Vomiting • Poor growth • Developmental delay or regression • Seizures	• Dehydration and shock • Organomegaly • Abnormal neurologic exam • Jaundice • Dysmorphic features • Abnormal odor • Tachypnea	• Inborn error of metabolism

TABLE 26.2   Clinical Presentation of Selected Diagnoses in Infants Presenting with Crying—cont'd

Review of Systems	Possible Physical Exam Findings	Diagnoses to Consider
Miscellaneous (cont'd)		
• Lethargy • With or without fever • Seizures	• Ill-appearing • Cardiorespiratory compromise	• Sepsis
• Infant or family history of sickle cell disease • Trouble breathing	• Respiratory distress • Splenomegaly • Swelling and tenderness of the hands and feet	• Sickle cell crisis
• Recent immunizations	• Nonspecific exam	• Vaccine reaction
• Dysfunctional or chaotic home environment • Significant caregiver stress	• Nonspecific exam	• Poor infant-caregiver interaction
• Content between crying bouts • Feeding well • Normal development	• Nonspecific exam	• Normal infant crying

- Computed tomographic (CT) scan or magnetic resonance imaging (MRI) of the head (for intracranial hemorrhage, mass, or hydrocephalus)
- Comprehensive urine drug screen

In the **consolable infant** without history or physical examination findings suggestive of a serious condition, nonemergent causes of crying are more likely (see Table 26.1). The most likely diagnosis in infants younger than 4 months of age is above average crying in a normal infant. However, because a definitive diagnosis has not been established, infants should receive a follow-up evaluation within 24 hours to ensure that a more serious illness was not missed and to address any additional concerns or questions about the crying. This element is especially critical if the clinician has any doubt concerning the establishment of the correct diagnosis.

ADDRESSING CAREGIVERS' RESPONSE TO CRYING

The distress, frustration, and anxiety that persistent or inconsolable crying may cause caregivers should be recognized and acknowledged with empathy, regardless of the cause. After addressing any urgent medical needs, caregivers should be educated about the normal pattern of infant crying and methods to soothe the infant.

Normal infant crying progressively increases after 2 weeks and peaks in the 2nd month of life, then gradually decreases by the 4th or 5th month. It generally peaks in the late afternoon and evening within the 1st 6 months of life. At times it may be unrelated to the needs of the infant. Therefore, even in healthy infants some episodes of fussiness will not be soothed with typical caregiver attempts to soothe, such as feeding, cuddling, carrying, and diapering, and may occur for up to 4-5 hours per day. This pattern of crying is consistent among normal infants regardless of caretaking styles, cultural groups, and socioeconomic status, and has been demonstrated even in some nonhuman mammalian species. The pattern may reflect a developmental stage characterized by infants' increased reactivity to their environment and an immature ability to self-regulate. Though this crying pattern seems to be universal, the frequency and duration of crying varies significantly between infants. This variation is due to a number of factors, including infant temperament, the caregivers' response to crying, and likely other unidentified factors.

Caregivers should be reassured that physical contact in the form of carrying and feeding on demand within the 1st months of life will not spoil the infant, but may reduce the amount of crying over the long term by creating a more secure attachment between the infant and caregiver. Room sharing, with the infant's crib or bassinet in the caregiver's bedroom, may also decrease infant crying in the 1st 3 months of life. Some other calming, evidence-based techniques include swaddling young infants and decreasing stimulation. A consistent daily routine may assist infants' ability to self-regulate, resulting in decreased duration of crying bouts. Parents can also try to respond to excessive crying by giving the baby a pacifier, rocking the infant in a calm environment, or providing some background noise or vibration. Promptly initiating soothing measures before the crying becomes inconsolable may help to decrease the duration of crying.

Although responding promptly to infant distress may decrease crying, at times even healthy infants will not be soothed with these interventions. The caregivers' inability to soothe the infant is often their primary source of negative feelings such as frustration, anger, or guilt, creating a loss of confidence in parenting skills and feelings of resentment toward the infant. Infants then respond to caregiver anxiety with increased crying. Caregivers may be reassured by information that bouts of fussing do not necessarily indicate illness or pain, but may simply reflect the infant's inability to regulate the crying once it has started. Medical providers can also reassure caregivers that most infant cry-fuss problems are transient and not necessarily predictive of ongoing behavior problems in childhood. In a prospective, community based study of outcomes in infants with sleep and cry-fuss problems, only 5% of mothers reported persistent problems at age 2.

The clinician must be aware that parental distress from prolonged, unexplained crying can lead to the use of ineffective, inappropriate, or even dangerous remedies. Fennel extract, oral sucrose, and herbal tea may show promise as a way to decrease crying; additional study of these treatments and possible negative effects is needed. If these supplements replace infant formula, they may lead to malnutrition and electrolyte abnormalities. Treatments that have been shown to have no significant or reproducible effect in treating crying are simethicone, dimethicone, fiber-enriched formula, chiropractic treatment, or the introduction of lactase enzyme into the infant's milk. Treatment with anticholinergic drugs (dicyclomine hydrochloride, dicycloverine, and cimetropium bromide) was effective in reducing infant crying, but is associated with unacceptable side effects. In addition, several reports have been published of hospitalization or death in infants treated for excessive crying with sedating medications such as dextromethorphan and diphenhydramine, dimenhydrinate, and opiates. Clinicians should counsel parents about the dangers of using these medications in young infants.

TABLE 26.3   Initial Ancillary Testing or Referrals to Consider for Specific Diagnoses

Potential Diagnoses	Ancillary Testing or Consultations to Consider
Eyes, Ears, Nose, Throat	
Corneal abrasion or foreign body	Fluorescein stain
Glaucoma	Ophthalmology consult
Foreign body	Radiographs and/or ENT consult
Respiratory	
Pneumonia or bronchiolitis	Chest radiography, pulse oximetry, nasopharyngeal viral testing
Airway obstruction (croup, foreign body)	Chest and/or neck radiography, pulse oximetry, ENT consult for bronchoscopy
Cardiovascular	
Congestive heart failure Supraventricular tachycardia Anomalous coronary artery Myocarditis	Chest radiography, pulse oximetry, electrocardiogram, echocardiography, CBC, CMP, BNP, Cardiology consult
Gastrointestinal System	
Incarcerated hernia	Ultrasonography with Doppler
Gastrointestinal obstruction (intussusception, volvulus, pyloric stenosis, Hirschsprung disease), peritonitis, abdominal trauma	CBC, CMP, amylase, lipase, abdominal and pelvic radiography, abdominal and pelvic CT, air contrast enema for intussusception, Surgical consult
Milk and/or soy protein allergy	Hemoccult testing
Genitourinary System	
Testicular torsion	Ultrasonography with Doppler, Surgical consult
Ovarian torsion	Pelvic ultrasonography or CT, Surgical consult
Urinary tract infection	UA with culture, CBC, blood culture
Musculoskeletal System	
Osteomyelitis Septic arthritis	CBC, ESR, CRP, blood culture, radiography, MRI, Orthopedics and Infectious Disease consult
Fractures	Skeletal survey
Diskitis	ESR, spine radiographs, spine MRI
Skin	
Cellulitis, infection	CBC, wound culture
Central Nervous System	
Encephalitis Meningitis	Lumbar puncture, head CT or MRI, CBC, blood culture
Increased intracranial pressure (abusive or nonabusive trauma, hydrocephalus, intracranial hemorrhage), neoplasm	Head CT or MRI
Miscellaneous	
Drug ingestion	Comprehensive urine drug screen (with confirmatory testing)
Neonatal abstinence syndrome	Urine or meconium drug screen
Inborn error of metabolism	CBC, ABG, CMP, serum ammonia, serum uric acid, UA, serum amino acids, urine organic acids, serum acylcarnitine profile, lactate, Genetics consult
Sepsis	CBC, LP, UA, urine and blood culture,
Sickle cell crisis	CBC, reticulocyte count, chest radiography, pulse oximetry
Physical abuse	Injury surveillance: Skeletal survey; head CT or MRI in infants <6 mo of age or current or prior symptoms of head injury; AST, ALT, amylase, lipase, UA; urine drug investigation screen with confirmatory testing, Child Protection Team consult

ABG, arterial blood gas; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BMP, basic metabolic panel; BNP, brain naturetic peptide; CBC, complete blood count; CMP, comprehensive metabolic panel; CRP, C-reactive protein; CT, computed tomography; ENT, Otolaryngologist; ESR, erythrocyte sedimentation rate; LP, lumbar puncture; MRI, magnetic resonance imaging; UA, urinalysis.

Given the stress that crying can place on a family and the fact that all families will inevitably be faced with the challenge of a fussy infant, this education should be a routine part of each well child evaluation in the 1st year of life. It should not only be given to the caregiver who presents with the child for medical care, but to all adults who will be caring for the child.

SPECIFIC DIAGNOSES

Child Maltreatment

Parental perceptions of prolonged or inconsolable crying place the infant at risk of abuse; parents may smother, slap, or shake their baby in response to crying. Crying is a common stimulus for abusive head trauma, and the abuse is often repeated because the head injury stops the crying.

Any injury in a nonmobile infant raises concern for abusive trauma and should prompt an evaluation for additional injuries. In mobile children, most accidental bruising occurs over bony prominences on the anterior surface of the body. Bruising to the ears, neck, genitals, and buttocks is unusual in nonabused children (Table 26.4). Patterned injuries and any significant, unexplained injury also may suggest abuse (Figs. 26.2, 26.3, and 26.4). The purpose of additional testing when infants present with suspicious findings is injury surveillance and identification of medical conditions that may mimic abusive trauma. The absence of additional injury does not rule out abuse. Even in isolation, the presence of a suspicious injury places the infant at risk for more severe ongoing abuse. In infants who were ultimately diagnosed with physical abuse, almost 30% of the infants had a history of previous, more minor suspicious injuries. Medical providers were reportedly aware of these injuries in 40% of cases, but did not recognize them as concerning (Table 26.5). If there are doubts about whether an injury should be considered suspicious or what tests are indicated, providers should consult a child abuse specialist.

Medical providers are in a unique position to identify infants at risk for maltreatment when they present for medical care, and to provide education and resources to high-risk families. In infants hospitalized for abusive head trauma, the majority of a victim's caregivers sought medical care for excessive crying prior to the abuse. Multiple phone calls and visits to the pediatrician for excessive crying is a warning sign that it is causing significant distress in the family. Ask caregivers how the crying is affecting the family and address any feelings of guilt or frustration. Clinicians can also ask how caregivers typically respond to the crying. All families who present with a fussy infant should be encouraged to seek support and periodic relief from the infant's care. Instruct the caregivers to safely place the infant in a crib or other safe location and walk away for a short time if they feel frustrated and at risk of harming the infant.

Even when child maltreatment is not a concern, more intensive educational and behavior modification interventions directed toward families with persistently fussy infants have shown promise as a way to reduce crying, improve parent-child relationships, and positively influence behavioral development in infants. Successful programs generally

FIGURE 26.2 Lash marks from an electric cord. Such marks are distinctive. The deep lacerations, which are looped if the cord is looped, result in deep tissue damage, and there is the potential for keloid formation on healing. (From Johnson CF. Inflicted injury versus accidental injury. *Pediatr Clin North Am.* 1990;37:791-815.)

(See *Nelson Textbook of Pediatrics,* p. 236.)

TABLE 26.5 **Pitfalls in Child Abuse Evaluation: 12 Costly Errors**
1. A desire to not make the diagnosis
2. Failure to assemble past information on medical conditions and medical encounters
3. Too great a reliance on the information developed by others
4. Transference-countertransference with custodial parent (formation of alliances or development of hostilities)
5. Overinterpretation or underinterpretation of signs and symptoms
6. Overinterpretation or underinterpretation of physical findings
7. Failure to know about conditions mistaken for sexual abuse
8. Faulty laboratory techniques resulting in either false-positive or false-negative reports
9. Use of techniques easily challenged in court
10. Impatience about arriving at a diagnostic conclusion
11. Failure to understand normative data with regard to psychosexual development
12. Failure to prepare adequately for court appearances

assess and address caregiver needs, sources of vulnerability, and infant health. They also provide respite and educate families about infant crying, soothing, and ongoing emotional care. In addition, multidisciplinary approaches may include family therapy or referrals to perinatal and infant mental health experts who can support parent-infant interactions.

Infantile Colic

A uniform definition for infantile colic is lacking but many use the definition derived from Wessel's Criteria, where crying occurs for at least 3 hours a day, at least 3 days a week, for at least 3 weeks in an otherwise healthy infant. Crying from colic generally occurs in the evenings, usually starts between 3 and 21 days of age, and subsides by 3-4 months of age. During crying bouts, parents describe that colicky infants often flex their legs over the abdomen, or may arch their backs with a "pained" look on their face. However, many of these criteria, including the appearance of pain, are also common features of normal infant crying. It is not clear whether the appearance of pain in these infants is due to a true organic etiology or related to caregivers' anxiety about the duration and unsoothable nature of the cry.

A single clear cause of colic remains elusive. Some suggest that the crying from colic is a response to pain from gastrointestinal dysfunction, such as milk protein or lactose intolerance, gastroesophageal reflux disease, abnormal peristalsis, or excessive gas. However, objective testing for these disorders has not revealed significant differences between colicky and noncolicky infants, and treatments have been inconsistently effective. Immaturity of the central nervous system and infant migraine are also suggested causes. Others theorize that colic symptoms are not caused by a single condition, but rather are a common end-point for multiple processes, including *infant temperament* and *caregivers' responses* to the crying. In this view, the term "colic" is used to describe a constellation of common symptoms rather than an underlying disease. Because of the significant overlap in the pattern and characteristics of crying in infants diagnosed with colic and normal infants, others suggest that colic represents a point further along a continuum of normal infant behavior. This perspective suggests that, in healthy infants, the clinical focus should be shifted from attempting to diagnose and treat a particular medical condition to providing education and support to caregivers. From a practical standpoint, the clinician should follow the same method of evaluation that

would be initiated for any crying infant regardless of whether or not the crying meets the definition of colic. The duration and frequency of crying in this population can be particularly distressing for caregivers, and education on soothing and coping with the crying should be emphasized.

Feeding and Gastrointestinal Dysfunction

A subset of otherwise healthy infants who present with excessive crying will have some form of gastrointestinal (GI) dysfunction. A history of crying that is associated with vomiting, hematochezia, or is temporally related to feeds may increase the likelihood. Common causes include constipation, gastroesophageal reflux disease (GERD), eosinophilic esophagitis, excessive gas, and cow's and/or soy milk protein allergy or intolerance. Congenital lactose intolerance is rare, but infants may develop transient intolerance from inflammation of the intestinal villi due to gastroenteritis or a milk protein allergy. In infants with hematochezia, a milk protein allergy is most likely. However, in less clear-cut cases, improper feeding volume or technique can cause symptoms that may be misdiagnosed as GERD or a milk protein allergy. Formula changes and pharmacologic interventions may not be without undesirable consequences, including premature cessation of breast-feeding or the development of parental anxiety concerning the possibility of an intrinsic abnormality in their infant.

When GI dysfunction is suspected, and after potentially serious medical conditions are ruled out, clinicians should first evaluate feeding volume and technique. Over- or underfeeding may contribute to infant irritability. Using a slow-flow nipple can cause excessive air intake in a very vigorous feeder. Appropriate burping, feeding the infant in an upright position, using a formula thickener, and using bottles with collapsible bags may also help reduce fussing from excessive intestinal gas or GERD. Poor attachment, latch, and oral motor dysfunction may contribute to feeding problems, fussing, and even infant aversion to feedings. Consider consultation with a lactation specialist in breast-feeding infants.

Unfortunately, no specific laboratory test exists for diagnosing protein allergy in relation to excessive infant crying, and the symptoms of GERD are often nonspecific. In fact, inflammation of the GI tract from cow's milk protein allergy may be the cause of the vomiting and symptoms of pain in up to 40% of infants diagnosed with GERD. Guidelines caution against empiric treatment with acid-reducing medications as a way to diagnose GERD in young infants with nonspecific symptoms due to potential side effects with the overuse of these medications, and because their efficacy in decreasing crying is low. There is evidence that a trial of whey hydrolysate formula, or a milk- and egg-free diet in breast-feeding mothers, may decrease crying compared to controls in otherwise healthy infants with suspected GI dysfunction. The introduction of soy formula may not resolve symptoms because a significant number of infants with milk protein allergies are also allergic to soy protein. There is also increasing evidence that probiotics may be beneficial to reduce low-grade intestinal inflammation and crying in some infants, especially those with symptoms of GERD or constipation. When potentially serious medical conditions have been excluded, and the infant's feeding volume and technique are appropriate, it is reasonable to try these interventions. Changes should be implemented one at a time and continued for at least 2 weeks to evaluate the effects of each change. In infants with persistent symptoms, clinicians can consider a trial of a proton pump inhibitor and/or referral to a gastroenterologist.

Teething

Many complaints, ranging from fever to irritability, have been ascribed to teething. The most common symptoms associated with teething are

(See *Nelson Textbook of Pediatrics,* p. 1972.)

(See *Nelson Textbook of Pediatrics,* p. 1776.)

irritability, excessive drooling, and loss of appetite. Some studies do support the belief that teething is associated with low-grade fever and diarrhea, but this finding is not consistent. No symptom or cluster of symptoms can reliably exclude other medical conditions; therefore, teething should be considered a diagnosis of exclusion.

Management consists of allowing the infant to bite on any appropriate hard object, such as a teething ring. Objects that are small or may break into pieces such as teething biscuits or frozen foods are not recommended due to the risk of choking. Chilling the object in the refrigerator may reduce gum inflammation and pain. However, plastic teething rings should not be frozen or boiled unless directed by the manufacturer. Extreme temperatures may damage plastic teething rings and cause fluid to leak, and frozen rings may injure gums. An oral systemic analgesic such as acetaminophen may provide additional relief, but topical anesthetic agents are no longer recommended due to potential serious side effects with the overuse of these medications.

Drug Reactions

Some therapeutic medications and illicit drugs may cause infant irritability when directly ingested or when transferred to the infant through breast milk. Substances associated with irritability include cocaine, amphetamines, opiates, fluoxetine, clemastine, and caffeine. Pseudoephedrine use in breast-feeding mothers may be associated with infant irritability, but this finding is not consistent among studies. However, when directly ingested by infants, pseudoephedrine can cause irritability as well as other more serious and life-threatening complications. In the evaluation of the irritable infant, a careful infant and maternal drug history are important to obtain along with a comprehensive urine drug screen if indicated.

In the neonate, irritability may also be a symptom of drug withdrawal or the continued effects of in utero exposure. Drugs associated with neonatal abstinence syndrome (NAS) include benzodiazepines, methamphetamine, heroin, methadone, buprenorphine, and other prescription opioid analgesics. Some antidepressants and anxiolytics have been found to potentiate withdrawal in infants as well. Manifestations include irritability, jitteriness, sneezing and congestion, emesis, seizures, poor feeding, hiccups, diarrhea, sleeplessness, hyperactivity, and tremors. Caregivers often describe the crying as high-pitched and inconsolable. NAS usually begins in the 1st week of life and may last for up to a month, depending on the type of substance used. This initial phase may be followed by a relapsing course that includes ongoing irritability and may last for several months. Newborns exposed to cocaine may display similar symptoms of irritability soon after birth, but these likely represent continued effects of the drug rather than withdrawal symptoms.

Mild cases of NAS are often treated with behavioral management such as reducing stimulation, swaddling, demand feeding, and other calming techniques. Pharmacotherapy is required when supportive therapy fails, or if more serious side effects such as seizures and dehydration develop. Education on coping with infant crying and methods to soothe the infant, as well as close monitoring of the home environment, are particularly important in this population due to the challenges of caring for an infant with irritability from NAS and to the lack of caregiver resources and coping skills often associated with maternal drug use.

SUMMARY AND RED FLAGS

Although at times a simple diagnosis is easily established, the infant with excessive irritability often presents a significant challenge. Establishment of the likely diagnosis, combined with exclusion of significant pathophysiologic processes (see Table 26.1), is a prerequisite to the formulation of an appropriate management plan. Through a logical and stepwise approach, the clinician can usually establish the cause and develop a treatment plan. When the clinician cannot determine the underlying cause, close follow-up monitoring should result in optimal patient care.

Red flags include inconsolability, abnormal level of consciousness, abnormal vital signs, evidence of trauma or anemia, abdominal tenderness or distention, eye tearing, photophobia or conjunctival irritation, and abnormalities of growth including increasing head circumference percentile. Consolability by being held by a parent is often reassuring.

In contrast, *paradoxical crying or irritability* when being held suggests that the holding process aggravates a painful process such as a fracture, osteomyelitis, or meningitis.

In all cases, clinicians should evaluate the level of distress that the crying is causing caregivers and should provide education and support. Families with a history of maltreatment, mental illness or drug use in caregivers, caregivers with limited social support, or those who frequently seek medical care or report significant distress and frustration from the crying are at a higher risk for adverse outcomes. When these risk factors are identified, a multidisciplinary approach involving education and resources for the caregivers, medical care for the infant, and family therapy or referrals to perinatal and infant mental health experts can improve parent-infant interactions and long-term outcomes for the child.

Unusual Behaviors

Ryan Byrne and Kirstin Kirschner

The history is the most important tool for identifying a psychiatric disorder. The initial focus in conducting the history is to establish rapport and to ensure the child's safety with respect to the risk of suicide or physical or sexual abuse. After safety is ensured, the history should focus on delineating the specific behaviors of concern, on identifying any stressors that may be precipitating the behavior (Table 27.1), and on recognizing any associated symptoms that may differentiate which disorder or disorders are causing the behavior. In addition to primary psychiatric diagnoses, the clinician should focus on possible medical causes of the behaviors in question, including medication side effects, substance abuse, and medical illnesses (Tables 27.2 and 27.3). Comorbidity is common in children with psychiatric illnesses, and as such, the clinician should consider whether a combination of medical and psychiatric diagnoses may be producing the patient's symptoms.

Information should be obtained from multiple sources whenever possible, including parents and any other adults who have spent a significant amount of time with the child, such as teachers. The child should be interviewed separately so as to provide a better chance of obtaining his or her perspective and of uncovering a history of abuse or destructive behaviors, such as substance abuse, self-harm, or high-risk sexual activity. As some psychiatric disorders demonstrate a strong genetic predisposition, a detailed psychiatric family history should be obtained. Psychiatric illness in family members may be undiagnosed; hence, the clinician should inquire about the presence of symptoms in addition to formal diagnoses in the family.

The following validated principles should guide history taking, particularly when discussing sensitive topics such as substance use, sexual abuse, and suicidal ideation or intent:

1. **Behavioral incident**: The clinician should break down complex patterns of behavior into discrete incidents and focus on concrete details chronologically. Doing so allows the clinician to objectively establish the sequence of behaviors behind sensitive events, particularly when the patient's subjective responses to the events may influence recall or reporting.
2. **Shame attenuation**: The clinician should assume a stance of unconditional positive regard so as to minimize the influence of guilt or shame while discussing taboo subjects.
3. **Gentle assumption**: By framing questions based on the assumption that a behavior exists, the clinician may overcome patient hesitation to acknowledge the presence of that behavior.
4. **Symptom amplification**: Similar to gentle assumption, by assuming a high frequency of the behavior and inquiring in a concrete manner (e.g., "How many days a week do you drink? 5-6?"), the clinician may make the patient feel more at ease by acknowledging the existence of a particular behavior, particularly if a patient is troubled by the frequency of the behavior.
5. **Denial of the specific:** By asking specific questions, the clinician may elicit more accurate information by prompting recollection of particular behaviors that may otherwise be denied when asked in general terms. For example, asking the patient whether they have ever used marijuana may be more likely to elicit a positive response than asking the patient whether they have ever used illegal drugs.
6. **Normalization:** By simply describing common patterns of symptoms or behaviors, the clinician may help the patient feel more at ease by endorsing the presence of similar patterns in his or her behaviors.

The history allows the clinician to define patterns of behavior that suggest a differential diagnosis. The *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition (DSM-5), contains descriptive diagnostic criteria based on the presence or absence of various symptoms and aids the clinician in assigning a specific diagnosis to these behavior patterns and symptom clusters. Terms frequently used in the diagnosis of psychotic illnesses are noted in Table 27.4.

CONDITIONS CHARACTERIZED BY DISRUPTIVE BEHAVIORS

Disruptive behaviors are broadly categorized by whether they violate the rights of others and are then further classified by whether there is associated difficulty in regulating emotions or behaviors (Fig. 27.1).

Conditions That Do Not Violate the Rights of Others

Attention-deficit/hyperactivity disorder. The cardinal features of attention-deficit/hyperactivity disorder (ADHD) are hyperactivity, distractibility, and impulsivity. Manifestations of these symptoms must be present in more than 1 setting (e.g., school and home) and must interfere with functioning or development. ADHD is more frequent in males than in females, with a ratio of about 2:1 in children. However, females may be underdiagnosed as they are more likely to present with inattention than with hyperactivity. The DSM-5 specifies that there must be a persistent pattern of inattention and/or hyperactivity–impulsivity with 6 or more symptoms in either category lasting at least 6 months. Adolescents 17 years of age or older require only 5 symptoms; however, symptoms should be present prior to 12 years of age.

Inattention

1. Lack of attention to detail or inaccurate work
2. Difficulty sustaining attention
3. Failure to listen when spoken to directly
4. Lack of follow-through
5. Disorganization
6. Avoidance of activities requiring sustained attention
7. Frequent loss of items
8. Easy distraction by extraneous stimuli
9. Forgetfulness

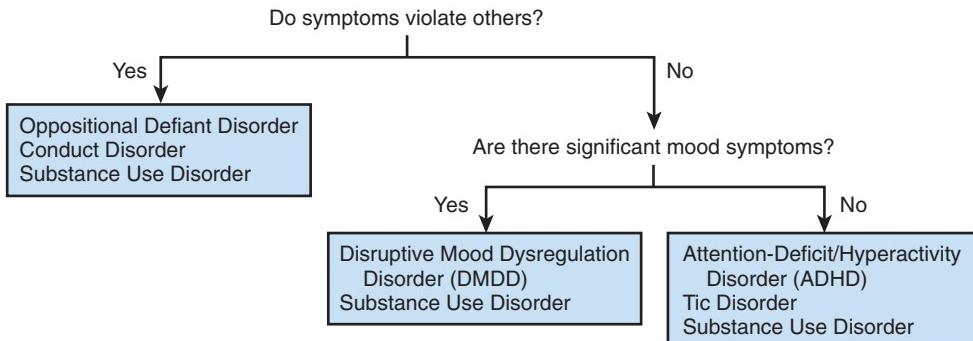
From Carlat DJ. *The Psychiatric Interview*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2011.


FIGURE 27.1 Evaluation of disruptive behaviors.

Hyperactivity/Impulsivity

1. Frequent fidgeting or squirming
2. Frequent need to walk around
3. Restlessness or need to run around/climb
4. Difficulty engaging in quiet activities
5. Acting "on the go," restlessness, or difficulty of caregivers to keep up with
6. Talking excessively
7. Frequently interrupting
8. Difficulty waiting turn
9. Intrusiveness

The chronicity of the **hyperactivity** in this disorder may be subtle. Although children with ADHD tend to move around more than other children, the hyperactivity may be of concern only in certain situations in which the child is expected to be quiet (e.g., in school or places of worship). Some children with ADHD can sit and be attentive in quiet and relaxed situations, whereas a noisy and active setting, such as an unstructured classroom, precipitates inappropriate behavior. As these children become older, they often become less overtly hyperactive. For instance, an adolescent may mostly feel restless without acting upon that feeling in a disruptive manner. This restlessness may contribute significantly to academic underachievement. Despite intentions for diligent studying, the restlessness may cause the affected teenager to feel the need to walk around, distracting from studying.

Impulsivity significantly contributes to morbidity. The impulsivity applies not only to actions but also to emotions. An impulsive child whose emotions change quickly is at risk for physically aggressive behaviors, such as hitting or biting. In school-aged children, the impulsive aggression is often manifested as explosive behavior. Because of their explosive behavior, inability to wait their turn in a game, and difficulty regulating emotions when interacting with teachers, these children have great difficulty with both peer and teacher relations. Impulsivity can also be potentially life threatening because the child may act before considering the consequences. Impulsivity may manifest as risk-taking behaviors in both children (e.g., running into the street after a ball without checking for traffic) and adolescents (e.g., high-risk sexual activity or substance abuse).

Hyperactivity and impulsivity in children are often readily apparent to adults; however, the manifestations of **inattention and distractibility** are often not as overt. In young children, inattentive behavior can consist of shifting from 1 activity to another and having difficulty finishing tasks. The parents may incorrectly consider these actions to represent lack of motivation. In adolescence, inattentive behavior may result in poor school performance. These children may forget to do homework or may need excessively long periods to complete assignments because of their inability to focus on their work and may be mislabeled as being lazy.

The challenge in diagnosing ADHD lies in defining when specific behaviors are abnormal, particularly when those behaviors may not be apparent in all situations or contexts. The clinician should not rely solely on observations obtained in the clinic setting, but should instead gather information from multiple sources, including parents, teachers, daycare workers, and even a direct classroom observation from a trained health care professional. The classroom teacher represents an excellent resource for determining whether the patient's level of activity and degree of impulsivity are abnormal. Standardized behavioral checklists filled out by the parents and teachers quantify the degree of abnormal behaviors with regard to an age-specific reference population.

Before establishing a diagnosis of ADHD, the clinician must rule out other psychiatric and medical causes of the patient's symptoms. With respect to psychiatric conditions, the differential diagnosis of ADHD includes learning disorders, oppositional behavior, mood disorders, anxiety disorders, and substance abuse. *Because of the high association of learning disorders with ADHD, each evaluation should include an assessment for learning problems.*

With respect to medical conditions, the differential diagnosis of ADHD includes iron deficiency, lead toxicity, thyroid disorders, seizures, hearing loss, and substance abuse. Screening for symptoms of **sleep-disordered breathing** is essential because chronically ineffective

(See *Nelson Textbook of Pediatrics,* p. 200.)

TABLE 27.4 Psychiatric Terms

Abulia is the state of reduced impulse to act and think associated with indifference about consequences of action.

Affect is the examiner's observation of the patient's emotional state. Frequently used descriptive terms include the following:

  Constricted affect is reduced range and intensity of expression.

  Blunted affect is further reduced. Usually, there is little facial expression and a voice that is monotone and lacking normal prosody.

  Flat describes severely blunted affect in which there is no affective expression.

  Inappropriate affect is an incongruous expression of emotion or behavior relative to the content of a conversation or social norms.

  Labile affect exhibits abrupt and sudden changes in both type and intensity of emotion.

Anxiety is the feeling of apprehension caused by anticipation of danger that may be internal or external.

Apathy is dulled emotional tone associated with detachment or indifference.

Comportment refers to self-regulation of behavior through complex mental processes that include insight, judgment, self-awareness, empathy, and social adaptation.

Compulsion is the uncontrollable impulse to perform an act repetitively.

Confusion is the inability to maintain a coherent stream of thought owing to impaired attention and vigilance. Secondary deficits in language, memory, and visual spatial skills are common.

Delusion is a false, unshakable conviction or judgment that is out of keeping with reality and with socially shared beliefs of the individual's background and culture. It cannot be corrected with reasoning.

Depression is a sustained psychopathological feeling of sadness often accompanied by a variety of associated symptoms, particularly anxiety, agitation, feelings of worthlessness, suicidal ideation, abulia, psychomotor retardation, and various somatic symptoms and physiologic dysfunctions and complaints that cause significant distress and impairment in social functioning.

Hallucination is a false sensory perception not associated with real external stimuli.

Mood is the emotional state experienced and described by the patient and observed by others.

Obsession is the pathologic persistence of an irresistible thought or feeling that cannot be eliminated from consciousness by logical effort. It is associated with anxiety and rumination.

Paranoia is a descriptive term designating either morbid-dominant ideas or delusions of self-reference concerning 1 or more of several themes, most commonly persecution, love, hate, envy, jealousy, honor, litigation, grandeur, and the supernatural.

Prosody is the melodic patterns of intonation in language that convey shades of meaning.

Psychosis is the inability or impaired ability to distinguish reality from hallucinations and/or delusions.

Thought process and content. Common descriptive terms include the following:

  Circumstantial thought follows a circuitous route to the answer. There may be many superfluous details, but the patient eventually reaches the answer.

  Linear thought demonstrates goal-directed associations and is easy to follow.

  Loose associations are thoughts that have no logical or meaningful connection with ensuing thoughts.

  Tangential thoughts are initially clearly linked to a current thought but fail to maintain goal-directed associations; the patient never arrives at the desired point or goal.

  Clang associations describe speech in which the sounds of words are similar but not the meanings. The words have no logical connection to each other.

  Flight of ideas describes a rapid stream of thoughts that tend to be related to each other.

  Magical thinking describes the belief that thoughts, words, or actions have power to influence events in ways other than through reality-based mechanisms.

  Thought blocking is characterized by abrupt interruptions in speech during conversation before an idea or thought is finished. After a pause, the individual indicates no recall of what was being said or what was going to be said.

---

or inefficient sleep can produce symptoms of inattention and hyperactivity.

Tic disorders. Tics are motor movements or vocalizations that are sudden, rapid, recurrent, nonrhythmic, and involuntary. Tics often become worse during stress but may improve during activities requiring moderate physical or mental activity. Tics need to be differentiated from other abnormal movements, such as chorea, athetosis, dystonia, myoclonus, and hemiballismus, which may be associated with an underlying neurologic condition or may be medication-induced. **Simple motor tics** are defined as repetitive movements of single muscle groups. They may consist of eye blinking, neck jerking, or shoulder shrugging. **Complex motor tics** are repetitive movements of several muscle groups in coordination, such as repetitive grooming behaviors, deep knee bends, or smelling of objects. **Simple vocal tics** are defined as nonverbal noises, such as throat clearing or grunting sounds, whereas **complex vocal tics** are intelligible words. Complex vocal tics may manifest as **coprolalia**, the repetitive, stereotyped vocalization of obscenities.

The DSM-5 categorizes tic disorders as follows:

1. **Provisional tic disorder:** motor and/or vocal tics lasting less than a year
2. **Chronic motor or vocal tic disorder:** either motor or vocal tics lasting longer than a year
3. **Tourette disorder:** both motor and vocal tics lasting longer than a year

Tourette disorder consists of multiple motor and vocal tics of at least 1 year in duration. The incidence of this condition is 4-5 per 10,000. In some families, this illness is inherited as an autosomal dominant condition, with 70% penetrance in females and near complete penetrance in males. Because of this difference in penetrance, Tourette disorder is 1.5-3 times more common in males than in females. The median age at presentation is 7 years, though some children may present as early as 2 years. While coprolalia is popularly thought to be a common feature of Tourette disorder, fewer than 10% of affected patients have this form of complex vocal tics.

The DSM-5 criteria for Tourette disorder are as follows:

1. Multiple motor and vocal tics lasting longer than a year with no tic-free intervals longer than 3 months
2. Symptom onset before age 18 years
3. No medical cause for the tics

Tics may lead to the patient being socially ostracized. Children with chronic tic disorders frequently have other psychologic conditions, such as ADHD or obsessive-compulsive disorder (OCD), which may lead to further difficulties in peer interactions and frequent frustration of teachers and family members. Such stressors can worsen the tics, which can further compound the problem.

Disruptive mood dysregulation disorder. While the predominant characteristic of disruptive mood dysregulation disorder (DMDD) is chronic, persistent, and severe irritability, it is often the behavioral issues that prompt presentation to a clinician. DMDD often manifests as irritable, depressed mood and temper tantrums with a low frustration tolerance. The DSM-5 requires the following for diagnosis:
1. Severe recurrent temper outbursts that manifest with verbal or behavioral aggression out of proportion to the situation in intensity or duration
2. Behavior is inconsistent with developmental level
3. Behavior occurs on average 3 or more times per week
4. The mood between outbursts is persistently irritable or angry
5. Symptoms present for 12 or more months
6. Symptoms present in at least 2 settings
7. Age of onset of symptoms must be before age 10 years, but diagnosis should not be made before age 6 years or after age 18 years

The overall prevalence of DMDD among children and adolescents is as high as 5%. Rates are higher in males and school-aged children than in females and adolescents. DMDD can cause significant difficulties with school performance and family/peer relationships. Many children with DMDD will also meet criteria for ADHD, oppositional defiant disorder (ODD), or anxiety disorders. The diagnosis of DMDD should be distinguished from bipolar disorder, which must have distinct episodes of mania or hypomania (Table 27.5). The age of the patient can also help differentiate DMDD and bipolar disorders because bipolar disorders rarely present prior to adolescence.

Substance Use Disorder. Substance use can lead to a wide range of disturbances in mood and behavior. The hallmark of a substance use disorder is the continued use of a substance despite it causing ongoing negative cognitive, behavioral, and physiologic symptoms. The other hallmark of substance use disorder is the significance of the negative behaviors, such as verbal or physical aggression, defiance, lying, or stealing. Sometimes these behaviors will reach the point of violating family and friends.

Conditions That Violate the Rights of Others

Oppositional defiant disorder. The characteristic feature of ODD is a persistent pattern of both defiant behavior and an angry or irritable mood. Affected individuals exhibit at least 4 of the following behaviors in a consistent manner over a 6-month period:
1. Frequently losing temper
2. Often arguing with authority figures
3. Defying rules
4. Deliberately annoying adults
5. Blaming others for his or her actions
6. Becoming easily annoyed by others
7. Being angry
8. Being vindictive

ODD should not be diagnosed if the patient meets the DSM-5 criteria for conduct disorder or if the symptoms occur in the context of a mood, anxiety, or psychotic disorder, in which children exhibit oppositional behavior as a reaction to their illness.

TABLE 27.5 Diagnostic Features of Primary Psychiatric Disorders

The following conditions require clinically significant distress or impairment in social or occupational functioning:
- **Schizophrenia** is a disorder that lasts for at least 6 mo and includes at least 1 mo of active symptoms (2 or more of the following: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, or negative symptoms).
- **Schizoaffective disorder** is a disorder in which a mood episode and the active symptoms of schizophrenia occur together and were preceded or are followed by at least 2 wk of delusions or hallucinations without prominent mood symptoms.
- **Major depressive disorder** is characterized by 1 or more major depressive episodes (at least 2 wk of depressed mood or loss of interest accompanied by at least 4 additional symptoms of depression). Additional symptoms of depression may include significant weight changes, sleep dysfunction, psychomotor agitation or retardation, fatigue or loss of energy, feelings of worthlessness or guilt, diminished concentration, and suicidal ideation or thoughts of death.
- A **manic episode** is defined by an abnormally and persistently elevated, expansive, or irritable mood persisting for at least 1 wk (or less if hospitalization is required). At least 3 of the following symptoms must be present if the mood is elevated or expansive (4 symptoms are required if the mood is irritable): inflated self-esteem or grandiosity, decreased need for sleep, pressured speech, flight of ideas, distractibility, increased goal-directed activities or psychomotor agitation, and excessive involvement in pleasurable activities with a high potential for painful consequences. Psychotic features may be present.
- **Bipolar I disorder** is characterized by the presence of both manic and major depressive episodes or manic episodes alone.
- **Bipolar II disorder** is characterized by the presence of major depressive episodes alternating with episodes of hypomania.
- **Hypomania** is characterized by an abnormally and persistently elevated, expansive, or irritable mood persisting for at least 4 days. Other criteria required for diagnosis are identical to that of a manic episode except that the symptoms are not so severe as to cause marked impairment in social or occupational functioning, hospitalization is not required, and no psychotic symptoms are present.

From Perez DL, Murray ED, Price BH. Depression and psychosis in neurological practice. In: Daroff RB, Jankovic J, Mazziotta JC, Pomeroy SL, eds. *Bradley's Neurology in Clinical Practice*. 7th ed. Philadelphia: Elsevier; 2015.

Prevalence ranges from 1-11%, depending on the population. In prepubertal children, it occurs more frequently in boys; however, in adolescents, its incidence is equal in both sexes. Most children present before 8 years of age. Affected preschool-aged children sometimes exhibit increased motor activity, difficulty being comforted, and overreacting to situations. Affected school-aged children have low self-esteem and a low tolerance for frustration. The disorder commonly occurs in families with a history of mood or psychotic disorders—particularly maternal depression—and with chronic disruptive behaviors, such as ADHD or conduct disorder.

Children with this disorder are at marked risk for other psychologic disorders, such as ADHD. In addition, these patients may be at increased risk for conduct disorder, antisocial personality disorder as adults, substance abuse, major depressive disorder, and suicide.

Conduct disorder. A child has conduct disorder if he or she has repetitively violated the rights of others and of society. Children with this diagnosis have performed 3 or more of the following behaviors

within the past year and with at least 1 occurring in the previous 6 months:

1. Aggression toward people or animals, such as intimidation, initiation of fights, use of weapons, cruelty to people, cruelty to animals, rape, confrontational theft or mugging
2. Destruction of property, such as arson or vandalism
3. Deceitfulness or theft, such as breaking into houses or cars or stealing items of nontrivial value
4. Serious violation of rules, such as curfew violation, running away, or truancy before the age of 13 years (for running away to qualify as a symptom, it must occur twice, or once if it was lengthy, and must not be an attempt to escape sexual or physical abuse)

Conduct disorder is classified as **childhood onset** if symptoms occur before 10 years of age and **adolescent onset** if symptoms occur at or after 10 years of age. It is further subdivided by severity of offense: mild (e.g., truancy), moderate (e.g., vandalism, nonconfrontational theft), and severe (e.g., rape, confrontational theft). The prevalence of conduct disorder is higher in males than in females. Children initially present with lying, initiating fights, and truancy; as they get older, they progress to more violent acts. Boys are more likely to exhibit acts of violence, such as fighting and stealing, than are girls, who are more likely to exhibit truancy, runaway behavior, and high-risk sexual activity. Half of these children may develop **antisocial personality disorder**, which is a severe conduct disorder of adulthood that is usually associated with criminal activity. The earlier the onset of conduct disorder, the greater the risk of developing antisocial personality disorder as an adult. These children also have a high frequency of depression, suicidal ideation, personality disorders, anxiety disorders, ADHD, and substance abuse.

Although the cause of conduct disorder is unknown, both genetic and psychosocial factors play a role. A history of parental rejection, difficult infant temperament, physical or sexual abuse, early institutional living, and lack of appropriate discipline are associated with the development of conduct disorder. A biochemical or genetic cause for this condition has been postulated due to the high prevalence of this condition in families with psychiatric disorders.

CONDITIONS CHARACTERIZED BY DISRUPTION IN MOOD

Mood disorders are divided into those characterized by a depressed mood and those characterized by extremes of mood lability. When assessing mood disturbances, it is essential to screen for symptoms suggestive of bipolar illness as these patients have a risk of becoming manic when treated with antidepressants (Fig. 27.2). The evaluation of any patient with a disruption in mood should include an assessment of the risk of suicide.

Conditions Characterized by Depressed Mood

Depressive disorders that may present in childhood include DMDD, major depressive disorder, premenstrual dysphoric disorder, persistent depressive disorder (i.e., dysthymia), substance/medication-induced depressive disorder, adjustment disorder with depressed mood, and depressive disorder related to another medical condition.

Major depressive disorder. Major depressive disorder is associated with serious risks of both suicide and significant social and academic impairment (see Table 27.5). Presentations may be subtle. Even though a child may be pervasively sad, he or she may also present with behavior problems and irritability. Patients may also present with somatic complaints, psychosis, or both. The psychotic symptoms are typically mood-congruent auditory hallucinations and delusions of guilt, medical illnesses, or deserving punishment. DSM-5 criteria for major depressive disorder consist of at least a 2-week period of a depressed mood—or irritability in some children—or loss of interest in pleasurable activities, resulting in significant impairment. During this period, the patient has to have at least 5 of the following symptoms:

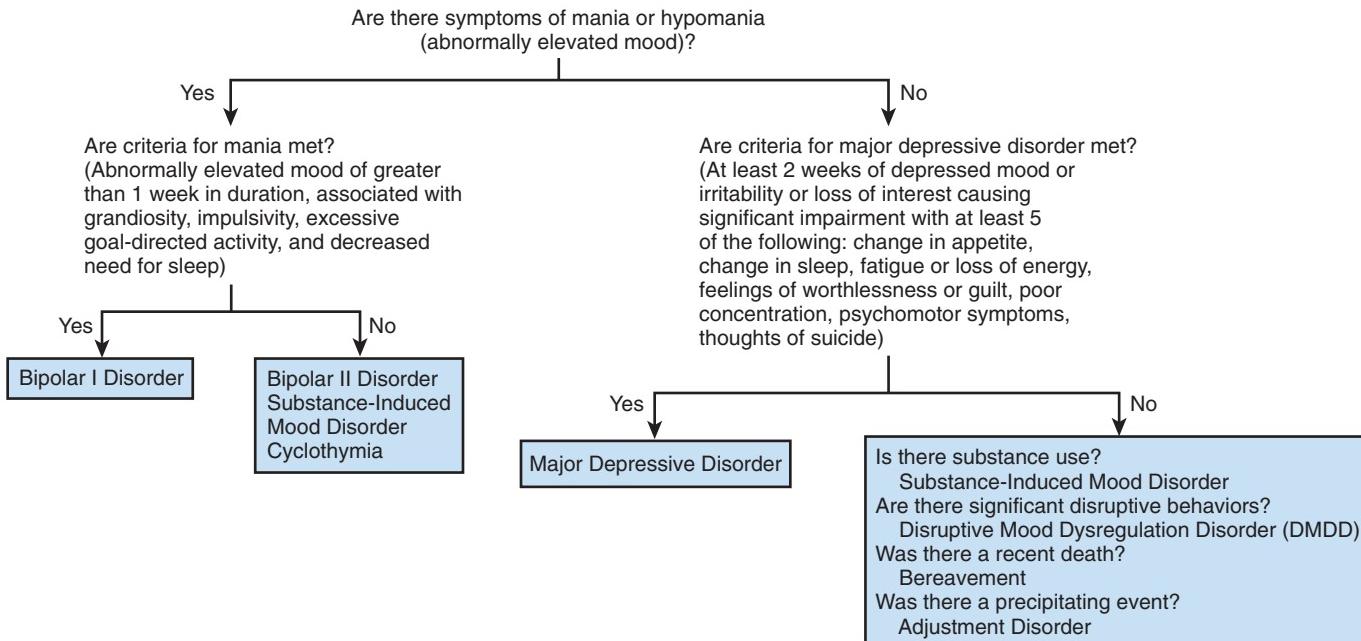
1. Depressed mood or irritability in some children
2. Loss of interest or pleasure
3. Loss of appetite or overeating
4. Insomnia or hypersomnia
5. Fatigue or loss of energy
6. Feelings of worthlessness or guilt


FIGURE 27.2 Evaluation of mood disorders.

(See *Nelson Textbook of Pediatrics,* p. 151.)

7. Poor concentration or indecisiveness
8. Suicidal ideation or thoughts of death
9. Psychomotor agitation or retardation

These symptoms should not be secondary to bereavement, medical conditions, substance abuse, or bipolar disorders. Emotional reaction to adverse stressors is a normal part of life. The clinician must decide whether the reaction to the stressor is normal, an adjustment disorder, or major depression.

The occurrence of major depressive disorders in adolescence is as high as 5%. There is also a 3-fold increase in major depression in children who have a parent with depression. The differential diagnosis of major depression encompasses various medical disorders, including neurologic disorders, endocrine disorders such as hypothyroidism or hyperparathyroidism, side effects from medications such as H_2-blockers or isotretinoin, and substance abuse or use (see Table 27.3). Numerous psychiatric conditions are comorbid with major depression. Among these are ODD, conduct disorder, ADHD, anxiety disorders, eating disorders, and substance abuse.

Major depressive disorder can manifest at any age; however, most patients present in early adulthood. Children usually present with somatic complaints, social withdrawal, and irritability, whereas adolescents often present with psychomotor retardation, thoughts of guilt and worthlessness, and excessive sleep. Approximately 15% of children with major depression eventually develop bipolar disorders. Fifty percent of children with major depression have multiple episodes, frequently associated with significant stressors. Approximately 25% of patients with certain chronic medical conditions such as cancer or diabetes develop major depressive disorder during the course of the illness. The main difficulty in diagnosing major depression is that the gravity of the depressive mood is often not always apparent to the parent and the clinician. Given that children and adolescents often present with irritability, sullenness, or mean-spiritedness, the parents and/or clinician may attribute this behavior to typical adolescent behavior. These children do not always appear sad and the clinician should have a high index of suspicion of major depression in any child who presents with sullenness and irritability. Guidelines for evaluating such a patient are as follows:

1. Assess suicidal ideation and ensure the patient's safety.
2. Obtain collateral information from other sources to determine the child's functioning and symptoms.
3. Obtain a thorough family history for symptoms and formal diagnoses of mood disorders.
4. Rule out bipolar disorders by assessing for symptoms of mania or hypomania.
5. Investigate primary or comorbid conditions, such as substance abuse.
6. Consider the role of life stressors in relationship to the symptoms.

Premenstrual dysphoric disorder. Both physical and mood symptoms can occur prior to a female's menstrual cycle. When the symptoms are severe, they may constitute premenstrual dysphoric disorder, the primary features of which are mood lability, irritability, dysphoria, and anxiety that appear recurrently during the premenstrual phase of a female's cycle and then resolve around the onset of menses. Delusions or hallucinations have been described but are rare. The 12-month prevalence is as high as 6% of menstruating women. Onset can be any time after menarche. Factors such as stress, a history of trauma, and seasonal changes can contribute. The DSM-5 states that the following criteria must be met:

1. In the majority of cycles, at least 4 of the following symptoms: marked affective lability (mood swings, increased sensitivity to rejection), irritability or anger, increased interpersonal conflicts, depressed mood, feelings of hopelessness or self-deprecating thoughts, anxiety, tension
2. At least 1 of the following: decreased interest in activities, difficulty concentrating, lack of energy, change in appetite, change in sleep, sense of being out of control, physical symptoms of breast tenderness, joint pain, bloating, or weight gain
3. Symptoms present during the majority of cycles over the year prior

The severity of symptoms is similar to that in other psychiatric disorders, such as major depression or generalized anxiety disorder, though the duration of symptoms is shorter. Nonetheless, symptoms do need to be severe and cause marked impairment in functioning in order to satisfy diagnostic criteria. To confirm the diagnosis, daily prospective symptom ratings are required for at least 2 cycles.

Substance-induced mood disorders. Substance-induced disorders are distinct from substance use disorders. Whereas the latter refer to the negative consequences of substance use over time, the substance-induced disorders refer to the immediate effects of substance use—**intoxication** and **withdrawal**—and to the **substance-induced mental disorders**, which include psychotic disorders, anxiety disorders, depressive disorders, bipolar and related disorders, obsessive-compulsive and related disorders, sleep disorders, sexual dysfunction, delirium, and neurocognitive disorders. The hallmark of substance-induced mental disorders is that the symptoms of the disorder are attributable to the ingestion of the substance and were not present prior to ingestion. While symptoms may abate as the pharmacologic activity of the substance abates, repeated use may lead to chronic changes in neurophysiology, and as such, behavioral effects may persist even when the substance is no longer used.

The substances specified in the DSM-5 include alcohol, caffeine, cannabis (also synthetic cannabinoids), hallucinogens (including phencyclidine and others), inhalants, opioids, sedatives/hypnotics/anxiolytics, stimulants, tobacco, and "other." Defining the symptom complex associated with each individual substance is out of the purview of this text; however, the possibility of substance use/abuse as a cause for behavioral and mood disruption is critical for all physicians to recognize. The patient interview should include time to speak with the patient individually, without a parent or other caregiver present, so as to establish rapport, to incorporate the techniques of normalizing and remaining non-judgmental, and to encourage a patient to discuss their substance use.

Adjustment disorder. Adjustment disorder is an excessive or maladaptive response to a stressor, and diagnosis is contingent upon the recognition of a particular stressor. Typical stressors for children and adolescents include separations, painful injuries, illness, hospitalization or surgery, parental divorce, change of residency, academic failure, and conflict with peers. The DSM-5 criteria for adjustment disorder are as follows:

1. The symptoms develop within 3 months of the stressor.
2. Significant social and/or academic impairment results.
3. The symptoms do not meet criteria for mood or anxiety disorder.
4. The symptoms do not represent bereavement.
5. The symptoms abate 6 months after termination of the stressor.

This disorder is further classified by the patient's symptoms, such as **depressed mood**, **anxiety**, and/or **conduct disorder**. Affected patients may be at increased risk for suicide, particularly if social and/or academic impairment are severe. If the stressor is an illness or its treatment, the morbidity of the medical condition may increase as a consequence of noncompliance. The differential diagnosis of adjustment disorder is a mood or anxiety disorder, exacerbation of a personality disorder, or post-traumatic stress disorder (PTSD).

Conditions Characterized by Extremes of Mood Lability

The **bipolar disorders** include bipolar I disorder, bipolar II disorder, and cyclothymic disorder. All are characterized by the presence of either mania or hypomania. **Mania** manifests acutely, leads to significant functional impairments, and is characterized by racing thoughts, distractibility, delusions of grandeur, and other disturbances in thinking. Problematic behaviors during a manic episode include recklessness (e.g., excessive participation in social activities, high-risk sexual activity, buying sprees), agitation, decreased sleep, and excessive talkativeness. A **manic episode** is defined as an abnormally elevated, euphoric, expansive, or irritable mood for at least 1 week unless treated. This mood disturbance is associated with at least 3 of the following symptoms or 4 if the mood is irritable:

1. Grandiosity
2. Decreased need for sleep
3. Talkativeness
4. Racing thoughts
5. Distractibility
6. Excessive goal-directed activity or psychomotor agitation
7. Reckless pursuit of pleasure

The symptoms of a **hypomanic episode** are the same, though are present for a shorter duration (i.e., 4 days or fewer), are not associated with psychotic symptoms of delusions or hallucination, and are not severe enough to cause major social or academic dysfunction. Up to 10% of patients with hypomania will eventually develop mania.

Bipolar I disorder is characterized by the presence of manic episodes. Patients may also have prior or subsequent episodes of hypomania or major depression, though these are not required. **Bipolar II disorder** is characterized by the presence of major depression episodes and hypomania. **Cyclothymic disorder** is a chronic, cyclic illness of hypomania and depressive symptoms without episodes of major depression.

Comorbid psychiatric conditions include eating disorders, ADHD, conduct disorders, panic disorders, social phobias, adjustment disorders, substance use disorders, and substance-induced disorders. The lifetime prevalence of bipolar I disorder is as high as 1.6%, and that of bipolar II disorder is 0.5%. Approximately 15% of adolescents with recurrent major depression eventually develop bipolar illnesses.

The differential diagnosis of the bipolar disorders includes schizophrenia and medical conditions that cause changes in mental status, particularly thyroid disorders, Cushing disease, and multiple sclerosis (see Table 27.3). Substance-induced mood disorders must also be considered, particularly those associated with cocaine, tricyclic antidepressants and selective serotonin reuptake inhibitors. The clinician should obtain a detailed family history as bipolar disorder frequently runs in families. Because the condition is often undiagnosed in parents, the questions should be directed toward the presence of the symptoms for bipolar disorders. The following principles should guide the evaluation of patients with symptoms of depression or mania:

1. Recognize the symptoms mania and hypomania.
2. Remember that depressed patients often have bipolar disorders.
3. Obtain a thorough family history to look for symptoms of mood disorders.
4. Consider bipolar illnesses in patients with any disruptive disorder that does not respond to treatment.
5. Assess for drug and/or alcohol use as substances may induce bipolar disorder, and substance use is frequently a comorbid condition.

Borderline personality disorder is a chronic personality disorder characterized by intense mood lability, impulsivity, identity disturbances, and unstable relationships. The diagnosis may be challenging in adolescents whose appropriate psychologic development includes the forging of identity and personality traits; however, since borderline personality disorder is associated with significant morbidity and potential mortality, it should be considered in the differential diagnosis of a patient presenting with significant mood or behavioral issues. Diagnosis requires 5 or more of the following:

1. Significant efforts to avoid real or imagined abandonment
2. Unstable and intense relationships with extremes of idolization and devaluation
3. Marked identity disturbances with unstable sense of self
4. Significant impulsivity in at least 2 areas that are potentially self-damaging: spending, sexual activity, substance abuse, reckless driving, or binge eating
5. Recurrent suicidal or self-mutilating behavior
6. Intense dysphoria, irritability, or anxiety
7. Chronic feelings of emptiness
8. Inappropriate anger
9. Transient, stress-related paranoia or dissociation

Both genetic and psychosocial factors are believed to be causative. Risk factors for borderline personality disorder include a history of abuse, neglect, or early parental loss. The median population prevalence is approximately 6% in primary care settings and is as high as 10% in outpatient mental health clinics. Females are more frequently diagnosed than males, at a ratio of 3:1.

Addressing Suicidal Thoughts and Attempts

Suicide is the second leading cause of death in adolescents, and assessing the risk of suicide is a critical component in the evaluation of any child or teen. Although depression is an important risk factor for suicide, only half of adolescents who attempt suicide have clinically diagnosable depression. In those without depression, strong predictors of suicide are impulsivity and low frustration tolerance. The approach to evaluating suicidality is complicated and includes a stepwise process of probing first for latent thoughts of suicidality (Table 27.6), then for active suicidal intent. Key to this process is assessing whether the child is considering acting on thoughts of death or suicide. To assess risk, the interviewer should focus on the **risk factors for completed suicide**, which include the following:

1. Male sex
2. Adolescence
3. Formation of a conscious plan
4. Presence of available means (e.g., medications, firearms)
5. Depression
6. Hopelessness
7. Impulsivity
8. Low frustration tolerance
9. Use of intoxicants
10. Sexual identity conflicts
11. Recent death of family member or friend
12. Previous suicide attempts

Once a patient's thoughts of suicide have escalated to suicide threats, plans, or attempts, this constitutes a medical emergency and the patient should be immediately referred to an experienced mental health professional or emergency department, and psychiatric hospitalization should strongly be considered.

CONDITIONS CHARACTERIZED BY WORRY, FEAR, AND PANIC

Conditions Characterized by Worry

Worries are primarily internal ruminations about the potential to experience negative outcomes from typically benign, everyday events. While often accompanied by somatic symptoms, such as stomach

(See *Nelson Textbook of Pediatrics,* p. 157.)

upset and headache, the hallmark of these disorders is the persistence of worry across 1 or more areas of a child's life. Conditions characterized by worry are categorized by whether they are associated with unusual behaviors (Fig. 27.3).

Worry Without Unusual Behaviors

Generalized anxiety disorder is characterized by excessive worry and concern over many issues. Chronic generalized anxiety may lead to

TABLE 27.6 Columbia Suicide Severity Rating Scale–Screener

1. Have you wished you were dead or wished you could go to sleep and not wake up?
2. Have you actually had any thoughts about killing yourself?
   If Yes to 2, answer questions 3, 4, 5, and 6. If No to 2, go directly to question 6.
3. Have you thought about how you might do this?
4. Have you had any intention of acting on these thoughts of killing yourself, as opposed to you having the thoughts but you definitely would not act on them?
5. Have you started to work out or worked out the details of how to kill yourself? Do you intend to carry out this plan?
6. Have you done anything, started to do anything, or prepared to do anything to end your life?
   Response Protocol to Screening, based on last item answered YES.
   Item 1 – Mental Health Referral at discharge
   Item 2 – Mental Health Referral at discharge
   Item 3 – Care Team Consultation (Psychiatric Nurse) and Patient Safety Monitor/Procedures
   Item 4 – Psychiatric Consultation and Patient Safety Monitor/Procedures
   Item 5 – Psychiatric Consultation and Patient Safety Monitor/Procedures
   Item 6 – If over a year ago, Mental Health Referral at discharge
      If between 1 wk and 1 yr ago, Care Team Consultation (Psychiatric Nurse) and Patient Safety Monitor
      If 1 wk ago or less, Psychiatric Consultation and Patient Safety Monitor

---

symptoms of depression or somatic complaints, including abdominal pain, nausea, appetite loss, and headaches. Diagnostic criteria are as follows:

1. Excessive anxiety and worry about various issues for more than 6 months
2. Difficulty controlling the worry
3. Anxiety and worry are associated with 3 of the following:
   a. Restlessness
   b. Being easily fatigued
   c. Difficulty concentrating
   d. Irritability
   e. Muscle tension
   f. Sleep disturbance
4. Anxiety, worry, or physical symptoms cause significant distress or impairment

The lifetime prevalence of generalized anxiety disorder is approximately 5%, with most cases initially presenting during childhood or adolescence. The disorder is chronic and worsens during periods of stress. Comorbid diagnoses include mood disorders, other anxiety disorders, and substance use disorders.

Adjustment disorder with anxiety. The hallmark of adjustment disorders is an excessive or maladaptive response to a stressor that is out of proportion to that stressor. In **adjustment disorder with anxiety**, the maladaptive response manifests as excessive worry. Stressors that children and adolescents may encounter include social separations, parental divorce, illness, injury, moving, academic failure, and peer conflict. Of note, the stressor should not represent a perceived threat to the life of oneself or a loved one. DSM-5 diagnostic criteria are as follows:

1. Symptoms develop within 3 months of the stressor
2. Significant impairment results
3. The symptoms do not meet criteria for an alternative anxiety disorder
4. The symptoms do not represent bereavement
5. The symptoms abate 6 months after termination of the stress

Worry With Unusual Behaviors

Obsessive-compulsive disorder (OCD) is characterized by obsessive worries that are briefly relieved by compensatory compulsive behaviors. **Obsessions** are recurrent and persistent thoughts, urges, or

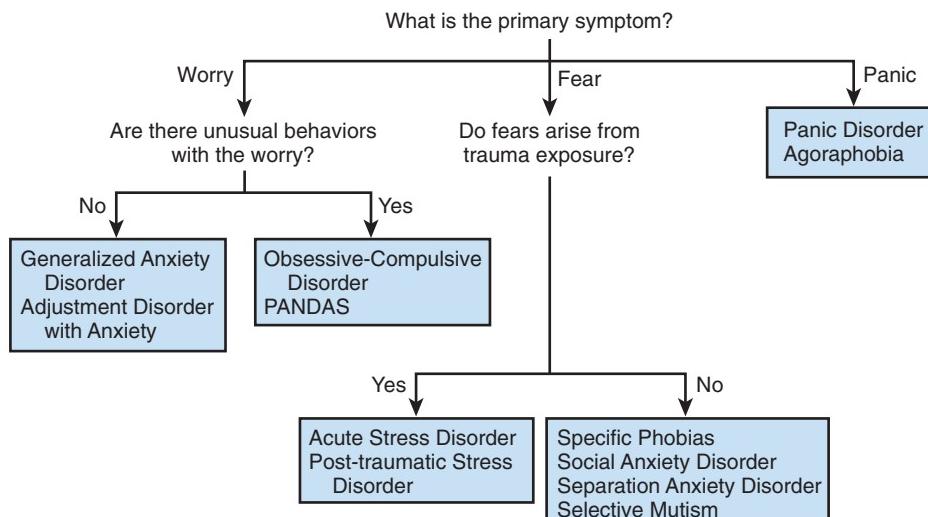

FIGURE 27.3 Evaluation of worry, fear, and panic. *PANDAS,* Pediatric Autoimmune Neuropsychiatric Dsorders Asociated with *Streptococcus pyogenes.*

(See *Nelson Textbook of Pediatrics,* p. 154.)

images that the individual attempts to ignore or suppress. Common obsessions include fear of contamination or illness, guilt regarding sexual thoughts, images of violent or horrific scenes, and urges to injure oneself or others. **Compulsions** are repetitive and excessive acts the patient performs to reduce the anxiety elicited by obsessions. Compulsions may include actions, such as repetitive hand-washing or checking locks, or mental acts, such as repeating certain words or counting internally. Some patients need to perform a particular action a specific number of times in order to satisfy the compulsion. To meet criteria for OCD, the compulsive actions must take over an hour a day or interfere with the patient's day-to-day life.

Lifetime prevalence of OCD is approximately 2.5%. While females are more frequently affected in general, males have a higher prevalence during childhood. Children generally present with vague anxiety symptoms or poor concentration before clear obsessions and compulsions are seen. In children, OCD is highly comorbid with Tourette disorder and ADHD. Other comorbidities include depression, anxiety disorders, and eating disorders.

Pediatric autoimmune neuropsychiatric disorders associated with Streptococcus pyogenes (PANDAS). *PANDAS* is the term proposed for a group of neuropsychiatric disorders (particularly OCD, tic disorder, and Tourette disorder) for which a possible relationship with group A streptococcal (GAS) infections has been hypothesized. This relationship has not been proven. It has been proposed that this subset of patients with obsessive-compulsive and tic disorders may produce autoimmune antibodies in response to a GAS infection that cross-react with brain tissue similar to the autoimmune response believed to be responsible for the manifestations of Sydenham chorea. Until carefully designed and well-controlled studies have established a causal relationship between neurobehavioral abnormalities and GAS infections, routine diagnostic laboratory testing for GAS and antistreptococcal antibodies, long-term antistreptococcal prophylaxis, or immunoregulatory therapy (e.g., intravenous immunoglobulin, plasma exchange) to treat exacerbations of this disorder clearly are not recommended. It has also been suggested that a broad spectrum of infectious agents may have the ability to trigger exacerbations in children with these neurobehavioral disorders.

Conditions Characterized by Fear

Fear is an intense emotion centered on a belief that something is dangerous or painful. Fears may be spontaneous or may arise from previous traumatic experiences. While all people experience fear as an emotion, in these disorders it causes significant functional impairment.

Fears Arising Spontaneously

Specific phobias. The hallmark of a specific phobia is intense fear upon exposure to a particular stimulus or situation, or occasionally upon thinking about or visualizing the stimulus. The fear is out of proportion to the actual danger. The fear response in children typically manifests as clinging, crying, having a tantrum, or "freezing." Common specific phobias include animals, heights, enclosed places, exposure to blood, or venipuncture. Specific phobias peak in childhood and early adulthood. Diagnostic criteria of a specific phobia are as follows:
1. Intense fear is caused by a particular stimulus.
2. The object or situation almost always provokes immediate fear or anxiety.
3. Stimuli are avoided or endured with great distress.
4. The fear is out of proportion to the actual danger.
5. The fear persists 6 months or longer.

Social anxiety disorder (social phobia). Social anxiety disorder is a specific phobia in which the stimulus is either a social or performance task. Diagnostic criteria include the following:

1. Marked fear about 1 or more social situations
2. Individual fears that he or she will act in a way that will be negatively evaluated
3. Social situations almost always provoke fear or anxiety
4. Social situations are avoided
5. Fear is out of proportion to the actual threat posed by the social situation
6. Fear or anxiety persists 6 months or longer

Social phobias most often begin in adolescence and are twice as common in boys as in girls. Children with social anxiety often refuse group play, stay close to familiar adults, and appear excessively timid in unfamiliar situations. Children may report somatic complaints, such as headaches or stomachaches, which abate when the child is allowed to remain home. Social phobia may be comorbid with panic disorder, other anxiety disorders, mood disorders, and substance abuse.

Separation anxiety disorder. The core fear in separation anxiety disorder is separation from a specific attachment figure or figures. Fear of separation is normal in infants and children aged 6-30 months but should be considered abnormal if increasing or not declining beyond this age range. Diagnosis requires the presence of symptoms for greater than 4 weeks. At least 3 of the following symptoms must be present:
1. Distress with separation
2. Worry about losing loved ones
3. Worry about an event causing separation
4. Refusal to go away from home
5. Reluctance to be alone
6. Refusal to fall asleep alone
7. Repeated nightmares of separation
8. Somatic complaints when separation occurs or is anticipated

The prevalence of separation anxiety disorder is as high as 5%, with onset typically in early childhood. Patients with separation anxiety disorder often display their worries as demands or behavioral outbursts, which may cause significant family conflict. Comorbid conditions include major depressive disorder and panic disorder with agoraphobia.

Selective mutism. Patients with selective mutism have a persistent failure to speak in specific, but not all, situations. Children with selective mutism are often shy in public but controlling at home in order to maintain proximity to parents. Diagnostic criteria include the following:
1. Consistent failure to speak in specific social situations
2. Failure to speak interferes with achievement or social communication
3. Duration of at least 1 month
4. Failure to speak is not due to lack of knowledge of the spoken language
5. Disturbance is not better explained by a communication or other psychiatric disorder

The differential diagnosis includes communication disorders, autism spectrum disorders, and social anxiety disorder. Selective mutism may be a more severe form of social anxiety disorder.

Fears Arising from Traumatic Events

A **traumatic event** is defined as an exposure to actual or threatened death, serious injury, or sexual violence. Responses to traumatic events include hyperarousal, avoidance of circumstances reminiscent of the event, or re-experiencing the event via nightmares and flashbacks. **Acute stress disorder** and **PTSD** are characterized by severe and persistent trauma responses that lead to impaired function. Symptoms are divided into 4 clusters: intrusion, avoidance, negative alteration in cognition and mood, and marked alterations in arousal and activity. **Acute stress disorder** is the persistence of at least 9 of the 14 defined

symptoms, regardless of symptom cluster designation, for 3 days to 1 month after exposure to a traumatic event. In contrast to acute stress disorder, **PTSD** must include symptoms from each of the separate symptom clusters. Exposure to the traumatic event includes directly experiencing the event, witnessing the event, learning the event occurred to a family member or close friend (caregiver for children under 6), or experiencing repeated or extreme exposure to details of a traumatic event.

1. Intrusion symptoms
   a. Distressing memories of the event
   b. Dreams in which content or effect of the dream is related to the event (in children, does not need to be related to event)
   c. Dissociative reactions in which the individual feels the event is recurring (flashbacks) (in children, may be reenactment in play)
   d. Psychologic distress at exposure to reminders of the event
   e. Marked physiologic reactions to reminders of the event
2. Avoidance
   a. Avoidance or efforts to avoid distressing memories (children may avoid places or physical reminders)
   b. Avoidance of external reminders (children may avoid people, conversations, or interpersonal relationships)
3. Negative alterations in cognition and mood
   a. Inability to remember an important aspect of the traumatic event (not a criterion for a child under 6 years of age)
   b. Persistent and exaggerated negative beliefs (not a criterion for a child under 6 years of age)
   c. Persistent, distorted thoughts about cause or consequences of trauma (not a criterion for a child under 6 years of age)
   d. Persistent negative emotional state (fear, guilt, sadness, shame)
   e. Decreased interest in activities (constriction of play in children)
   f. Feelings of detachment (socially withdrawn behavior in children)
   g. Persistent inability to experience positive emotions (express positive emotions in children)
4. Alterations in arousal
   a. Irritable behavior and angry outbursts (with little provocation)
   b. Reckless or self-destructive behaviors (not a criterion in a child under 6 years of age)
   c. Hypervigilance
   d. Exaggerated startle response
   e. Problems with concentration
   f. Sleep disturbance

While as many as 30% of children will have some symptoms of acute stress disorder following a trauma, only 10% will meet diagnostic criteria. The significance of acute stress disorder in predicting eventual development of PTSD remains unclear.

Comorbid diagnoses include panic disorder, social phobia, substance abuse, OCD, somatic symptom disorder, and major depressive disorder. In addition to PTSD, childhood trauma and other significant stressors, together known as adverse childhood experiences, have been found to predispose children to chronic medical and mental health conditions. These medical conditions include ischemic heart disease, cancer, chronic lung disease, skeletal fracture, and liver disease.

Conditions Characterized by Panic

Panic disorder. Panic attacks may be a component of many psychiatric disorders. While panic disorder is characterized by recurrent and unexpected panic attacks, the hallmark of panic disorder is persistent concern over having additional attacks, worry about the consequences of an attack, or a significant change in behavior related to the attacks. **Panic attacks** occur suddenly, peak within 10 minutes, often

resolve without intervention, and consist of at least 4 of the following symptoms:

1. Palpitations or tachycardia
2. Diaphoresis
3. Trembling or shaking
4. Shortness of breath or sensation of smothering
5. Feelings of choking
6. Chest pain
7. Nausea or abdominal discomfort
8. Dizziness or feeling faint
9. Chills or heat sensation
10. Paresthesias
11. Derealization (feelings of unreality) or depersonalization
12. Fear of losing control or "going crazy"
13. Fear of dying

The 1-year prevalence rate of panic disorder is as high as 3.5%. The age of onset is bimodal, with the largest peak occurring in adolescence and a smaller one in the mid-30s. Panic disorder in prepubertal children is rare.

Patients with panic disorder have a high degree of comorbid conditions. Over half of patients may have major depressive disorder. There is a high frequency of other anxiety disorders, such as social phobia, OCD, and generalized anxiety disorder. Patients with panic disorder are also at great risk for substance abuse as a consequence of self-medicating.

Agoraphobia. Agoraphobia is characterized by intense anxiety over developing a panic attack or other incapacitating or embarrassing symptoms in a place from which the person cannot escape or in which help may not be available. Diagnosis requires that the anxiety manifest in at least 2 of the following situations:

1. Riding public transportation
2. Being in open spaces
3. Being in enclosed spaces
4. Standing in line or in a crowd
5. Being outside of the home alone

The anxiety is present nearly every time an individual is exposed to the situation they fear and may also develop when the child knows that he or she may be placed in one of these situations. While agoraphobia does present in childhood, the peak of onset is late adolescence and early adulthood. It is seen in about 1.7% of adolescents. Females are affected twice as frequently as males. Agoraphobia is typically preceded by panic disorder, phobias, and separation anxiety disorder. Other comorbidities, such as depression and substance use disorder, often follow the presentation of agoraphobia.

CONDITIONS CHARACTERIZED BY MENTAL STATUS ABNORMALITIES

The evaluation of mental status changes (Fig. 27.4) involves first determining whether the abnormality is limited—such as hallucinations unaccompanied by changes in cognition or consciousness—or pervasive (see also Chapter 31). The abnormality should then be classified by whether it is episodic or persistent. Finally, the mental status change should be classified as either acute or chronic. An example of a limited, episodic, acute change in mental status is the development of hallucinations secondary to acute anxiety. In contrast, autism represents a pervasive, persistent, and chronic alteration in mental status.

Conditions Characterized by Hallucinations

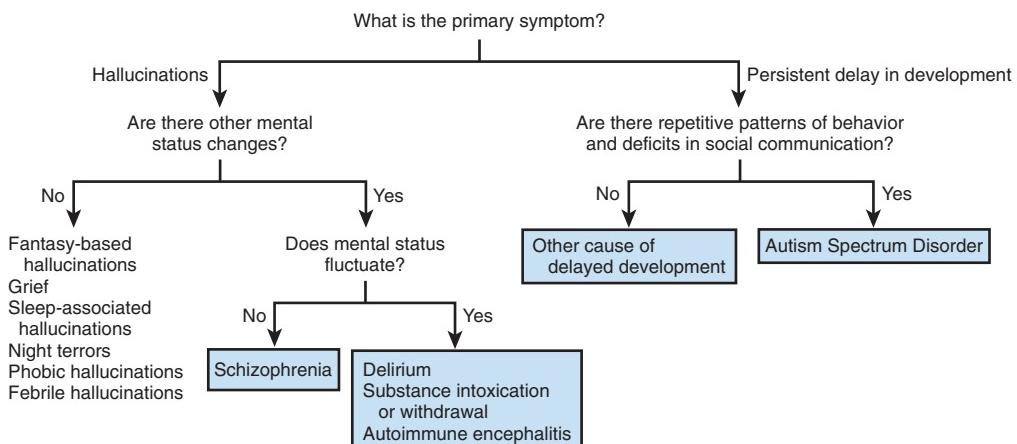
Hallucinations—the apparent perception of something that does not exist in reality—may be an indication of a medical condition, poor visual or auditory function, the ingestion of a substance, or a


FIGURE 27.4 Evaluation of abnormal mental status findings.

psychiatric illness (see Fig. 27.4). The vast majority of hallucinations in preadolescent children do not ultimately represent a serious psychiatric or medical illness. Hallucinations occur in as many as 5% of normal children.

The first step in evaluating hallucinations is to assess the patient's mental status. Most children with hallucinations have an otherwise normal mental status. If the primary alteration in mental status is confusion, medical **delirium** should be considered (see Chapter 31). The presence of **delusions**—beliefs that are maintained despite being objectively contraindicated by reality—should prompt consideration of schizophrenia or mood disorders. Most hallucinations associated with delirium are visual, whereas those observed in psychoses are typically auditory. Auditory hallucinations may be perceived as chatter or as a voice that chastises the child. Culture can often shape the content of hallucinations and whether the sensory experiences are considered worrisome or abnormal by the patient and family. Children with an otherwise normal mental status may hallucinate in the context of fantasy, grief, sleep, acute phobia, and fever.

Fantasy-based hallucinations. To define a subjective perceptual experience as hallucinatory, the person experiencing the phenomenon has to be able to distinguish imagination from reality. As they develop, children gradually learn that imagination and reality are two separate entities. Children under 3 years of age confuse reality with imagination. By 4 years of age, children understand the concept of "pretend," and by 7 years of age, they understand imagination but act as though the fantasy is still real. They may still describe having an imaginary friend. By 8 years of age, most children are reliably able to distinguish inner thoughts from voices. Some children are involved in more fantasy than are their peers and may engage in fantasy for entertainment or comfort. On occasion, they may get carried away by their fantasies and become quite fearful. Most of these children proceed to healthy psychologic adjustment. Children who have intellectual disability or other developmental delays may, appropriately, have imaginary friends or voices into adolescence.

Grief-induced hallucinations. The grieving process following the death of a loved one may include visual hallucinations of the deceased. These hallucinations can also be auditory, in which the child hears the voice of the deceased speaking to the child. The child's and the family's reaction to these hallucinations is dependent on their cultural and religious beliefs. Some families may perceive these events as a supernatural or a religious experience. Although these experiences may be frightening to some young children, many find reassurance or comfort.

Hallucinations associated with sleep. Dreamlike hallucinations can occur during various stages of sleep. Some may be considered bizarre by the patient and may include partial preservation of consciousness. **Hypnagogic hallucinations** occur during sleep onset and **hypnopompic hallucinations** occur during awakening. The overall prevalence of hypnagogic hallucinations is as high as 37%; that of hypnopompic hallucinations is as high as 12.5%. Patients with insomnia or excessive daytime sleepiness may be more likely to experience sleep-related hallucinations. As many as 30% of patients with **narcolepsy** experience both hypnagogic and hypnopompic hallucinations. These hallucinations can also occur as part of PTSD, in which case they often take the form of a flashback or re-experiencing of the traumatic event. **Night terrors** may resemble hallucinations, though are a distinct entity of non–rapid eye movement sleep arousal. The DSM-5 defines **sleep terror disorder** as recurrent episodes of night terrors. During episodes, the child appears to arouse from sleep and cries or screams inconsolably, may speak unintelligibly, and exhibits intense fear and autonomic arousal (e.g., tachycardia, sweating). On awakening, the child has no memory of the event. Episodes of night terrors last from 1-10 minutes. Night terrors occur during stage 4 sleep and not during rapid eye movement sleep and tend to occur in the first half of the night. Over 30% of 18-month-old toddlers will experience a night terror, with the prevalence decreasing to 2.2% by adulthood. **Seizures**, especially of the temporal and frontal lobes, can produce fear and complex behavior patterns resembling night terrors, and should be considered in the differential diagnosis of night terrors.

Phobic hallucinations. Acute phobic hallucinations occur in preschool-aged children and consist of episodes of hallucinations coupled with terror. These hallucinations last from 10-60 minutes and may occur any time of the day but mostly at night. During episodes, the child may become very frightened, state that bugs are crawling over him or her and attempt to remove them, cry, or hide. Because of the acute change in mental status, this condition must be differentiated from the medical and psychotic causes of hallucinations, such as delirium. The cause of acute phobic hallucinations is unknown. Phobic hallucinations are most frequently seen in children with a personal or family history of anxiety. Symptoms usually last 1-3 days and diminish over 1-2 weeks.

Febrile hallucinations. Preschool-aged children may hallucinate during high fevers. The hallucinations are temporary and are not associated with future psychiatric disorders. The phenomenon may represent a mild form of delirium and typically requires only reassurance for management, as well as evaluation for the source of fever. Persistent hallucinations, impaired consciousness, and changes in cognition, such as not recognizing parents or difficulty completing previously accomplished tasks, suggest frank delirium and require further evaluation.

Schizophrenia. Schizophrenia is a disorder of chronic, persistent psychosis (loss of reality testing) that often presents in adolescence or young adulthood. Symptoms are divided into 4 domains: positive symptoms, negative symptoms, cognitive symptoms, and mood symptoms. **Positive symptoms** consist of psychotic symptoms (such as hallucinations), delusions (fixed false beliefs), and disorganized speech and behavior (loose associations). **Negative symptoms** consist of social withdrawal, flattening of affect, alogia (i.e., speaking in brief sentences), abulia, apathy, and avolition (i.e., lack of desire to do anything) (see Table 27.4). The flat affect may consist of a reduction in body language, lack of eye contact, and emotional unresponsiveness (see Table 27.4). **Cognitive symptoms** are characterized by deficits in executive function and an inability to appreciate and react appropriately to social cues. **Mood symptoms** often consist of depression though may also consist of context-inappropriate cheerfulness or sadness. The symptoms may fluctuate over time, and as such, schizophrenia is divided into 2 phases: prodromal and active. Diagnostic criteria for schizophrenia specify 2 or more of the following **characteristic symptoms:**

1. Delusions
2. Hallucinations
3. Disorganized speech
4. Grossly disorganized or catatonic behavior
5. Negative symptoms, such as flat affect

At least 1 symptom must be delusions, hallucinations, or disorganized speech and the symptoms must appear in the context of significant social and educational dysfunction. There must also be continuous indications of the disturbance for at least 6 months, with at least 1 month of active-phase symptoms. Medical causes and mood disorders need to be excluded (Table 27.7; see Table 27.3).

During the **prodromal phase**, the patient exhibits progressive **negative symptoms**. During this period, the patient may also have unusual beliefs that are not of the magnitude of true delusions or hallucinations. The patient may have magical thinking or may perceive that someone is talking to him or her, but no words are hallucinated.

During the **active phase** of schizophrenia, the patient has at least 2 characteristic symptoms for more than 1 month, unless the symptoms have been shortened by treatment. The most common **delusions** in this disorder are persecutory (e.g., the patient is being spied on) and referential (e.g., external events or comments are directed toward the patient). Other less common delusions may be somatic (e.g., internal organs are replaced by others), religious, or grandiose in nature. Hallucinations are most commonly auditory, but may emanate from any sensory modality.

The **disorganized speech** may be incomprehensible, and the patient may be unable to organize a logical conversation. The behavior problems consist of inappropriate dress, disheveled appearance, unprovoked aggression, and **catatonia,** decreased responsiveness to the environment. If symptoms have not been present for 6 months, the provisional diagnosis of **schizophreniform disorder** is applied. Approximately 65% of patients with schizophreniform disorder have symptoms that last longer than 6 months and are reclassified as having schizophrenia.

Schizophrenia is exceedingly rare and is often a misdiagnosis prior to 13 years of age. If diagnosed prior to this age, it is labeled as **childhood onset** or **very early onset schizophrenia**. Prevalence is approximately 2.5/100,000 in children under 13 years of age and 6/100,000 in adolescents. Forty percent of males and 23% of females with schizophrenia will have onset during adolescence. The differential diagnosis of schizophrenia consists of delirium, dementia, mood disorder, pervasive developmental disorders, and substance ingestion (Table 27.8; see Table 27.3). The prognosis of schizophrenia is guarded, with

TABLE 27.7 Features Suggesting Neurologic Disease in Patients with Psychiatric Symptoms

Atypical Psychiatric Features
Late or very early age of onset
Acute or subacute onset
Lack of significant psychosocial stressors
Catatonia
Diminished comportment
Cognitive decline
Intractability despite adequate therapy
Progressive symptoms

History of Present Illness
New or worsening headache
Inattention
Somnolence
Incontinence
Focal neurologic complaints such as weakness, sensory changes, incoordination, or gait difficulty
Neuroendocrine changes
Anorexia/weight loss

Patient Medical History
Risk factors for cerebrovascular disease or central nervous system infections
Malignancy
Immunocompromised status
Significant head trauma
Seizures
Movement disorder
Hepatobiliary disorders
Abdominal crises of unknown cause
Biologic relatives with similar diseases or complaints

Unexplained Diagnostic Abnormalities
Screening laboratories
Neuroimaging studies or possibly imaging of other systems
Electroencephalogram
Cerebrospinal fluid

significant morbidity and mortality. The risk of suicide is high early in the illness. The disorder is chronic and is associated with exacerbations and remissions. Even with optimal therapy, patients with schizophrenia have significant social deficits, poor initiative, and abnormal thought processes.

Conditions Characterized by Fluctuating Mental Status

Delirium. Delirium is characterized by deficits in cognition and consciousness that develop over a short time (see Chapter 31). Diagnostic criteria include the following:
1. Disturbance in awareness and attention (i.e., reduced ability to direct, focus, sustain, and shift attention)
2. Change in cognition (e.g., memory deficit, disorientation, language disturbance, perceptual disturbance) that is not better accounted for by a preexisting, established, or evolving dementia
3. Disturbance develops over a short period of time and tends to fluctuate over time
4. There is evidence of a medical, substance-induced, or toxin-induced cause

Children with delirium may misinterpret auditory or visual stimuli or may have actual hallucinations. The hallucinations of delirium are different from those seen in psychosis in that they are more often visual and acute in onset, whereas those resulting from psychoses are usually auditory and are subacute or chronic.

Besides altered sensorium, patients often have decreased sleep or reversal of the sleep/wake cycle and may exhibit psychomotor agitation or retardation. Delirium is indicative of global cerebral dysfunction. Because causes of delirium are potentially life threatening, an expedient and comprehensive medical evaluation is needed.

Substance intoxication. Intoxication is defined as clinically significant behavioral or psychologic changes following the use of a substance. The most common signs of intoxication are changes in perception, wakefulness, attention, thinking, judgment, coordination, and interpersonal behavior. Physical findings suggest particular classes of medications and cluster into recognizable patterns of signs and symptoms termed **toxidromes** (Table 27.9). If the suspected cause of altered mental status in a patient is substance intoxication, urine and blood toxicology testing should be performed.

Patients who present with substance intoxication should be evaluated for whether the ingestion represented an attempt at self-harm or suicide. Some substance intoxications will require medical hospitalization, if severe. Patients being treated for psychiatric illnesses may be at risk of 2 particular toxidromes related to their medical therapy, **serotonin syndrome** and **neuroleptic malignant syndrome**.

TABLE 27.9 Clinically Relevant Toxidromes

Toxidrome	Clinical Findings	Example Agents
Cholinergic	Diarrhea, fecal incontinence, enuresis, miosis, tachycardia followed by bradycardia, lacrimation, sialorrhea, sweating, muscle fasciculations followed by weakness and/or paralysis, altered mental status	Organophosphate and carbamate insecticides; *Amanita muscaria*; Nicotine
Anticholinergic	Agitated delirium, flushing, decreased sweating, tachycardia, mydriasis, urinary retention, decreased peristalsis, hyperthermia	Atropine; Benztropine; Scopolamine; Diphenhydramine
Sympathomimetic	Mydriasis, hyperthermia, seizures, hyperactivity, hypertension, tachycardia, diaphoresis, delusions, piloerection	Cocaine; Methamphetamine; MDMA
Sympatholytic	Miosis, hypotension, bradycardia or reflex tachycardia, CNS depression	Clonidine; Methyldopa; Oxymetazoline
Opioid	Miosis, CNS depression, respiratory depression or apnea, may have hypotension	Heroin; Morphine; Fentanyl; Oxycodone
Serotonin syndrome	Mental status changes, autonomic hyperactivity, neuromuscular abnormalities, akathisia, tremor, clonus, muscle hypertonicity, hyperthermia	Sertraline; Fluoxetine; Citalopram; Linezolid; Trazodone; Meperidine; Tramadol
Neuroleptic malignant syndrome	Fever, "lead pipe" muscular rigidity, altered mental status, autonomic dysfunction (in setting of recent treatment with neuroleptics)	Haloperidol; Chlorpromazine; Promethazine; Prochlorperazine; Ziprasidone; Quetiapine

CNS, central nervous system; *MDMA,* methylenedioxymethamphetamine.
From Skolnik AB, Wilcox SR. General toxicology and toxidromes. In: *Critical Care Secrets.* 5th ed. St. Louis: Mosby; 2013:545-551.

Serotonin syndrome. The triad of cognitive-behavioral changes, autonomic instability, and neuromuscular signs and symptoms are characteristic of the central serotonin syndrome. Patients frequently manifest behavior alterations that include confusion, disorientation, agitation, and irritability. Coma, anxiety, seizures, hallucinations, and hypomania are less common.

Central serotonin syndrome results from excessive central nervous system serotonin activity from dietary supplements or the use of substances that modify central nervous system serotonin levels. Most commonly, these agents are selective serotonin reuptake inhibitors or other substances that inhibit serotonin reuptake, including tricyclic antidepressants, meperidine, dextromethorphan, and 3,4-methylenedioxymethamphetamine (MDMA). Other substances, such as amphetamines, cocaine, and levodopa, increase synaptic serotonin release, while others such as lithium and lysergic acid diethylamide, are serotonin agonists. Monoamine oxidase inhibitors inhibit serotonin degradation.

Autonomic features of serotonin syndrome include hyperthermia, diaphoresis, and tachycardia. Hypertension, mydriasis, and tachypnea are less common. Neuromuscular features include myoclonus, hyperreflexia, tremor, restlessness, hyperactivity, and ataxia. **Neuroleptic malignant syndrome** is included in the differential diagnosis and is distinguished by neurologic exam since neuroleptic malignant syndrome presents with hyporeflexia and lead-pipe muscular rigidity.

Neuroleptic malignant syndrome. The hallmark of neuroleptic malignant syndrome is severe generalized rigidity, fever, and altered mental status consisting of delirium or stupor. Other findings include diaphoresis, significant creatine kinase elevation, autonomic instability, urinary incontinence, tachypnea, and pallor. While rare, as many as 0.02% of individuals treated with antipsychotics are affected and fatality rates are as high as 20% if the condition is not recognized and managed appropriately. Differentiation from serotonin syndrome is based on medication review, and the presence of significant rigidity, which serotonin syndrome lacks.

Conditions Characterized by Persistent Delay in Development

Delayed development (see Chapter 24) is a broad category of illnesses that can cause specific or global delays. The causes of general developmental delay encompass many conditions; in more than half the cases, a medical condition has caused the delay. These medical conditions include genetic disorders (5%), alterations of embryonic development (30%), perinatal or prenatal disorders (10%), and other medical illness of childhood (5%). Another 15-20% of cases are caused either by deprivation or by severe mental disorders, such as autism spectrum disorder. Specific developmental delays may be secondary to a medical condition such as cerebral palsy, learning disorders, or communication disorders.

Autism spectrum disorder. Autism spectrum disorder is characterized by severe impairment in social communication and interaction, as well as restricted, repetitive patterns of behavior, interests, or activities. In the DSM-5, the previously distinct subtypes of autism, Asperger disorder, and pervasive developmental disorder not-otherwise-specified have been incorporated into a unified diagnosis of autism spectrum disorder. Diagnosis requires the presence of the following 3 deficits in social communication:
1. Deficits in social-emotional reciprocity
2. Deficits in nonverbal communicative behaviors used for social interaction
3. Deficits in developing, maintaining, and understanding relationships

The patient also needs to demonstrate 2 of the following symptoms of repetitive patterns of behavior, interests, or activities:
1. Stereotyped or repetitive motor movements, use of objects, or speech
2. Insistence on sameness, inflexible adherence to routines, or ritualized behaviors
3. Highly restricted, fixated interests
4. Hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of the environment.

Autism spectrum disorder typically is recognized during the 2nd year of life, when the lack of interest in social interaction, loss or lack of developing language skills, odd play patterns, and unusual communication patterns become more apparent. Despite potential loss of language early in life, autism is not a degenerative disorder, and developmental gains are typically seen. Intellectual disability may be seen with autism spectrum disorder and is listed as a specifier for diagnosis. However, patients with autism typically have uneven intellectual profiles, making thorough neuropsychologic testing highly recommended. Other comorbidities are common and include ADHD, anxiety disorders, developmental coordination disorder, specific learning disorders, avoidant/restrictive food intake disorder, seizures, and depressive disorders. Medical comorbidities are common and include epilepsy, sleep problems, and constipation.

CONDITIONS CHARACTERIZED BY PHYSICAL FINDINGS OR COMPLAINTS

Parents may present to the primary care provider with unexplained physical complaints on behalf of the child. These complaints may be inconsistent with the results of the medical evaluation and may fail to respond to any medical therapy. These unexplained physical complaints may be the manner in which a patient copes with a stressor. The patient may not be aware of the stressor, nor may the patient realize that these symptoms emanate from his or her effort to cope with the problem. The clinician should empathize with the patient, validate the presence of the symptoms, then state which potentially serious medical conditions are reasonably felt to be unlikely based on the patient's history, examination, and diagnostic evaluation. The clinician should highlight the notion that stress can produce or worsen symptoms and should recommend that the possibility of stress be evaluated while the clinician continues to monitor the patient for other medical illnesses. Key to the evaluation is determining whether the symptoms are more concerning primarily to the parent or to the child.

Conditions Characterized by Parental Concerns

Parental worry. Parents may worry excessively about their child's health because of a preceding life-threatening event or illness, mistrust of the medical profession, or as an expression of their own fear of having a serious condition themselves. These parents do not invent the child's symptoms but instead experience an exaggerated worry about symptoms. The evaluation of a parent's excessive concern over the child's health may be further subdivided into specific concerns versus general medical worries.

Specific medical concerns are often related to prior life-threatening events or illnesses, or previous negative experiences with the health care system. Reassurance after an appropriate and thorough medical evaluation may reduce parental anxiety. When the parent reveals the past incident that led to distrust of the reassurances of doctors, the clinician may be able to reduce the parent's worry through open discussion on the differences between past and current events.

If the parent reports that he or she worries about everything, the clinician should determine whether this is a recent development or a

chronic concern. Parents with an acute onset of general medical worries about their children may suffer from a recent stressor or may have anxiety, depression, or OCD. Reassurance alone may be insufficient under these circumstances and the parent's generalized worries may not improve until their own symptoms improve.

Factitious disorder imposed on another (formerly Munchausen syndrome by proxy) (see also Chapter 26)**.** This disorder is a condition in which the patient either feigns or produces symptoms and physical findings in their child to fulfill an underlying need to assume the sick role and receive care. There is no external reward for these symptoms, in contrast to **malingering**, in which the symptoms result in either economic gain or in avoidance of responsibilities.

Red flags include unexplained and prolonged illnesses, incongruous symptoms and signs, ineffective medical treatments, and prior episodes of sudden infant death syndrome. The offending caregiver may not seem worried about the child's medical condition. Some caregivers may form an unusually close relationship with the medical staff; however, there are many exceptions, in which the caregiver is instead neglectful, disruptive, and argumentative.

When this entity is suspected, the first step in evaluation is to ensure the child's safety, which may require hospitalization on a medical ward. With safety assured, the next step is to develop a definitive investigative plan with a multidisciplinary team consisting of mental health professionals, physicians, social services, child abuse specialists, and the legal system. This plan may include surveillance by covert video camera, with appropriate hospital legal advice and oversight, and an approved protocol.

Conditions Characterized by the Patient's Physical Complaints

Psychologic stressors may result in the development of physical symptoms. Evidence that supports a stressor as a cause of the symptom is the potential gain from the symptom and the temporal relationship of the stressor and the symptom. For example, a child may develop chronic fatigue symptoms on the anniversary of his or her mother's death, or a patient's persistent abdominal pain from inflammatory bowel disease may prevent the patient from returning to school, despite medical evidence that the disease is in remission. These symptoms seem real to the child and cause a great deal of distress. Extreme manifestations of these concerns include the somatic symptom disorders.

Illness anxiety disorder (hypochondriasis). In illness anxiety disorder, the child either fears that he or she has a serious illness or focuses on minor discomforts with a worry that he or she may have a life-threatening illness. The hallmark is not the physical symptom but the anxiety over what the symptom represents. Illness anxiety disorder is often associated with other anxiety and depressive disorders; consequently, these patients may appear sad, irritable, or fatigued and should be screened for suicidal ideation or intent, as well as evidence of other comorbid psychiatric disorders.

Somatic symptom disorder. Somatic symptom disorder requires the presence of a physical symptom that is distressing. That symptom must then lead to 1 of the following 3 behaviors:
1. Disproportionate and persistent thoughts about the seriousness of one's symptoms
2. Persistently high level of anxiety about health or the symptom
3. Excessive time and energy devoted to the health concern.

In addition, the patient must have at least 1 symptom for 6 months. This is separate from illness anxiety disorder as the patient's complaints are focused on the symptom, not anxiety about developing a life-threatening illness. It is important to note that, in contrast to conversion disorder, the symptom does not have to be medically unexplainable.

Associated comorbid conditions are major depressive disorder, panic disorder, substance abuse, borderline personality disorder, and antisocial personality disorder. This is a chronic condition that rarely remits. The psychiatric differential diagnosis is extensive and includes major depression, schizophrenia with somatic delusions, panic disorders (in which symptoms occur only during an attack), generalized anxiety disorder, and factitious disorder.

Factitious disorder. Factitious disorder consists of a patient inducing symptoms or signs to assume the role of being sick and to receive care. There is no secondary gain, such as escaping responsibilities or receiving money, as is found with malingering. The onset of this disorder usually occurs in early adulthood; it can also occur in childhood. Patients are at risk for substance use disorders (secondary to using agents to induce symptoms) as well as for complications from associated diagnostic evaluations and unnecessary surgical procedures. On confrontation, they may either change their symptoms or try to seek medical care elsewhere.

Conversion disorder (functional neurologic symptom disorder). The diagnosis of conversion disorder is based on the presence of 1 or more symptoms of altered voluntary motor or sensory function. Symptoms may take the form of weakness, paresthesias, or paroxysmal episodes of erratic movements that may be mistaken for seizure activity. The history, physical examination, and neurologic diagnostic evaluation, including the use of long-term video electroencephalogram monitoring in the case of paroxysmal movements, demonstrate incompatibility between the symptom and any medical condition. Unlike somatic symptom disorder, in which patients have excessive thoughts, feelings, or behaviors associated with the voluntary motor or sensory function, conversion disorder is an unconscious phenomenon.

Onset is usually in late adolescence or early adulthood. A typical episode is acute, follows a recent stressor, and is of relatively short duration, typically less than 4 weeks. The symptoms may solve a psychologic conflict. For example, complaints of blindness may prevent a patient from being witness to traumatic events in his or her environment. Common childhood stressors associated with conversion disorders are grief, bullying, and abuse. Major depressive disorder and anxiety disorders are associated with conversion disorders.

Conditions Characterized by Changes in Eating or Weight

Anorexia nervosa. Anorexia nervosa is an eating disorder in which the patient restricts caloric intake due to a significant fear of gaining weight and distorted body image. There are 2 subtypes, **restricting type** and **binge-eating/purging type**. Diagnostic criteria are as follows:
1. Restriction of energy intake leading to a significantly low body weight
2. Intense fear of gaining weight or becoming fat
3. Distorted perception of body size, undue influence of body weight or shape on self-evaluation, or lack of recognition of severity of low body weight.

Patients with anorexia nervosa will often go to great lengths to hide their intent and symptoms, oftentimes by wearing baggy clothes, by explaining that excessive and vigorous exercise are required for sports participation, by rationalizing food restriction as health consciousness, by complaining that allergies ruin the taste and smell of food, or by concealing purging behaviors, such as induced vomiting or diarrhea. Because of frequent concealment, the detection of these behaviors is challenging.

The prevalence of anorexia nervosa is as high as 1%; almost 90% of cases occur in females. Although this condition is associated with higher socioeconomic status, it can occur in persons from a variety of socioeconomic backgrounds and in all ethnic groups.

Besides weight loss, patients with anorexia nervosa may develop symptoms of depression or may withdraw socially secondary to the physiology of starvation. Actual loss of appetite is rare, though patients with anorexia have been found to have higher levels of leptin, which suppresses appetite. Patients with anorexia may develop obsessive-compulsive behavior regarding food, such as collecting recipes or hoarding food. These patients may also have inflexible thinking or feel the need to control their environment.

Anorexia nervosa may affect every organ system, and presenting symptoms and signs are secondary to malnutrition and purging. The symptoms of **malnutrition** are fatigue, depression, and amenorrhea. The physical findings of malnutrition are bradycardia, hypothermia, hypotension, emaciation, hair loss, yellow skin, and lanugo. If the patient controls caloric intake through **purging** via vomiting, findings may include hypertrophic salivary glands, dental erosions secondary to gastric acid irritation, and abrasions or calluses on the dorsum of the hand secondary to manual induction of vomiting. The metabolic abnormalities related to starvation and purging consist of leukopenia, anemia, hyperamylasemia from parotid gland irritation, vomiting-related metabolic alkalosis or laxative-associated metabolic acidosis, thyroid abnormalities, hypomagnesemia, hypocalcemia, hypozincemia, and electrolyte abnormalities resulting from diuretic abuse and dehydration. These patients also have regression of the hypothalamic-pituitary-gonadal axis, which results in low estrogen levels in girls and low testosterone levels in boys.

In evaluating an adolescent with unexplained weight loss, the examiner must rule out the medical causes of cachexia such as malignancy, malabsorption (celiac disease), or inflammatory bowel disease. Interview data that support a diagnosis of anorexia nervosa are a restrictive dietary history, distorted perception of body shape, and rationalization of the causative behaviors. Once the medical causes for weight loss have been ruled out, the examiner must consider the psychiatric differential diagnosis for anorexia nervosa and its associated comorbid conditions. These conditions are major depressive disorder, the abuse of stimulants, OCD, social phobia, body dysmorphic disorder, and bulimia nervosa. If the patient has symptoms of depression that fail to resolve with the correction of malnutrition, the clinician should also consider the diagnosis of major depressive disorder.

Anorexia nervosa is associated with both life-threatening psychologic conditions (i.e., suicide) and medical conditions (e.g., electrolyte abnormalities, cardiac failure, starvation). The lifelong rate of mortality secondary to anorexia nervosa in patients who require hospitalization is more than 10%. Some of the possible medical complications are osteoporosis resulting from hypocalcemia with low serum estrogen levels, cardiomyopathy, anemia, sepsis resulting from malnutrition-induced immunodeficiency, arrhythmias resulting from electrolyte abnormalities, and superior mesenteric artery syndrome. The **superior mesenteric artery syndrome**, which is characterized by postprandial vomiting and pain secondary to intermittent gastric outlet obstruction, is more common in anorexia nervosa as profound weight loss is believed to result in the loss of the intraabdominal fat pad between the duodenum and superior mesenteric artery.

Bulimia nervosa. Diagnostic criteria for bulimia nervosa are as follows:

1. Recurrent episodes of **binge eating** (eating more than what most individuals would eat in a discrete period and a sense of lack of control over eating)
2. Recurrent inappropriate **purging** (compensatory behaviors for controlling weight gain, such as induced vomiting, laxative misuse, diuretic misuse, prolonged fasting, or excessive exercise)
3. Binge eating and compensatory measures occur at least once a week for 3 months

4. Self-evaluation is unduly influenced by body shape and weight
5. Does not occur within anorexia nervosa

Bulimia nervosa is twice as common as anorexia nervosa and has a later onset, typically in late adolescence. Unlike anorexia nervosa, there is not significant food restriction or low body weight. Like anorexia nervosa, it is more common in females (90%) and can occur in any socioeconomic background. Almost 90% of patients control their weight gain by purging. Other methods for controlling weight are excessive exercise and fasting before binge eating.

Comorbid psychologic conditions are common in bulimia nervosa and include mood disorders, personality disorders, anxiety disorders, and substance use. Approximately 30% of patients who use medications to control weight also have substance use disorders, typically of alcohol or stimulants. In contrast to anorexia nervosa, significant medical complications occur less commonly in bulimia nervosa. If present, comorbid medical conditions of bulimia nervosa are associated with vomiting or medication abuse. These conditions are esophagitis and gastritis, cardiomyopathy (particularly if syrup of ipecac is used to induce vomiting), hypokalemia and nephrolithiasis from diuretic abuse, metabolic alkalosis from vomiting and metabolic acidosis from laxative abuse, and increased amylase levels.

Concealment of symptoms coupled with the lack of cachexia makes bulimia nervosa difficult to detect. Some patients may present to the clinician because of a parent's detection of binge eating and purging. Physical findings that suggest recurrent vomiting are dental erosion, parotid hypertrophy, callus abrasions on the dorsum of the hand known as **Russell sign**, and pharyngeal irritation.

Binge eating disorder. Binge eating disorder consists of recurrent binge eating episodes without compensatory behaviors to prevent weight gain. Patients with binge eating disorder may be of normal weight or overweight. DSM-5 criteria are as follows:

1. Recurrent episodes of binge eating (eating more than what most individuals would eat in a discrete period and a sense of lack of control over eating)
2. Binge-eating episodes are associated with 3 of the following:
   a. Eating much more rapidly than normal
   b. Eating until feeling uncomfortably full
   c. Eating large amounts of food when not hungry
   d. Eating alone because of embarrassment by how much one is eating
   e. Feeling disgusted, depressed, or guilty afterward
3. Marked distress regarding binge eating is present
4. Binge eating occurs, on average, at least once a week for 3 months

Binge eating disorder is distinct from obesity as most individuals with obesity do not engage in recurrent binge eating episodes. At this time, there is limited data regarding the prevalence of binge eating disorder in youths. In adults, it is roughly twice as common in females.

Avoidant/restrictive food intake disorder (ARFID). The hallmark of this condition is avoidance or restriction of food intake in infancy or early childhood that is not related to a disturbance in the way in which one's body weight or shape is experienced. The restriction in eating must be associated with 1 or more of the following:

1. Significant weight loss
2. Significant nutritional deficiency
3. Dependence on enteral feeding tubes or supplements
4. Marked interference with psychosocial functioning

Two common reasons that patients develop ARFID are an aversion to the sensory characteristics of food or a conditioned negative response to eating. Examples of sensory aversions include extreme sensitivity to appearance, color, smell, texture, or taste of food. It is separate from "picky eating" in that the restriction leads to 1 of the above outcomes. A conditioned negative response to eating could

result from an episode of choking, trauma to or traumatic investigations of the throat or upper gastrointestinal tract, or repeated vomiting. Risk factors for ARFID include anxiety disorders, autism spectrum disorder, OCD, ADHD, familial anxiety, gastroesophageal reflux disease, vomiting, and other gastrointestinal conditions.

SUMMARY AND RED FLAGS

Suicide is the second leading cause of death in adolescents. Identifying suicidal ideation and intent is crucial in the evaluation of patients presenting with changes in mood or behavior. Changes in mood or behavior carry a significant burden for patients, their family members, and society as a whole. Many psychiatric illnesses have comorbid psychiatric and medical conditions that require thoughtful and deliberate assessment, and many psychiatric symptoms may be secondary to an underlying medical condition. Red flags include risk-taking behavior, violence, poor school performance, poor attention to personal appearance and hygiene, deteriorating social interaction, reduced appetite, weight loss, reduced or excessive sleeping, delusions, and hallucinations.

Headaches

Sara M. Lauck and Sandra Gage

INTRODUCTION

Headaches are classified as primary or secondary. **Primary headaches** are benign, are not caused by underlying disease or structural problems, and include migraines, tension-type headaches, and the trigeminal autonomic cephalgias (Table 28.1). While primary headaches may cause significant pain and disability, they are not intrinsically dangerous. **Secondary headaches** are caused by an underlying disease, such as infection, tumor, intracranial hemorrhage, or a vascular disorder, and may indicate an innocuous etiology or portend a serious illness. Most headaches in children are primary headaches or harmless secondary headaches. History and physical examination guide the diagnosis of primary headache disorders, assess the degree of headache-related disability, and reveal information that may prompt evaluation for secondary headaches. Each subsequent visit allows for assessing the response to therapy and considering secondary headaches, the causes of some of which may be life threatening.

◆ History

The specific headache diagnosis is determined by the headache phenotype, which is defined in terms of laterality, location (Figs. 28.1, 28.2, and 28.3), timing, frequency, duration, quality, severity, associated symptoms, and alleviating and aggravating factors. In most cases, a single phenotypic headache is present. If the patient has more than 1 type of headache, the clinician must obtain a specific history for each type. Ideally, the history should be obtained from the child, parent, and any other caregivers, including teachers. Even a young child should be given the opportunity to describe the symptoms experienced with each headache episode and may use drawings to do this.

The laterality and location of the pain should be established (see Figs. 28.1, 28.2, and 28.3). If the pain is unilateral, it should be noted whether the pain is always on 1 side or if the side varies. The location may be fairly restricted or more widely distributed; if the location varies from 1 episode to another, this should be noted as well. The timing, frequency, and duration of headaches should be described, as the temporal patterns of headaches are useful in both creating a differential diagnosis and classifying the subtype of a particular headache diagnosis. The temporal categories of headache include acute, acute recurrent, chronic nonprogressive, and chronic progressive (Table 28.2).

The severity of a headache does not necessarily correlate with the seriousness of its etiology. Pain caused by brain tumors may initially be mild, whereas the pain of tension-type headaches may be excruciating. Pain is subjective and may be influenced by age, culture, duration, and previous encounters with medical care, leading some patients to unintentionally minimize or exaggerate their pain; as such, pain alone should not be used to narrow the differential diagnosis. An exception to this principle is the **thunderclap headache**, in which pain onsets suddenly, reaches maximum severity within seconds, and is oftentimes described by patients as the worst headache they have ever had. Such headaches may indicate subarachnoid hemorrhage, arterial dissection, or venous sinus thrombosis, among other causes (Table 28.3). Numerical scales, or visual scales for younger children, are helpful for quantifying pain and determining the efficacy of treatment. In older patients, descriptive phrases, such as *mild, moderate, severe,* and *excruciating,* may suffice.

Associated symptoms such as hemiparesis, ataxia, visual loss, diplopia, scotomas, vertigo, seizure-like activity, confusion, mood or behavioral changes, autonomic symptoms, and hemisensory occurrences may suggest neurologic dysfunction or a migraine-related aura. Any history of fevers, syncope, nausea, vomiting, and appetite changes should also be ascertained. Special note should be made if the pain awakens the patient from sleep, is present upon awakening in the morning, or worsens when recumbent; these findings may indicate increased intracranial pressure. Events associated with the onset or aggravation of headaches, such as trauma, intake of particular foods, or physical exertion, may provide insight into the etiology of headaches, as well as potential triggers to avoid. Alleviation via rest or positional changes should be noted, as should the response of the headaches to particular medications. A thorough medication history is essential for diagnosing analgesic overuse headaches and headaches caused by medication side effects. The use of over-the-counter medication and prescription medications, including medications that have not been prescribed for the patient, should be delineated, as well as any supplements or traditional remedies. Both primary and secondary headaches may respond to medications and such a response is not diagnostic of any particular headache disorder. For example, relief of an acute headache by triptans is not diagnostic of migraine, as triptans may also be effective for other causes of headache. An exception is certain trigeminal autonomic cephalgias, which respond only to indomethacin.

In patients with recurring headaches, the history may be clarified by keeping a **headache diary**, which can additionally determine headache patterns, identify triggers, aid diagnosis, and assess the efficacy of therapy (Table 28.4). A headache diary may also assist in determining the degree of disability caused by the headache. Disability evaluation

(See *Nelson Textbook of Pediatrics,* p. 2863.)

TABLE 28.1	Differential Diagnosis of Headache				
Headache Type	**Genetics**	**Epidemiology**	**Characteristic Features**	**Length**	**Accompanying Symptoms**
Migraine headache	Complex genetics but usually a family history	More frequent in women	Unilateral, bilateral; throbbing; moderate to severe; worsens with activity	Hours to days	Photophobia, phonophobia, nausea and/or vomiting
Tension-type headache	Usually a family history	Equal frequency in men and women	Tight bandlike pain; bilateral; pain may be mild to moderate; improves with activity	Hours to days	No nausea or vomiting; small amount of light or sound sensitivity, but not both
Cluster headache	May have a family history	More frequent in men	Unilateral severe pain in the face	Minutes to hours	Ipsilateral ptosis, miosis, rhinorrhea, eyelid edema, tearing
Paroxysmal hemicrania	Usually no family history	More frequent in women	Unilateral pain in the face	Minutes	Ipsilateral ptosis, miosis, rhinorrhea, eyelid edema, tearing; responds to indomethacin
Short unilateral headache with conjunctival injection, tearing	No family history	More frequent in men	Unilateral eye pain; orbit pain	Typically 4 minutes or less	Conjunctival injection, tearing
Hemicrania continua	No family history	More frequent in women	Unilateral continuous headache with episodic stabbing pains	Continuous	Ipsilateral ptosis, miosis, rhinorrhea, eyelid edema, tearing

TABLE 28.2 Four Temporal Patterns of Childhood Headache

Acute: Single episode of pain without a history of such episodes. The "first and worst" headache, which raises concerns for aneurysmal subarachnoid hemorrhage in adults, is commonly due to a *febrile illness* related to upper respiratory tract infection in children. Regardless, more ominous causes of acute headache (hemorrhage, meningitis, tumor) must be considered.

Acute recurrent: Recurrent attacks of pain separated by symptom-free intervals. Primary headache syndromes, such as *migraine* or *tension-type headache,* usually cause this pattern. Infrequently, recurrent headaches can sometimes also be attributed to certain epilepsy syndromes (benign occipital epilepsy), substance abuse, or recurrent trauma.

Chronic progressive: Most ominous of the temporal patterns; implies a gradually increasing frequency and severity of headache. The pathologic correlate is *increasing intracranial pressure.* Causes of this pattern include pseudotumor cerebri, brain tumor, hydrocephalus, chronic meningitis, brain abscess, and subdural collections.

Chronic nonprogressive or chronic daily: Pattern of frequent or constant headache. Chronic daily headache generally is defined as >4-mo history of >15 headaches/mo, with headaches lasting >4 hr. Affected patients have normal neurologic examinations; psychologic factors and anxiety about possible underlying organic causes are common.

TABLE 28.3 Main and Rare Causes of Thunderclap Headache

Main Causes	Rare Causes
Vascular Disorders	
Subarachnoid hemorrhage	Pituitary apoplexy, arteritis, angiitis
Intracerebral hemorrhage	Unruptured vascular malformation,
Cerebral venous thrombosis	aneurysm
Spontaneous intracranial	Arterial hypertension
hypotension	Cerebral segmental vasoconstriction
Cervical artery dissection	
Nonvascular Disorders	
	Greater occipital neuralgia
	Intermittent hydrocephalus by
	colloid cyst
Infections	
Meningitis, encephalitis	Erve virus
	Sinusitis
Primary Headache Disorders	
Migraine	Cluster headache
Primary thunderclap headache	Tension headache, new daily
Primary exertional headache	persistent headache
Primary cough headache

TABLE 28.4   **The Headache Diary for Recurring Headaches***
Date
Time of onset
Time of resolution
Maximum level of pain (mild, moderate, or severe *or* according to a visual or numerical pain scale)
Triggers:
Sleep
Foods
Activities
Medications
Modifiers:
Response to position changes or Valsalva maneuver
Medications used (dose, response)
Other modifiers
Additional symptoms

*If more than 1 type of headache exists, the types should be defined and labeled, and separate data should be recorded for each type.

may be augmented by school attendance and performance records. For example, headaches that improve with the onset of the summer school holiday may suggest that a child is struggling academically or is being bullied at school. In younger children, where detailed personal descriptions of pain may be more difficult to obtain and record in a diary, videos of the headache episodes may aid diagnosis.

The past medical history may reveal potentially serious causes of secondary headaches that require prompt evaluation, such as sickle cell disease, thyroid disorders, parathyroid dysfunction, malignancy, hypercoagulability, hypertension, immunodeficiency, congenital heart disease, and arteriovenous malformations. Allergic rhinitis and other

atopic disorders are also associated with headaches. Infantile colic, benign paroxysmal torticollis, cyclic vomiting syndrome, and benign paroxysmal vertigo are considered episodic syndromes that may be associated with migraine and may precede the development of typical migraine symptoms later in life. In females, a menstrual history should be obtained, including details of the cycle and the timing of headaches with respect to the menstrual cycle. A history of secondary amenorrhea could suggest pituitary or other central nervous system neoplasms.

The family history should be probed for any genetic predisposition to migraines, aneurysms, other vascular malformations, or brain neoplasms. A negative family history for primary headaches should cause the clinician to be more cautious in assigning the diagnosis of a primary headache disorder. Social history should investigate for psychosocial factors that may influence or be influenced by headaches, such as school performance, the relationships between family members, recent changes in social structure, and substance abuse in the patient or the family. The provider should also screen for indications of neglect or abuse. Detailed psychologic evaluation with screening for symptoms of depression and anxiety may be indicated.

Throughout the history, the clinician should constantly assess for warning signs of serious and sometimes life-threatening causes of secondary headache. The identification of any of these red flag symptoms should cause concern and lead promptly to further investigation (Table 28.5).

Physical Examination

Abnormalities in the examination may provide clues to the underlying etiology of secondary headaches, and red flags may identify specific diagnoses of concern (Table 28.6). Vital signs assessment may reveal elevated blood pressure, which may be the cause of headache, signal increased intracranial pressure, or herald an underlying renal abnormality. Fever may be a sign of an infectious or inflammatory process. Growth parameters, including height, weight, body mass index, and head circumference should be obtained. Poor weight gain may indicate an underlying chronic illness associated with headaches, such as celiac disease, respiratory disorders, neurofibromatosis type 1, or neglect. Obesity should alert the clinician to assess for symptoms of obstructive sleep apnea or pseudotumor cerebri. Enlarged head circumference associated with signs of headache or other evidence of increased intracranial pressure warrants alarm.

The general examination starts with assessment of mental status and overall level of distress. The head and neck examination should assess specifically for nasal congestion, sinus tenderness, and signs of allergic rhinitis, such as boggy nasal turbinates. Frontal bone tenderness could be an early sign of Pott puffy tumor, a complication of frontal sinusitis. Tenderness over the mandibular condyle in children with dental malocclusion, or jaw crepitus in patients with arthritis, may indicate temporomandibular joint dysfunction as a cause of headache. Thorough lymphatic, respiratory, cardiac, and abdominal examinations should also be completed. Genitourinary examination should include pubertal stage, as headaches may be associated with

TABLE 28.5 History-Related Red Flags for Secondary Headaches

Quality:
- "Thunderclap" headache or the "worst headache of my life"
- Recent worsening in severity or frequency
- Change in quality
- New-onset symptoms consistent with cluster headache

Location:
- Unilateral without alteration of sides
- Chronic or recurrent occipital headache

Timing:
- Awakens from sleep
- Occurs in morning or causes morning vomiting
- Chronic progressive pattern

Positional or activity-related variations:
- Worsened in the recumbent position
- Headache experienced with cough or the Valsalva maneuver

Associated neurologic history:
- Altered sensorium during headache
- Sensory deficits or changes in vision, gait, or coordination
- Other focal neurologic deficits
- Seizures or syncope
- Mental status changes (e.g., confusion or disorientation)
- Regression in fine or gross motor developmental skills
- Decline in cognition or school performance
- Change in behavior or personality

Associated general history:
- Vomiting without nausea
- Polyuria or polydipsia
- Preschool or younger age
- History of head trauma
- Medical comorbidities
- Negative family history of primary headache disorders

TABLE 28.6 Physical Examination Red Flags for Secondary Headaches

Hypertension
Growth failure
Increased head circumference or bulging fontanel
Meningeal signs with or without fever
Evidence of cranial trauma
Cranial bruit
Frontal bony tenderness
Abnormal ophthalmologic findings:
- Papilledema
- Abnormal ocular movements
- Squinting
- Pathologic pupillary response
- Visual field defects

Abnormal neurologic findings:
- Impaired mental status
- Cranial nerve palsy
- Ataxia
- Abnormal gait
- Abnormal coordination
- Abnormal reflexes
- Asymmetric motor or sensory examination
- Hemiparesis
- Developmental regression

Precocious, delayed, or arrested puberty
Skin findings:
- Café-au-lait or ash leaf macules
- Petechiae or purpura
- Facial hemangioma
- Malar rash

TABLE 28.7	**Headache Disorders Associated with Neurologic Signs**	
Headache	**Pain Profile**	**Neurologic Sign**
Complicated migraine	AR	Hemiparesis, aphasia, paresthesia, hemianopsia
Migraine with brainstem aura	AR	Dysarthria, vertigo, tinnitus, hypoacusis, diplopia, ataxia, decreased level of consciousness
Acute confusional migraine	AR	Alteration in migraine sensorium, stupor, agitation, fugue state
Vasculitis	CP, AR	Seizure, changes in sensorium
Brain neoplasm or mass	CP	Papilledema, focal deficit
Hydrocephalus	CP, AR	Papilledema, bilateral sixth nerve palsies, increased motor tone, impaired upward gaze and Parinaud syndrome
Pseudotumor cerebri	CP	Papilledema, constricted visual fields, enlarged blind spot
Subarachnoid hemorrhage, ruptured aneurysm	A	Changes in sensorium, focal neurologic signs, meningismus
Subdural or epidural hemorrhage	CP	Focal neurologic signs, papilledema, changes in sensorium

Meningitis, encephalitis	A	Papilledema, focal neurologic deficits, changes in sensorium, seizures
Optic neuritis	A	Papillitis, decreased visual acuity, afferent pupillary defect

A, acute; AR, acute recurrent; CP, chronic progressive.

endocrine disorders. Skin should be evaluated for petechiae, atopic findings, and lesions associated with neurocutaneous syndromes such as neurofibromatosis or tuberous sclerosis. Signs of trauma should be noted. Neurologic examination should be detailed and include assessments of mental status, cranial nerves, auditory function, sensation, motor strength, reflexes, gait, coordination, and speech. Whenever possible, a thorough ophthalmologic examination should be undertaken, including visual acuity testing and a funduscopic evaluation for papilledema. In a young child, much of the neurologic examination is completed through observation or engaging the child in play to elicit findings. A complete ophthalmologic evaluation may be limited by lack of cooperation or comprehension. If the clinician is unable to complete or interpret the neurologic and ophthalmologic assessments, the support of a neurologist and ophthalmologist may be required. If the results of either examination suggest a structural brain lesion or increased intracranial pressure, neuroimaging is warranted (Table 28.7). However, many causes of headache, including some serious diseases early in their course, do not present with abnormal findings on physical examination or have fluctuating abnormal findings (Table 28.8). A single normal physical examination does not exclude pathology; thus, periodic reassessments are essential if headache persists.

◆ **Neuroimaging**

Most children do not require neuroimaging for headaches, particularly children with recurrent headaches and normal neurologic examinations. Neuroimaging in the assessment of headaches in children is indicated under the following circumstances: (1) abnormal neurologic findings, (2) headaches occurring early in the morning or waking the child from sleep, (3) associated confusion, disorientation, or signs of increased intracranial pressure, (4) presence of a ventricular shunt, (5) recent trauma, and (6) age less than 3 years. Additional indications for neuroimaging include recent onset of severe headache, incompatibility of headache with a primary headache disorder diagnosis, change in the pattern or severity of a previously stable headache, and a history of neurologic dysfunction beyond typical aura symptoms (Table 28.9). In specific cases, neuroimaging may be considered when there is history of a brain tumor in the family, fear by the patient or the parents of underlying pathology, or an inability to obtain an accurate physical examination due to lack of patient cooperativity.

TABLE 28.8	**Headache Disorders with No Neurologic Signs**

Conversion disorder	CN

A, acute; AR, acute recurrent; CN, chronic nonprogressive; CP, chronic progressive.

Magnetic resonance imaging (MRI) and computed tomography (CT) are the 2 neuroimaging modalities to consider (Table 28.10). CT remains the most sensitive and rapid method for detecting acute intracranial bleeding, and is preferred in emergency situations or when MRI is contraindicated or unavailable. *MRI is otherwise the preferred imaging modality,* offering superior visualization of soft-tissue contrast and gray-to-white matter differentiation without exposing the patient to the ionizing radiation associated with CT scanning. While gadolinium contrast for MRI is considered safe, it is not usually necessary. MRI may involve the need for sedation, particularly in younger children. Normal neuroimaging and a single normal neurologic examination should not give complete reassurance. Follow-up assessment of ongoing symptoms or for changes in the physical examination remains necessary.

TABLE 28.9 Reasons to Obtain Neuroimaging in a Child with Headache

Abnormal neurologic findings (including papilledema)

Associated confusion, disorientation, or signs of increased intracranial pressure

Change in pattern or severity of previously stable headache

Cough headache

Headache consistent with trigeminal autonomic cephalgia

Headache occurring in the morning or waking the child from sleep

Headache with known concerning underlying disorder or insult

History of neurologic dysfunction (outside of typical aura symptoms)

Incompatibility of headache with primary headache disorder or unusual headache in a child

Meningeal signs without fever

Recent onset of severe headache

Recent trauma

Seizures

"Thunderclap" headache or "worst headache of my life"

Ventriculoperitoneal shunt

Young age (less than 6 yr) or inability to describe headache

TABLE 28.10 Neuroimaging Modalities

Advantages of Magnetic Resonance Imaging

Most vascular malformations are detected

Accurate detection of tumors in temporal lobes and posterior fossa, and small tumors that obstruct CSF flow (quadrigeminal plate and third ventricular)

Paranasal sinuses usually included in the examination without special request

More sensitive for detecting transependymal CSF in cases of borderline hydrocephalus

Diagnostic for Chiari malformations

Magnetic resonance angiography can detect many aneurysms

Magnetic resonance venography can detect cortical vein and dural sinus thrombosis

Advantages of Computed Tomography

Can rapidly diagnose intracranial bleed

Shorter imaging time, important in evaluating ill patients

May be used in patients with pacemakers, metal implants (surgical clips), and cosmetic tattoos (MRI may turn off pacemakers and dislodge the clips; tattoos distort the image)

Less expensive and easier access than MRI

CSF, cerebrospinal fluid; MRI, magnetic resonance imaging.

◆ Laboratory Investigations

Routine blood work is not indicated when history suggests a primary headache disorder and physical and neurologic examinations are normal. Findings in the history, physical examination, or neuroimaging that dictate directed laboratory evaluation are listed in Table 28.11.

CLASSIFICATION OF HEADACHES

Headaches are classified broadly as primary or secondary. The acuity or chronicity of the headache helps to guide the development of the differential diagnosis (Fig. 28.4).

TABLE 28.11 Potentially Useful Laboratory Tests in Children with Headaches

Laboratory Test	Possible Cause of Headache
Complete blood count	Infection (elevated white blood cell count); bleeding diathesis (thrombocytopenia); anemia
CSF examination with opening pressure	Infection, vasculitis, pseudotumor cerebri, subarachnoid hemorrhage after CT is normal
Toxicology assays	Substance abuse, possible toxin exposure, carbon monoxide
Hypercoagulation panel	Unexplained venous sinus thrombosis
ESR, ANA, ANCA	Vasculitis
Genetic tests	Familial hemiplegic migraine, MELAS
EEG	Seizure disorder
Electrolytes, ECG, UA	Hypertension
VP shunt radiographic series	Malfunctioning VP shunt
Blood glucose	Hypoglycemia or hyperglycemia
Serum calcium	Hyperparathyroidism

ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibodies; CSF, cerebrospinal fluid; CT, computed tomography; ECG, electroencephalography; EEG, electroencephalogram; ESR, erythrocyte sedimentation rate; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; UA, urinalysis; VP, ventriculoperitoneal.

Primary Headaches

There are 3 categories of primary headaches: tension-type headache, migraine headache, and the trigeminal autonomic cephalgias. Tension-type headache and migraine are the most common headache types in children and adolescents.

Tension-Type Headaches

Tension-type headache (**TTH**) occurs in up to 15% of older children. Prevalence increases with age such that TTH is the most frequent headache type in children between 8-12 years of age. Younger children also experience both episodic and chronic TTH, usually with mild to moderate symptoms.

These headaches have a typical pattern. Patients awaken feeling well, with pain beginning gradually and escalating throughout the day. Pain is constant, squeezing, nonpulsatile, and located in a band extending from the front of the head, across the temples, and toward the occiput or neck. Photophobia and phonophobia may accompany these headaches but are not a constant feature; patients with tension-type headache typically do not experience both photophobia and phonophobia in the context of a single episode. Unlike migraine headaches, routine physical activity does not tend to influence the severity of the headache. In patients with long-standing pain, the headaches may assume characteristics of migraines; indeed, tension-type headaches often accompany other headache disorders.

Tension-type headaches are classified as either episodic or chronic. Both episodic and chronic TTH are further classified as having associated pericranial tenderness or as lacking such tenderness. This tenderness is typically present between headaches and increases during episodes. **Episodic tension-type headache** is categorized as either infrequent or frequent. Infrequent episodic TTH is defined as 10 or more episodes total, occurring less than once per month on average. Frequent episodic TTH is defined as 10 or more episodes total, occurring on 1-14 days per month on average for over 3 months. Individual

episodes of either may last from 30 minutes to as long as a week and have at least 2 of the following features: (1) bilateral location, (2) pressing or tightening (nonpulsating) quality, (3) mild or moderate intensity, (4) not aggravated by routine physical activity such as walking or climbing stairs. Nausea or vomiting must be absent; if present, migraine should be considered. Either photophobia or phonophobia may be present; if both are present simultaneously, migraine should be considered. **Chronic tension-type headaches** are defined as headaches occurring at least 15 days a month for over 3 months, with features otherwise similar to episodic TTH.

Psychosocial history may uncover the cause of the headache. Adjustment disorders and depression may be either the underlying causes or reactions to chronic pain. Sleep disturbances, school absences, and chronic analgesic use are common. However, some patients with chronic TTH may have negative psychosocial histories. In some highly motivated and successful children, the headaches may be a reaction to the stress associated with achievement. In this instance, school attendance is usually perfect and the patient continues to achieve in all realms.

Patients with tension-type headaches have normal neurologic and physical findings, except for possible tenderness along the affected muscles. These muscles often feel tight, and palpation may trigger the pain. Laboratory tests are not required in the evaluation of tension-type headaches.

Migraine Headaches

The diagnosis of migraine headache is typically based on the historical description of episodes. Childhood migraines are similar to those in adults; however, several features distinguish migraine in children from adult migraine. In children, the headaches are less frequent, are shorter in duration, and respond better to treatment. Vomiting and abdominal pain are more common in children than in adults. Pain is more frequently bilateral in children, though tends to become unilateral after the onset of puberty. The pain may be frontal or facial, instead of the more typical temporal location. Prevalence is higher in boys prior to puberty, though prevalence is higher in girls following the onset of puberty. In the adult population, 18% of females and 6% of males have migraines. A family history of migraines is common, with up to 90% of children having a 1st- or 2nd-degree relative with recurrent headaches.

By 15 years of age, at least 10% of children will have had a migraine headache. Migraine and migraine variants occur in early childhood but with an unknown prevalence, as diagnostic criteria for migraine are often insufficient in young children and infants, in whom the headaches tend to be shorter or have less typical features. While the diagnosis of migraine is typically made later in childhood, a careful retrospective history of infancy and early childhood events may reveal early episodic symptoms consistent with migraine, including pallor, vomiting, photophobia, phonophobia, fussiness, and sleepiness occurring outside the context of concurrent illnesses. Furthermore, benign paroxysmal torticollis, cyclic vomiting syndrome, and benign paroxysmal vertigo are episodic syndromes that may be associated with the diagnosis of migraines later in life.

The pattern of migraines is variable. Without prophylactic treatment, most patients have between 1-4 migraines a month. There is often no temporal pattern, although in postmenarchal females, migraines may cluster around particular phases of the menstrual cycle. Unless the migraines tend to cluster, patients rarely have migraines more than twice a week. Mild or moderate headaches often occur between more severe migraine attacks.

Certain exposures trigger migraine attacks in susceptible patients. The most common migraine precipitants are specific foods and food additives, such as chocolate, hard cheeses, onions, yeast, and beans. Other precipitants include menstruation, caffeine withdrawal, hunger, estrogen exposure (typically via oral contraceptives), sleep deprivation, stress, heat, and exertion.

Migraines are categorized based on the presence or absence of an associated aura. Migraine without aura is the most common migraine phenotype in pediatric patients.

Migraine without aura. Criteria assist in the diagnosis of **migraine without aura** and are based on the number and duration of episodes, as well as symptoms and associated findings (Table 28.12). It has been recognized that children may have shorter-duration headaches, so an allowance has been made to reduce the duration to 2-72 hours or 1-72 hours with diary confirmation. The pain typically onsets gradually and is dull and constant. At times, though, the pain of an episode may be sudden and severe, prompting concern for a thunderclap headache. More typically, pain increases in severity over the course of an individual episode and becomes throbbing. As the headache proceeds, the pain may generalize to the entire cranium. Intense nausea often accompanies migraines, with occasional vomiting. Skin pallor is a common finding. Nasal congestion and tearing may be present. Because most patients are sensitive to motion, light, and noise during a migraine attack, they search for a dark and quiet place to sleep. The patient usually awakens within hours feeling fatigued but pain free.

TABLE 28.12 Migraine Without Aura

A. At least 5 attacks fulfilling criteria B-D
B. Headache attacks lasting 4-72 hr (untreated or unsuccessfully treated)
C. Headache has at least 2 of the following 4 characteristics:
1. Unilateral location
2. Pulsating quality
3. Moderate or severe pain intensity
4. Aggravation by or causing avoidance of routine physical activity (e.g., walking or climbing stairs)
D. During headache at least 1 of the following:
1. Nausea and/or vomiting
2. Photophobia and phonophobia
E. Not better accounted for by another ICHD-3 diagnosis

ICHD-3, International Classification of Headache Disorders, 3rd edition. From Hersey AD, Kabbouche MA, O'Brien HL. Headaches. In: Kliegman RM, ed. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016:2866.

TABLE 28.13 Migraine with Typical Aura

A. At least 2 attacks fulfilling criteria B and C
B. Aura consisting of visual, sensory, and/or speech/language symptoms, each fully reversible, but no motor, brainstem, or retinal symptoms
C. At least 2 of the following 4 characteristics:
1. At least 1 aura symptom spreads gradually over 5 or more min, and/or 2 or more symptoms occur in succession
2. Each individual aura symptom lasts 5-60 min
3. At least 1 aura symptom is unilateral
4. The aura is accompanied, or followed within 60 min, by headache
D. Not better accounted for by another ICHD-3 diagnosis, and transient ischemic attack has been excluded

ICHD-3, International Classification of Headache Disorders, 3rd edition. From Hersey AD, Kabbouche MA, O'Brien HL. Headaches. In: Kliegman RM, ed. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016:2866.

Migraine with aura. In migraine with aura, the headache is preceded by sensory signs or symptoms termed an **aura**, which is caused by vasoconstriction and diminished blood flow to the affected region of the brain. In **migraine with typical aura** (Table 28.13), the aura is visual and may consist of blurred vision, spreading scintillating scotomas, flashing lights, zigzag lines, and hemianopsia. These features typically last less than 60 minutes. Sensory auras are less common than visual auras and may consist of numbness or tingling. Further types of migraine with aura are classified by the specific aura symptoms.

Migraine with brainstem aura (Table 28.14), previously known as *basilar artery migraine,* has aura limited to brainstem symptoms such as dysarthria and ataxia. In some patients, the headache may be a minor component of the syndrome. Visual changes may also occur and may include vivid visual images. Vertigo and tinnitus are less common symptoms. Diplopia, vertigo, and vomiting should prompt evaluation for a posterior fossa abnormality, such as a mass or a vascular malformation.

Hemiplegic migraine has an aura that consists of unilateral motor weakness and visual, sensory, and/or speech/language symptoms that are fully reversible. Both familial and sporadic forms have been described. The familial hemiplegic migraine is an autosomal dominant disorder with mutations described in 3 separate genes: (1) *CACNA1A,* (2) *ATP1A2,* and (3) *SCN1A.*

(See *Nelson Textbook of Pediatrics,* p. 2866.)

TABLE 28.14   **Migraine with Brainstem Aura**
A. At least 2 attacks fulfilling criteria B-D
B. Aura consisting of visual, sensory, and/or speech/language symptoms, each fully reversible, but no motor or retinal symptoms

C. At least 2 of the following brainstem symptoms:
  1. Dysarthria
  2. Vertigo
  3. Tinnitus
  4. Hypacusis
  5. Diplopia
  6. Ataxia
  7. Decreased level of consciousness

D. At least 2 of the following 4 characteristics:
  1. At least 1 aura symptom spreads gradually over 5 or more min, and/or 2 or more symptoms occur in succession
  2. Each individual aura symptom lasts 5-60 min
  3. At least 1 aura symptom is unilateral
  4. The aura is accompanied, or followed within 60 min, by headache

E. Not better accounted for by another ICHD-3 diagnosis, and transient ischemic attack has been excluded

ICHD-3, International Classification of Headache Disorders, 3rd edition. From Hersey AD, Kabbouche MA, O'Brien HL. Headaches. In: Kliegman RM, ed. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016:2866.

TABLE 28.15   **Cluster Headache**
A. At least 5 attacks fulfilling criteria B-D
B. Severe or very severe unilateral orbital, supraorbital, and/or temporal pain lasting 15-180 min (when untreated)*

C. Either or both of the following:
  1. At least 1 of the following symptoms or signs, ipsilateral to the headache:
    a) Conjunctival injection and/or lacrimation
    b) Nasal congestion and/or rhinorrhea
    c) Eyelid edema
    d) Forehead and facial sweating
    e) Forehead and facial flushing
    f) Sensation of fullness in the ear
    g) Miosis and/or ptosis
  2. A sense of restlessness or agitation

D. Attacks have a frequency between 1 every other day and 8 per day for more than half of the time when the disorder is active
E. Not better accounted for by another ICHD-3 diagnosis

*During part (but less than half) of the time course of cluster headaches, attacks may be less severe and/or of shorter or longer duration.
ICHD-3, International Classification of headache Disorders, 3rd edition. From Headache Classification Committee of the International Headache Society (IHS). The international classification of headache disorders. 3rd ed. (beta version). *Cephalalgia.* 2013;33:629-808.

Retinal migraine involves monocular visual disturbance. This migraine subtype is extremely rare, and other causes of the vision disturbance should be investigated prior to designating this diagnosis.

The **childhood periodic syndromes**, or episodic syndromes that may be associated with migraine, are a group of potentially related symptoms that occur with increased frequency in children with migraine. The hallmark of these symptoms is the recurrent episodic nature of the events. Some of these have included gastrointestinal-related symptoms (motion sickness, recurrent abdominal pain, recurrent vomiting including cyclic vomiting, and abdominal migraine), sleep disorders (sleepwalking, sleeptalking, and night terrors), unexplained recurrent fevers, and even seizures.

Confusional migraine and **Alice in Wonderland syndrome** are rare migraine with aura variants that occur primarily in children. Confusional migraine begins after 5 years of age and usually converts to typical migraine as the patient gets older. Episodes begin with an alteration in consciousness, which may include varying degrees of lethargy, agitation, and stupor. A fuguelike state has also been described with these migraines. Attacks last a few hours, with the child eventually falling asleep. The child awakens without memory of the incident. The aura of Alice in Wonderland syndrome is characterized by perceptual disturbances in which the sense of proportion or distance, particularly with respect to the body, is distorted.

Complications of migraine. Some patients have an aura that lasts longer than 1 week. This duration is uncommon and the aura is typically bilateral in these cases. Patients with migraine may have neurologic deficits that persist during and after the headache. These deficits include hemisensory symptoms, hemiparesis, aphasia, visual loss, and alteration in consciousness. In most cases, the neurologic deficit precedes the headache. These symptoms usually last for the duration of the headache but may remain for days following headache abatement. Permanent neurologic deficits are rare but may occur if the vasoconstriction is severe and causes infarction.

Status migrainosus is defined as a migraine headache that lasts over 72 hours. This prolonged headache is usually associated with protracted vomiting and dehydration. Diagnosis is based on a propensity for previous prolonged migraine attacks.

Some disorders that feature migraine with aura episodes have an identified genetic etiology. **Autosomal dominant familial hemiplegic migraine** and **episodic ataxia type 2** are caused by mutations in genes encoding transmembrane ion channels and ATPases. Patients may present with hemiplegic migraine, episodic ataxia, or both. **MELAS** (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes) is a mitochondrially inherited disorder with a high frequency of hemiplegic migrainous attacks. Recovery from attacks is variable. This diagnosis must be considered in children with coexisting epilepsy, mental retardation or regression, and myopathy. A DNA test for the most common mitochondrial mutation is available. Migraines are also common in a variety of other mitochondrial disorders.

Trigeminal Autonomic Cephalgias

Trigeminal autonomic cephalgia (TAC) is rare in children under 7 years of age, but has been reported in a child as young as 3 months. Onset typically occurs during adolescence or adulthood. Cluster headaches and paroxysmal hemicranias are types of TAC.

Cluster headache. **Cluster headaches** are characterized by episodes of pain interspersed between long periods of remission (Table 28.15). Pain is unilateral and localized to the eye and temple but may spread to other parts of the head. The pain begins suddenly and rapidly increases to an excruciating level. These headaches usually occur at a particular time of day, most often at night. Cluster headaches may be as short as 15 minutes or may last as long as 3 hours. Lacrimation, rhinorrhea, sweating, and nasal stuffiness usually accompany the headache. Patients find it impossible to rest, and they become agitated and restless during an attack. They may yell, scream, pace around, or bang their head against the wall. This is in sharp contrast to a migraine, in which the patient is quiet and withdraws to a dark cool room for sleep.

Cluster headache is categorized as either episodic or chronic. Episodic cluster headaches occur in a series that may last for weeks or months, separated by remission periods of months to years, whereas chronic cluster headaches are defined as occurring for more than 1 year without such a remission period, or with remission periods that last less than 1 month. Cluster headaches are more common in individuals who smoke tobacco.

Paroxysmal Hemicrania

Paroxysmal hemicrania is characterized by shorter attacks (2-30 minutes) and absolute prevention with and response to indomethacin. Chronic paroxysmal hemicrania consists of frequent and intense unilateral headaches. This disorder is much more common in women than in men. Although it usually begins in adulthood, chronic paroxysmal hemicrania may affect older children and adolescents. The average headache lasts about 10 minutes. Patients have at least 20 attacks a day, and the pain may awaken the patient from sleep. Sudden head movement may also precipitate an attack. This headache responds dramatically to indomethacin therapy. Relief of symptoms occurs within a few days of beginning the medication. Other nonsteroidal anti-inflammatory drugs (NSAIDs) are of no benefit. Because the symptoms of chronic paroxysmal hemicrania are similar to those of vascular malformations of the brain, a neuroimaging study should be performed to rule out malformation before the diagnosis of chronic paroxysmal hemicrania is made.

Secondary Headaches
Headache Associated with Trauma

Acute headache. If a child presents with a headache after trauma and has abnormal neurologic signs or symptoms, noncontrast CT of the head should be obtained emergently to assess for subarachnoid, subdural, or epidural intracranial bleed. Cervical spine radiographs should be obtained if cervical injury is suspected. If the child has focal neurologic deficits indicating possible vascular injury, MRI is indicated, potentially with MR angiography.

Persistent headache. Headaches may occur as part of the postconcussive or post-traumatic syndrome. The headache is generally constant and may have qualities of both chronic tension-type and migraine headaches. For example, some patients may have nausea, vomiting, and visual auras. Other features of this syndrome are fatigue, dizziness, vertigo, poor memory, decreased reaction times, and inability to concentrate. The neurologic findings are usually normal. Symptoms begin within 1-7 days of the head injury and may persist for years. About 70% of patients recover within a year, but 15% are still symptomatic after 3 years. Post-traumatic headache is considered acute if duration is less than 3 months and chronic if over 3 months. The pathophysiology of this syndrome is unknown.

Even though postconcussive syndrome is more common in persons with a history of psychologic or psychosomatic illness, a neuroimaging study may be necessary to exclude the rare possibility of a chronic subdural hematoma. Patient education is the most important element of treatment. Some patients may also benefit from psychotherapy. Amitriptyline, NSAIDs, and propranolol may be helpful, but opioids should be avoided because of their addictive potential in the treatment of chronic headaches. Trauma may also lead to the development of primary headaches such as migraines.

Headaches Associated with Vascular Disorders

Acute ischemic stroke. Headache is a feature of up to one-third of acute ischemic strokes. More commonly experienced symptoms are focal neurologic deficits such as weakness of the limbs and face or speech abnormalities; as such, every child presenting with a focal neurologic deficit must undergo evaluation for stroke. The headache in acute ischemic stroke is typically of moderate intensity, and otherwise lacks consistent features, though may occasionally present as a thunderclap headache. Similar headaches may also accompany transient ischemic attacks.

Aneurysms and Arteriovenous Malformations

Arterial aneurysms may be congenital (berry) or caused by an infectious process (mycotic). Rupture of an arterial aneurysm is rare in children. The rupture produces an excruciating headache, known as a thunderclap headache. Patients will often describe the pain as the worst headache of their lives. The pain is acute in onset and associated with nuchal rigidity, emesis, and changes in sensorium. The neurologic examination findings may be nonfocal. CT scan reveals blood in the cisterns and meninges in 85% of cases. If the CT scan shows no pathologic process, a lumbar puncture (LP) is necessary in all patients thought to have a ruptured aneurysm. The spinal fluid in a ruptured aneurysm is bloody, xanthochromic, or both. In half of the cases, patients report having previous headaches before having the headache associated with the rupture. These earlier headaches may be caused by leakage of blood from the aneurysm. If the clinician suspects a leaking or ruptured aneurysm, rapid neurologic and neurosurgical care is mandatory. Arteriovenous malformations may produce similar manifestations.

Arteritis, Cerebral Venous Thrombosis, and Vascular Dissection

Vascular dissection may present with a headache that precedes ischemic symptom development by hours to days. These headaches are typically persistent, nonthrobbing, and unilateral but may be throbbing, thunderclap, and steadily worsening. Infection, coughing, vomiting, and connective tissue disorders such as Ehlers-Danlos disease are risk factors. MRI with angiography of the head and neck is required for diagnosis.

Vasculitis

Vasculitis is an important cause of headaches in adults; however, in children, headache is rarely the presenting manifestation of this disorder and is instead a less frequent associated finding. Because of the increased risk of systemic hypertension in patients with vasculitis, it is important to include a blood pressure measurement as part of the complete history and physical examination. When systemic lupus erythematosus and mixed connective tissue disorders affect the central nervous system, children may present with seizures and mental status changes. These symptoms may occur with or without headaches.

Genetic Vasculopathies

Genetic vasculopathies also cause headaches. **Mitochondrial Encephalomyopathy, Lactic Acidosis, and Stroke-like Episodes (MELAS)** may present with recurrent, oftentimes migrainous headaches and is associated with short stature, hearing deficits, ophthalmologic problems, learning disabilities, hemiparesis, cardiac problems, and diabetes. **Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy (CADASIL)** is a mitochondrial disorder that may present with headaches and should be considered in children with subcortical infarcts, migraines, and multifocal T2/FLAIR hyperintensities in the deep white matter. CADASIL is inherited in an autosomal dominant fashion and may lead to early stroke and/or dementia, so a suggestive family history should increase suspicion.

Headaches Associated With Nonvascular Intracranial Disorders

This category includes headaches due to a variety of causes including increased cerebrospinal fluid (CSF) pressure, decreased CSF pressure,

(See *Nelson Textbook of Pediatrics,* p. 2871.)

noninfectious inflammation, neoplasms, intrathecal injection, seizures, and Chiari type I malformations.

Disorders Associated with Increased CSF Pressure

Pseudotumor cerebri is characterized by increased intracranial pressure (ICP) in the absence of a tumor, and is a disorder associated with significant morbidity. Headache in pseudotumor cerebri may be intermittent or constant and may resemble a migraine. Papilledema is usually present at the time of presentation. The characteristic findings are chronic progressive or nonprogressive headaches, papilledema, normal neuroimaging, and raised ICP.

Pseudotumor cerebri may be either primary or secondary to a variety of medical conditions. In **idiopathic intracranial hypertension**, a subset of primary pseudotumor cerebri, the typical patient is postpubertal, obese, and female. Pseudotumor cerebri may also be due to obstructive, toxic, metabolic, or hormonal causes that may often be revealed through a thorough history and physical examination (Table 28.16).

In addition to headache and papilledema, signs and symptoms may include sixth and seventh cranial nerve palsies and visual field changes. In severe cases, the retinal blind spot may enlarge, and the visual fields may become constricted. Physical examination otherwise is usually normal. Diagnosis in most cases is based on the historical presentation and the demonstration of an elevated cerebrospinal fluid opening pressure on a lumbar puncture obtained in the lateral position.

Cerebrospinal fluid opening pressure values of 280 mm H_2O or greater are considered elevated in sedated or obese children; values of 250 mm H_2O are considered elevated in nonobese, nonsedated children. The CSF profile is typically normal. If papilledema is present, neuroimaging should be obtained prior to lumbar puncture to evaluate for other causes of papilledema, such as a tumor or hydrocephalus (see Table 28.9). MRI with venography should be considered in patients who are at risk for venous thrombosis or in those whose presentation does not fit the typical idiopathic intracranial hypertension profile (e.g., males, young children, and nonobese females), in order to assess for dural sinus thrombosis.

Pseudotumor cerebri may be diagnosed in the absence of papilledema if a sixth cranial nerve palsy is present and the patient has a normal neurologic examination, normal neuroimaging (including venography if indicated), an elevated CSF opening pressure, and a normal CSF profile. If the patient does not have a sixth cranial nerve palsy, then the diagnosis may be suggested (but not confirmed) if 3 of the following imaging requirements are met: empty sella, flattening of the posterior aspect of the globe, distention of the perioptic subarachnoid space with or without a tortuous optic nerve, and transverse venous sinus stenosis. Ongoing observation with recurrent exams, imaging, and studies is indicated to confirm the diagnosis.

All patients with pseudotumor cerebri should be monitored closely with special attention to ocular findings, as they are at risk for development of permanent visual impairment.

TABLE 28.16   Conditions Associated with Pseudotumor Cerebri

Intracranial Venous Drainage Obstruction	**Vitamin Metabolism**
Mastoiditis and lateral (sigmoid) sinus obstruction	Chronic hypervitaminosis A
Extracerebral mass lesions	Acute hypervitaminosis A
Congenital atresia or stenosis of the venous sinuses	Hypovitaminosis A
Head trauma	Cystic fibrosis and hypovitaminosis A
Cryofibrinogenemia	Vitamin D deficiency rickets
Polycythemia vera	
Paranasal sinus and pharyngeal infections	**Drug Reaction**
	Tetracyclines
Cervical or Thoracic Venous Drainage Obstruction	Perhexiline maleate
Intrathoracic mass lesions and postoperative obstruction of venous return	Nalidixic acid
	Sulfamethoxazole
Endocrine Dysfunction	L-Asparaginase
Pregnancy	Indomethacin
Menarche	Penicillin
Marked menstrual irregularities	Prophylactic antisera
Oral contraceptives	
Obesity	**Miscellaneous**
Withdrawal of corticosteroid therapy	Galactosemia
Addison disease	Galactokinase deficiency
Hypoparathyroidism	Lyme disease
"Catch-up" growth after deprivation, treatment of cystic fibrosis, correction of heart anomaly	Sydenham chorea
	Sarcoidosis
Initiation of thyroxine treatment for hypothyroidism	Roseola
Adrenal hyperplasia	Hypophosphatasia
Adrenal adenoma	Paget disease
	Maple syrup urine disease
Hematologic Disorders	Turner syndrome
Acute iron deficiency anemia	
Pernicious anemia	
Thrombocytopenia	
Wiskott-Aldrich syndrome	

Modified from Burg FD, Ingelfinger JR, Wald ER, eds. *Gellis and Kagan's Current Pediatric Therapy*. 14th ed. Philadelphia: WB Saunders; 1993:67.

Hydrocephalus usually causes a generalized headache. Slowly developing hydrocephalus initially causes mild pain, whereas rapidly developing hydrocephalus causes severe pain. Most patients with hydrocephalus have morning headaches that lessen after they arise, though pain may also be constant. Physical examination reveals signs of increased intracranial pressure, such as papilledema or tenderness of the neck. Papilledema is usually absent in children with an open fontanel. Macrocephaly is present in young children with unfused cranial sutures and in those with long-standing hydrocephalus. Other signs of hydrocephalus are a bulging fontanel and widened cranial sutures. The head growth chart is especially important in the evaluation of children with hydrocephalus. Head growth is abnormal if the plot of sequential head circumferences crosses percentile lines.

Cough headaches are intermittent headaches caused by transient increases in ICP resulting from activities that elevate intrathoracic pressure, such as exertion, coughing, or bending. The pain is maximum and severe at the onset of the activity and then resolves in seconds. Patients are usually asymptomatic between events. Cough headaches, which are much shorter than are exercise-induced vascular headaches, may be caused by both benign and life-threatening conditions. Structural causes of cough headache include brain tumors, cysts, and Chiari malformations. The results of the physical examination are usually normal, even when structural lesions cause this syndrome. Patients with cough headaches should undergo MRI.

Disorders Associated with Decreased CSF Pressure

Intracranial hypotension may occur from a tear in the dura caused by trauma, surgery, or lumbar puncture. The etiology of the headache is due to traction on the dura and vessels at the base of the brain. The headache associated with intracranial hypotension typically improves while the patient is recumbent and worsens upon sitting or standing.

The most common cause of a headache from intracranial hypotension is a persistent cerebrospinal fluid leak following lumbar puncture. Risk factors for post–lumbar puncture headache include the use of large-bore spinal needles and multiple attempts at obtaining CSF. Patients describe a severe headache within seconds after assuming an upright position. The headache disappears soon after the patient lies down. Other causes of low-pressure headaches include CSF leaks from fractures or tumors at the base of the skull.

Intracranial Masses

Brain neoplasms are the second most common type of childhood malignancy, though the overall incidence is low. As such, tumor is an infrequent cause of headache in children. The mechanisms by which tumors produce headaches include obstruction of CSF flow leading to hydrocephalus, or direct traction on dural or vascular structures. Headaches caused by hydrocephalus may develop rapidly, whereas traction on dural or vascular structures from tumor growth causes a slow and progressive headache. At the time of presentation, most patients with tumors or hydrocephalus have chronic and progressive headaches, with a history of increasing frequency and severity of pain over time.

Headache secondary to a tumor may or may not be localized to the tumor site. For example, patients with posterior fossa tumors usually have occipital pain, but if hydrocephalus is also present, the pain may be generalized. Headache secondary to tumor typically demonstrates a slow increase in the severity and frequency of painful episodes; initially, pain may be mild, and over-the-counter analgesics provide adequate pain relief. However, it is important to note that many patients with brain tumors have no particular pattern to their headaches. Patients with brain tumors near the optic chiasm may have visual disturbances, endocrine deficiencies, or galactorrhea. Diplopia may be

present if the third or sixth cranial nerve is compressed; ptosis may also be present. Other historical features concerning for intracranial neoplasm include changes in school performance, reported motor or balance disturbances, personality or behavior changes, or seizures.

Physical examination often reveals abnormal findings, including papilledema and neurologic deficits. Focal neurologic findings may include eye movement abnormalities, anisocoria, facial weakness, ptosis, swallowing difficulties, hemiparesis, sensory deficits, cranial nerve deficits, altered mental status, and ataxia. Papilledema may be absent in children with posterior fossa tumors (with or without hydrocephalus) or in children with open fontanels. Nonlateralizing signs include increased motor tone as well as third and sixth nerve palsies. Increased motor tone may not be a constant finding and may manifest as transient shivering.

The **Parinaud syndrome** is the triad of upward-gaze paresis, poor pupillary reaction to light, and retraction nystagmus on convergence. This constellation of physical findings is seen in patients with hydrocephalus or tumors in the pineal region. The presence of Parinaud syndrome always warrants neuroimaging.

Increased intracranial pressure secondary to hydrocephalus and/or a brain tumor should be suspected in any child with chronic progressive headaches, abnormal neurologic examination findings, nuchal rigidity, or abnormal head growth. Patients with these signs and symptoms should undergo neuroimaging (see Table 28.9).

Intracranial cysts are classified as arachnoid, epidermoid, or dermoid. Slow-growing cysts often produce headache patterns similar to those of neoplasms. Epidermoid and dermoid cysts may have sinus tracts that communicate with the skin. If these cysts become infected, their clinical manifestations resemble that of a brain abscess.

A **colloid cyst of the third ventricle** is a potentially life-threatening cause of headache. With changes in position, this cyst functions as a ball valve and intermittently impedes the flow of CSF. This obstruction causes transient increases in intracranial pressure. During some episodes of obstruction, the patient may be asymptomatic. At other times, symptoms may be severe and include debilitating thunderclap headaches, neurologic posturing, coma, and even death. The ICP returns to normal when position is changed or when the increased CSF pressure overcomes the obstruction. Physical findings are normal between events. MRI confirms diagnosis. Treatment consists of CSF diversion or removal of the cyst.

Headaches Associated with Epileptic Seizures

Headache may be a preictal phenomenon in patients with focal epilepsy syndromes, or a consequence of an epileptic seizure. Postictal headaches tend to remit within hours of the cessation of seizure activity, but may last as long as 72 hours. Headache occurring as an ictal phenomenon in partial seizures remits with or soon after the cessation of seizure activity.

Chiari I Malformations

Chiari I malformation may present with headaches that worsen with cough and Valsalva maneuvers, and may be associated with radicular extremity pain. Patients presenting with this pattern of findings require neuroimaging.

Headaches Related to a Substance

Carbon monoxide poisoning should be suspected in any child with chronic headaches, as mild exposure may cause headache and nausea. The diagnosis is difficult to confirm with an arterial hemoglobin carbon monoxide (HbCO) level because the half-life of HbCO in room air is only 4 hours. Hence, the level may be normal only a few hours after exposure. One way of diagnosing and treating this condition is

by removing the cause of the exposure. Sources of carbon monoxide exposure include heavy urban traffic in which the patient is a car passenger, methylene dichloride paint strippers, kerosene space heaters, a gasoline engine running in an attached garage, cigarette smoking, and faulty home furnaces. Typically co-inhabitants have similar symptoms. Patients exposed to carbon monoxide may have behavioral and neurologic findings days to months later.

Other substance exposures may also lead to headaches. Ingestion of alcohol may lead to headache either during or after consumption. Use of cocaine causes headaches through various mechanisms, including hypertension, vasoconstriction, hypersensitivity vasculitis, and subarachnoid hemorrhage. Elevations in serum lead levels may cause headache (lead encephalopathy).

Medication-Overuse Headaches

A thorough medication history is essential as many analgesics may be associated with overuse headaches. All classes of headache medications can paradoxically cause headaches that may be worse on waking and exacerbated by activity. Stopping the medication improves the situation.

Caffeine Withdrawal Headaches

The threshold for withdrawal for each person is variable, but when caffeine is ingested in sufficient quantities for prolonged periods, sudden withdrawal may lead to vascular headaches. In the most common scenario, consumption occurs on weekdays, and because of schedule differences, the caffeinated beverage is not consumed on the weekend. This syndrome is easily diagnosed by history or by the use of a headache diary.

Intracranial and Systemic Infections

Infectious causes of headache are common and are typically benign, with the most common etiology being a viral upper respiratory tract infection. However, serious and life-threatening infections may present with headache. **Meningitis** and **meningoencephalitis** may present with a headache that is acute in onset and generalized. Fever, nuchal rigidity, alteration in sensorium, and abnormal neurologic findings may be present as well. Children presenting with this constellation of findings require an emergent lumbar puncture with cell counts and differential, glucose and protein quantification with a simultaneous determination of serum glucose, Gram stain, bacterial culture, and any indicated viral studies based on history, physical findings, or local epidemiology.

The child with a **brain abscess** may present with progressive neurologic dysfunction and may deteriorate quickly. Brain abscess should be considered in any child with a right-to-left cardiac shunt, chronic mucosal surface infections (sinus, otitis, dental), endocarditis, and a recent onset of persistent, chronic headaches. These patients may present with focal neurologic findings and signs of increased intracranial pressure rather than fever and nuchal rigidity. Neuroimaging should be considered prior to lumbar puncture, due to risk of herniation with space-occupying lesions.

Headache may accompany infections of the eye and orbit. The signs and symptoms of **periorbital cellulitis** are periorbital redness and tenderness, whereas in **orbital cellulitis**, the patient may also have chemosis, proptosis, ophthalmoplegia, and visual loss. Inflammation of the eye and orbit usually causes localized pain.

Children affected by **Lyme disease** commonly have headache in conjunction with other systemic symptoms. Lyme disease can cause an indolent lymphocytic meningitis, or may cause an isolated increased intracranial pressure in the absence of other findings that, if left untreated, may lead to permanent vision loss.

Disorders Affecting Homeostasis

Anoxia and **hypoxia** (<70 mm Hg) may produce headaches through dilatation of cerebral arteries, which in turn causes an increase in cerebral blood flow. Headaches are typically bifrontal, throbbing, and worsen with exertion, straining, or supine positioning. In children with illnesses that predispose them to hypoxia (chronic lung disease, obstructive sleep apnea), treatment should be directed at alleviating the source of the hypoxia. High altitudes may also lead to an acute hypoxic state. Hypercapnia (levels >50 mm Hg) may also cause throbbing headaches. For nocturnal or morning headaches, in addition to neuroimaging, polysomnography should be considered to assess for obstructive sleep apnea.

Systemic hypertension, both acute and chronic, may be associated with headaches. The pain is related to altered regulation of cerebral blood flow. Acute hypertension typically occurs in a child with underlying renal disease due to poststreptococcal glomerulonephritis, renal failure, or collagen vascular disease. Although hypertension is an uncommon cause of headaches in children, the diagnosis of hypertension is straightforward, and treatment of the hypertension alleviates the headaches. Headaches may be part of **malignant hypertension syndrome**, in which retinal exudates and microscopic hematuria are usually present. Severe hypertension may also cause intracerebral hemorrhage.

Headaches triggered by **fasting** may occur in individuals with and without primary headache disorders. Children may fast due to dieting or irregular schedules. These headaches may occur within 1 hour but generally take 12 hours to develop. A thorough diet history will reveal prolonged fasting as the etiology of the headache.

Headaches and/or Facial Pain Related to Dysfunction of Head and Neck Structures (Table 28.17)

Asthenopia or eye strain may be a cause of headache and mild, dull, aching discomfort of the eyes. Because it is due to muscle strain that occurs while trying to correct visual acuity, it is not present on awakening and worsens with prolonged visual duties. Referral to an ophthalmologist should be made if asthenopia is suspected. Physical examination is otherwise normal. Abnormal extraocular movements should prompt neuroimaging to evaluate for possible intracranial lesions.

A **corneal abrasion** should be suspected in the irritable infant and in the patient with excruciating eye pain. Diagnosis is made by fluorescein examination of the cornea. Corneal irritation, keratoconjunctivitis sicca, and recurrent erosion syndrome may present with recurrent eye pain that must be differentiated from cluster headaches.

Optic neuritis (inflammation of the optic nerve) often causes ipsilateral retro-orbital pain. Optic neuritis may occur as a single entity, or it may be part of the manifestation of multiple sclerosis. This disorder is rare in children but common in adolescents. The ophthalmologic examination reveals papillitis, an afferent pupillary defect, and decreased visual acuity. Often, the findings are normal except for decreased visual acuity. A neuroimaging study should be performed to fully evaluate the orbit and optic nerve and to rule out multiple sclerosis.

The headache associated with **sinusitis** may be acute or chronic. When the frontal or maxillary sinuses are involved, pain is frontal or orbital in location. When the ethmoid or sphenoid sinuses are infected, the headache may be frontal or occipital. Signs and symptoms of sinusitis include purulent rhinorrhea, halitosis, cough, tenderness to palpation over the sinuses or teeth, and fever. A prior history of allergic rhinitis or sinusitis may be present. The diagnosis of sinusitis in

TABLE 28.17 **Chronic Facial Pain: Differential Diagnosis**

Orbital Pain	**Nasal/Cheek Pain**
Ocular disease	Sinusitis
Migraine	Facial cellulitis
Cluster headache	Neoplasm (nasopharynx, sinus)
Sinusitis	Vasomotor rhinitis
Orbital cellulitis	Allergic rhinitis
Tolosa-Hunt syndrome	Trigeminal neuralgia
Intracranial aneurysm	Midline granuloma
Cavernous sinus disease	Wegener granulomatosis
Giant cell arteritis	TMJ syndrome
Neoplasm	Dental disease
Graves disease	Postherpetic neuralgia
Neoplasm, frontal lobe	Atypical odontalgia
Trigeminal neuralgia	Cluster headache
Postherpetic neuralgia	
Zoster	**Poorly Localized/Vague**
	Sinus disease
Ear/Periauricular Pain	TMJ syndrome
Chronic external otitis	Depression
Relapsing polychondritis	Conversion reaction
Cholesteatoma	Neoplasm
TMJ syndrome	Muscle contraction
Migraine	
Carotidynia	**Dental/Jaw Pain**
Glossopharyngeal neuralgia	Toothache
Thyroiditis	TMJ syndrome
Muscle contraction	Sinusitis
Carotid aneurysm	Neoplasm
Cervical spine disease	Trigeminal neuralgia
Neoplasm	Parotid disease
Zoster	Atypical odontalgia
	Postherpetic neuralgia

TMJ, temporomandibular joint.
Modified from Reilly BM. *Practical Strategies in Outpatient Medicine*. 2nd ed. Philadelphia: WB Saunders; 1991:106.

pediatric patients may be made if symptoms of nasal discharge or daytime cough persist without improvement for more than 10 days, clinical course worsens after symptoms improve or stabilize, fever develops following a period of symptom stabilization or abatement of initial fever, or symptoms are severe at onset, defined as fever of or above 39°C with purulent nasal discharge for at least 3 days. Imaging studies are not required to confirm a diagnosis of sinusitis.

Dental abscesses may produce headaches that are aching or stabbing, and may occur as a complication of dental caries, tooth extractions, or root canal procedures. Physical examination may be normal or may reveal gingival swelling, redness, or pain. Palpating each tooth individually with a tongue blade may reveal the source of pain.

Malocclusion of the temporomandibular joint (TMJ) may cause chronic headaches. The pain is localized to the side of the affected joint. Some patients report constant pain, whereas others have pain only with jaw movement. An identifying "click" occurs when the patient opens the mouth. Full depression of the mandible may be limited in range. Not every person with a click has **TMJ syndrome,** and not everyone with TMJ syndrome has headaches. Gum chewing may exacerbate the pain associated with TMJ syndrome. In patients without TMJ syndrome, gum chewing may cause headaches through overuse of the temporalis muscles. Patients with symptomatic TMJ syndrome often find relief with the use of an occlusal splint worn during sleep.

Psychologic Factors

There is a high rate of comorbid psychiatric diagnoses in children with headaches, of which anxiety and depression are the most common. Primary headaches are more commonly seen in children with a history of psychiatric disorders. Consequently, screening for mental health symptoms should occur in conjunction with the medical history. History should also aim to determine child coping skills, family relationships, and parental reactions to pain.

Conversion disorder may manifest as headaches. Headaches associated with conversion disorder are very difficult to diagnose and treat appropriately. The frequency and severity of these headaches increase without lasting relief from any pharmacologic or physical therapy. Some patients appear as if they are in pain, whereas others look perfectly normal despite claiming to be in considerable pain. Secondary tension-type headache pain may occur, which further complicates the diagnosis. The neurologic findings in conversion disorder are normal.

The 2 problems in approaching conversion disorder headaches are (1) to convince the family that there is no physical cause for these headaches, and (2) to uncover the origin of the conversion disorder. The physician with a pre-established rapport with the family is clearly at an advantage in convincing the family that no physical cause exists for the headaches. The origins of a conversion disorder are difficult to uncover and require the finesse of an experienced therapist. Psychologic intervention is mandatory, not only to identify the source of the problem but also to offer appropriate counseling.

SUMMARY AND RED FLAGS

Headaches are a common cause of morbidity and health care utilization in children. Most children who present with headaches will have a benign secondary headache or the primary headache disorders of tension-type headache or migraine. However, the clinician must always consider conditions associated with significant morbidity or mortality in the evaluation of each patient with a headache. A thorough history and physical examination are the best tools to aid the clinician in determining which patients have a serious and life-threatening cause for their headaches. Certain symptoms should be considered red flags and prompt further evaluation (see Tables 28.5 and 28.6). Indications for neuroimaging are shown in Table 28.9.

In the evaluation of the patient with headache, a single normal neurologic examination or 1 normal neuroimaging study should not provide complete reassurance. If headache persists, children require continued follow-up and ongoing physical examination assessments. Maintenance of a headache diary for patients with frequent or chronic headaches may be invaluable in determining the diagnosis and assessing the response to therapy. Assessment of headaches requires a strong patient-physician relationship in order to provide continued review of associated symptoms, ongoing assessments, appropriate evaluation, consideration of psychosocial factors, and reassurance when indicated.

Hypotonia, Weakness, and Stroke

Chamindra Konersman

MUSCLE WEAKNESS AND HYPOTONIA

Hypotonia, or abnormally diminished muscle tone, is defined as decreased resistance to passive movement of a limb through its range of motion. Hypotonia affects children of all ages and may be acute or chronic, progressive or static, isolated or part of a complex clinical situation, and may or may not be associated with weakness. The evaluation of children with hypotonia can be simplified by a thoughtful, analytic approach to the differential clues that are useful in identifying an underlying cause starting with detailed general and neurologic examinations (Table 29.1 and Fig. 29.1). Localizing the lesion based on examination in conjunction with laboratory, genetic, and imaging studies is key to arriving at a diagnosis (Table 29.2).

The assessment of muscle tone can be made by several observations, including:
- Evaluation of spontaneous posture
- Extent of mobility of joints
- Response to flapping of distal extremities
- Response to postural changes

The method of evaluating muscle tone and strength depends on the age of the patient.

Muscle tone is defined as the resistance experienced by the examiner to movement of limbs about joints. Muscle tone is divided into postural and phasic. **Postural tone** is that experienced by the steady flexion or extension of a joint and is caused by the resultant uniform resistance of muscle to passive movement. Antigravity posture of muscle is caused by postural tone. **Phasic tone** is the catch experienced when an extremity is rapidly flexed or extended. The anatomic structures responsible for muscle tone are contained in a closed circuit formed by the muscle spindle, which is connected to the spinal cord by sensory afferent pathways. The sensory afferent fibers synapse directly or indirectly with anterior horn α and γ motor neurons. The α motor neurons end at the neuromuscular junction (NMJ), and the γ motor neurons end at the muscle spindle, completing the closed circuit (Fig. 29.2). It is the level of activity of the γ motor neurons and its influence on the muscle spindle that sets the level of resting muscle tone. This lower motor neuron pathway is closely monitored and influenced by descending pathways from the cerebral cortex, basal ganglia, brainstem, and cerebellum. These descending pathways constitute the upper motor neuron pathways that influence resting muscle tone.

The maintenance of normal muscle tone requires the integrity of the entire central and peripheral nervous systems from the cerebral cortex, cortical white matter pathways, basal ganglia, cerebellum, brainstem, spinal cord, peripheral nerve, NMJ, and muscle. Diseases that affect the function of the nervous system at any level may result in abnormal muscle tone (Table 29.3; see Table 29.2). Broadly categorizing hypotonia into central versus peripheral nervous system causes based on history and examination is a useful initial diagnostic step

(Table 29.4). An estimated 80-90% of infantile hypotonia is central in origin, with the remaining 10-20% being peripheral.

Most cases of acute *lateralized* body weakness result from abnormalities of the blood supply to a portion of the central nervous system (CNS). **Stroke** serves as a term to denote the sudden onset of symptoms attributable to such an interruption of cerebral or spinal perfusion. The clinical presentations and causes of stroke are best considered with respect to each of three age groups: neonates, children between 1 and 13 years of age, and adolescents, and are discussed later in this chapter.

HYPOTONIC INFANT

◆ Clinical Evaluation

In an infant, historical information must include a complete obstetric history as well as accurate data about perinatal events, diet, toxic exposure, and family diseases. The muscle strength, passive tone, joint extensibility, and postural reflexes including responses to traction, axillary suspension, and ventral suspension of the hypotonic infant should be compared to that of the normal infant (Fig. 29.3).

Muscle Strength

Muscle strength cannot be measured directly in infants (Table 29.5), but numerous clinical clues allow the careful observer to identify weakness. The most important of these is the spontaneous posture. The weak infant has diminished or no spontaneous movement, often in striking contrast to the usual vigorous and plentiful movements of the infant with normal strength. The lower extremities are abducted, and the lateral surfaces of the thighs lie against the examination table, whereas the upper extremities lie extended alongside the body or flexed in a flaccid position beside the head (Figs. 29.4 and 29.5A). With marked weakness, there are no movements that overcome the pull of gravity. The immobility of the weak infant results in flattening of the occipital bone, which is often associated with occipital hair loss. When placed in a sitting posture, the infant droops forward, the shoulders droop, the head falls forward, and the arms hang limply.

Passive Tone

Passive tone can be assessed by evaluating the resistance to movement of the limbs through a range of motion at the joints. Evaluation of the shoulders, elbows, wrists, hips, knees, and ankles is especially helpful. The examiner senses a "looseness" of the limbs as the limbs are moved.

In addition, grasping the midportion of the infant's limb and passively flapping the extremity allow the examiner to evaluate the degree of limpness of the distal extremity. In the hypotonic infant, the hands and feet wave limply; in the normal infant, the ankle and wrist are maintained fairly rigidly in line with the rest of the extremity.

Even in normal infants, there is a wide variation of muscle tone. Passive muscle tone varies and is particularly diminished after feeding

(See *Nelson Textbook of Pediatrics,* p. 3397.)

TABLE 29.1 Causes of Hypotonia and Weakness

	Systemic	Connective Tissue	Cerebral	Spinal Cord	Anterior Horn Cell	Peripheral Nerve	Neuromuscular Junction	Muscle
Common	Sepsis; Heart failure; Acidosis; Hypoxia; Renal failure; Hypoglycemia; Down syndrome; Prader–Willi syndrome; Fragile X syndrome; Hypothyroidism; Other chromosomal disorders; Maternal-fetal drug effects	Stickler syndrome; Marfan syndrome; Achondroplasia	Hypoxic-ischemic brain injury; Intracranial hemorrhage; Brain malformation*; Intrauterine infection; Postnatal brain injury	Myelodysplasia; Spinal cord tumor; Epidural abscess; Transverse myelitis; Trauma (transection or compression); Syringomyelia	Spinal muscular atrophy	Postinfectious polyneuropathy (Guillain–Barré syndrome); Toxic neuropathies (isoniazid, vincristine, platinum-based antineoplastic medications, nitrofurantoin)	Botulism; Infantile myasthenia; Transient acquired neonatal myasthenia	Duchenne muscular dystrophy; Becker muscular dystrophy; Myotonic dystrophy; Dermatomyositis
Uncommon	Disorders of amino acid metabolism; Urea cycle disorders; Peroxisomal disorders; Scurvy; Rickets; Sotos syndrome; Angelman syndrome; Rett syndrome; Smith–Lemli–Opitz syndrome	Ehlers–Danlos syndrome; Osteogenesis imperfecta; Velocardiofacial syndrome	Progressive encephalopathies; Mitochondrial disease	Neonatal spinal cord transection; Hypoxic-ischemic myelopathy; Arteriovenous malformation	Möbius syndrome	Chronic inflammatory demyelinating polyneuropathy; Charcot–Marie–Tooth disease; Hereditary sensory and autonomic neuropathies	Toxic (organophosphate poisoning, aminoglycosides, magnesium); Postneuromuscular blocking agents (vecuronium)	Pompe disease
Rare	Lowe syndrome; Zellweger syndrome; Neonatal adrenoleukodystrophy; Mucolipidosis type IV; Tay–Sachs disease; Gangliosidosis; Mannosidosis; Infantile neuroaxonal dystrophy		Miller–Dieker syndrome; Congenital muscular dystrophy; Metachromatic leukodystrophy; Krabbe disease		Poliomyelitis; Incontinentia pigmenti; Fazio–Londe disease; Brown–Vialetto–Van Laere syndrome	Refsum disease; Giant axonal neuropathy; Metachromatic leukodystrophy; Krabbe disease	Congenital myasthenic syndromes	Other muscular dystrophies; Congenital myopathies; Metabolic myopathies; Mitochondrial myopathies

*Examples of brain malformations include agenesis of the corpus callosum, lissencephaly, Joubert syndrome, and Dandy-Walker malformations.

Hypotonic Newborn

History and exam...
evaluate seizures,
alertness, autonomic sx's

Signs of encephalopathy

Yes → Obtain head CT or MRI scan, observe course

No → Hypotonia without encephalopathy

and before sleep. There is profound hypotonia in all infants during sleep. Tone can also be affected by the position of the head. The child whose head is turned to one side may be manifesting an **asymmetric tonic neck response**, with increased extensor tone on the side of the body to which the head is turned and increased flexor tone on the contralateral side. This asymmetry of tone may be elicited even in the child who does not exhibit the typical "fencer's" posture (Fig. 29.6). Therefore, examination of an infant should always be conducted while the infant's head is at the midline; the same is true for eliciting muscle stretch reflexes. Hypotonia can also be associated with heart failure, sepsis, acidosis, failure to thrive, and other systemic conditions (see Table 29.1).

Joint Extensibility

The extent to which the joints may be extensible provides an indirect clue to the presence of hypotonia. Examination of **mobility** at the elbows, wrists, hips, and knees is helpful. The hypotonic infant may assume unusual postures in the presence of joint hyperextensibility. The "scarf sign" is a useful sign of hyperextensibility in the young infant. With the infant in a semireclining position, the hand is pulled across the chest toward the opposite shoulder and the position of the elbow is noted (see Fig. 29.3A). If the elbow passes the midline, then there is hypotonia.

Postural Reflexes

Traction response (pull-to-sit). The traction response is the most useful and most sensitive of the postural reflexes in infants. With the infant lying supine, the infant's hands are grasped, and the infant is pulled up to a sitting position. Once the sitting posture is attained, the head is held erect in the midline. During the maneuver, the examiner notes the infant's attempt to counter the traction by flexion of the arms (see Fig. 29.3B).

In an infant younger than 3 months, the **plantar grasp** should also be evident. In addition, there should be flexion at the elbow, knee, and ankle in response to the maneuver. The degree to which the head and neck pull up along with the trunk depends on the child's age.

In infants younger than 33 weeks' gestation, there is no traction response. From 33 weeks to term, the infant has head lag but responds to the traction maneuver by flexing the neck flexors in an attempt to lift the head. The full-term infant exhibits a traction response with minimal head lag, and when the sitting posture is attained, the head may be held erect momentarily and then falls forward.

By age 3 months, there should be no head lag, and the head should be aligned with the plane of the back as the child is pulled to sitting. The absence of flexion of the limbs in response to the examiner's pull

TABLE 29.2	**Differentiating the Causes of Infantile Hypotonia**		
Localization	**Cause**	**History and Exam Findings**	**Investigation to Aid in Diagnosis**
Central nervous system	HIE Intracerebral hemorrhage	Prematurity, difficult delivery	Brain MRI
	Brain malformations	Cranial nerve abnormalities, Babinski sign, gradual development of hypertonia (especially axial), respiratory or feeding difficulties, global delay	Cerebral ultrasound Brain MRI
	Intrauterine infection	Fever, altered mental status	Microbial cultures/evaluations, CSF evaluation
	Postnatal birth injury	Seizures, focal neurologic deficits	Brain MRI, EEG
	Progressive encephalopathies (leukodystrophies, progressive myoclonic epilepsies, Lennox–Gastaut syndrome, infantile spasms)	Seizures, developmental regression, ataxia, focal neurologic deficits, visual loss	Brain MRI, EEG, EMG/NCS (useful in adrenoleukodystrophy, Krabbe disease and metachromatic leukodystrophy), specific genetic testing
	Mitochondrial disease	Seizures, focal neurologic deficits, global delay, visual loss, hyper- or hyporeflexia	Brain MRI, muscle biopsy, mitochondrial DNA sequencing and deletion on muscle or affected tissue, elevated lactic acid, elevated CK, EMG/NCS
Spinal cord	Spinal cord tumor Syringomyelia HIE Trauma AVM	Spinal level on exam, weakness below a defined spinal level, absent reflexes (acutely) or hyperreflexia (chronically) below the level, may have Babinski sign, history of trauma	Brain MRI, complete spinal MRI
Anterior horn cell	Spinal muscular atrophy	Absence of antigravity movements, tongue fasciculations, absent reflexes to hyporeflexia, normal cognition, breathing/feeding difficulties; weakness in legs more than arms in SMA types II–III	*SMN* deletion analysis
	Poliomyelitis	Neck stiffness, muscle spasms, areflexia, asymmetric flaccid paralysis of a limb, respiratory distress, muscle atrophy, normal sensation	Isolate poliovirus from stool, confirm using RT-PCR or genomic sequencing, acute and convalescent serology showing 4-fold increase in titer, EMG/NCS showing pure motor neuronopathy
	Incontinentia pigmenti	Skin blistering, wartlike skin lesions, hyperpigmented streaks, pale/hairless atrophic linear streaks that respect Blaschko lines, dental abnormalities, intellectual delay	DNA analysis, EMG/NCS showing pure motor neuronopathy
	Fazio-Londe disease Brown–Vialetto–Van Laere syndrome (BVVL)	Bulbar palsy, facial weakness, hearing loss (BVVL only), respiratory compromise, muscle weakness	DNA analysis
Peripheral nerve	Guillain–Barré syndrome (GBS) Chronic inflammatory demyelinating polyneuropathy (CIDP)	Sensory ataxia with walking difficulties, rapidly (GBS) or slowly (CIDP) progressive weakness, absent reflexes or hyporeflexia, autonomic dysfunction, antecedent gastrointestinal/respiratory illness in GBS	EMG/NCS with absent or prolonged F-waves, prolonged distal latencies, conduction block, demyelinating nerve conduction velocities, CSF showing cytoalbuminologic dissociation, MRI with edematous enhancing nerve roots
	Toxic neuropathies	History and temporal correlation with exposure to a neurotoxic drug, distal then proximal muscle weakness, absent reflexes or hyporeflexia, sensory ataxia with walking difficulties	EMG/NCS showing mixed axonal/demyelinating features, plasma drug levels
	Charcot–Marie–Tooth disease	Family history of similar disease, pes cavus and hammer toe foot deformities, ataxic gait, foot drop, absent reflexes or hyporeflexia	EMG/NCS to determine if axonal or demyelinating subtypes, DNA analysis

TABLE 29.2	**Differentiating the Causes of Infantile Hypotonia—cont'd**		
Localization	**Cause**	**History and Exam Findings**	**Investigation to Aid in Diagnosis**
Peripheral nerve (cont'd)	Hereditary sensory and autonomic neuropathies	Sensory loss in a stocking/glove distribution, chronic skin ulceration and poor wound healing, distal muscle weakness with foot deformity, absent reflexes or hyporeflexia, variable anhidrosis	EMG/NCS showing normal or mildly abnormal motor responses and abnormal sensory responses, nerve biopsy showing reduced myelinated and unmyelinated fibers, DNA analysis
	Refsum disease	Autosomal recessive inheritance, stocking/glove distribution of sensory and motor weakness, anosmia, hearing loss, ataxia, ichthyosis, short metacarpals and metatarsals, cardiac arrhythmia, and cardiomyopathy	Elevated plasma phytanic acid concentration, DNA analysis
	Giant axonal neuropathy	Stocking/glove distribution of sensory loss and motor weakness, cerebellar ataxia, absent reflexes or hyporeflexia, kinky hair (tightly curled), nystagmus, dysarthria, pyramidal tract signs, optic neuropathy, seizures	Brain MRI with white matter abnormalities, axonal sensorimotor polyneuropathy on EMG/NCS, nerve biopsy showing giant axons (axonal swelling) and disorganized neurofilaments, DNA analysis
	Metachromatic leukodystrophy Krabbe disease Adrenoleukodystrophy	Developmental regression, absent reflexes or hyporeflexia, Babinski signs	EMG/NCS showing demyelinating neuropathy, brain MRI showing white matter disease, DNA analysis
Neuromuscular junction	Botulism	Sudden poor feeding, constipation, weak cry, gradual muscle weakness, dilated poorly reactive pupils, exposure to soil/dust with bacterium or honey consumption	Presence of toxin in stool/serum, culture bacterium from stool, EMG/NCS showing low-amplitude motor responses or decrement on repetitive nerve stimulation in a weak muscle
	Transient acquired neonatal myasthenia	Ptosis, feeding and respiratory difficulties, aspiration, mother with signs or symptoms of autoimmune myasthenia	Maternal history of myasthenia, EMG/NCS showing decrement on repetitive nerve stimulation in a weak muscle, good response to acetylcholinesterase inhibitors
	Infantile (autoimmune) myasthenia	Ptosis, episodic weakness, recurrent feeding and respiratory difficulties, easy fatigability	EMG/NCS showing decrement on repetitive nerve stimulation in a weak muscle, good response to acetylcholinesterase inhibitors, antiacetylcholine receptor antibody serology
	Congenital myasthenic syndrome	Ptosis, episodic weakness, recurrent feeding and respiratory difficulties, easy fatigability	EMG/NCS showing decrement on repetitive nerve stimulation in a weak muscle, DNA analysis, negative anti-acetylcholine receptor antibody serology
Muscle	Duchenne/Becker muscular dystrophy	X-linked recessive pattern of inheritance, enlarged calves, proximal muscle weakness with a Gower maneuver	Markedly elevated CK, DNA analysis
	Congenital myotonic dystrophy	Autosomal dominant pattern of inheritance, frog-leg position, open down-turned mouth, minimal antigravity movements in infants, distal > proximal weakness in children, impaired relaxation of grip, dysarthria, myopathic facies with temporal wasting	Test mother (then father) for clinical myotonia or electrical myotonic discharges, EMG/NCS with myopathy in newborn period and myotonic discharges in older children, normal to mildly elevated CK, *DPMK* gene CTG repeat analysis
	Dermatomyositis	Subacute proximal muscle weakness, rash (Gottron papules, heliotrope rash), cutaneous calcinosis	Normal to mildly elevated CK, muscle biopsy showing perimysial and perivascular inflammation, and MAC deposition on microvasculature
	Pompe disease	Absence of antigravity movements, severe cardiomegaly, feeding/respiratory difficulties, hepatomegaly	GAA enzyme activity in dried blood spot, lymphocytes or fibroblasts, *GAA* gene analysis to confirm

TABLE 29.2	**Differentiating the Causes of Infantile Hypotonia—cont'd**		
Localization	**Cause**	**History and Exam Findings**	**Investigation to Aid in Diagnosis**
Muscle (cont'd)	Congenital muscular dystrophy	Family history, proximal > distal muscle weakness, feeding and respiratory difficulties, early-onset contractures in specific subtypes, keloids/hyperkeratosis pilaris in specific subtypes, CNS dysfunction in specific subtypes	Brain MRI, mild to markedly elevated CK, muscle biopsy showing dystrophic changes, muscle MRI, EMG/NCS to assess for demyelinating neuropathy component and myopathy, DNA analysis
	Congenital myopathies	Family history, proximal > distal muscle weakness, feeding and respiratory difficulties, ptosis and ophthalmoparesis in specific subtypes	Normal to mildly elevated CK, muscle biopsy showing specific changes (nemaline rods, cores, centrally-placed nuclei), DNA analysis
	Metabolic myopathies	Family history, proximal muscle weakness, history of rhabdomyolysis or myoglobinuria, 2nd-wind phenomenon in some subtypes	Normal to markedly elevated CK, EMG/NCS usually myopathic, muscle biopsy, DNA analysis
	Mitochondrial myopathies	Maternal inheritance pattern, proximal > distal weakness, ptosis, ophthalmoparesis, short stature, variable cardiac and CNS involvement, recurrent rhabdomyolysis	Normal to moderately elevated CK, EMG/NCS showing myopathy and variable neuropathy, muscle biopsy with ragged red fibers, mitochondrial DNA analysis

AVM, arteriovenous malformation; CK, creatine kinase; CNS, central nervous system; CSF, cerebrospinal fluid; CTG, cytosine-thymine-guanine; GAA, α-glucosidase; HIE, hypoxic-ischemic encephalopathy; EEG, electroencephalogram; EMG/NCS, electromyography/nerve conduction study; GI, gastrointestinal; MAC, membrane attack complex; MRI, magnetic resonance imaging; RT-PCR, reverse transcription polymerase chain reaction; SMA, spinal motor atrophy.

Tone	Spastic (hypotonia at onset possible)	↓Acutely; ↑	↓, flaccid	↓	↓	↓
DTR	Normal to ↑	↓Acutely; ↑	↓ to absent	↓ to absent (lost early)	Normal	Normal to ↓ to absent
Babinski	Present	Present usually	Absent	Absent	Absent	Absent
Fasciculations	Absent	Absent	Present	Rarely	Absent	Absent
Atrophy	Mild to moderate	Mild to moderate	Present	Present	Absent	Present Pseudohypertrophy
Sensation	Normal	Absent below level of lesion	Normal	Abnormal in defined peripheral nerve distribution or glove/stocking	Normal	Normal
CK	Normal	Normal	Normal to moderately elevated (several 1000s IU/L)	Normal or mildly elevated (100s IU/L)	Normal	Normal to severely elevated
Overall pattern	Hemibody deficits	Spinal level present	Proximal weakness in SMA; asymmetric weakness in other diseases	Distal, length-dependent usually, defined nerve territory	Symmetric, painless weakness of tonically active muscles	Proximal > distal weakness
Other	Seizures Developmental delay Regression Cortical signs (e.g., language)	Radicular back pain, bowel/bladder dysfunction			Fluctuating diurnal variation	Myalgia, Gower sign

CK, creatine kinase; DTR, deep tendon reflexes; SMA, spinal muscular atrophy.

TABLE 29.4 Exam and Historical Findings to Distinguish Central from Peripheral Hypotonia

Finding	Central	Peripheral
Seizures	Present	Absent
Altered mental status	Present	Absent
Delayed cognitive milestones	Present	Absent
Deep tendon reflexes	Normal or increased	Absent or decreased usually
Babinski sign	Present	Absent
Infantile reflexes	Persistent	Not persistent
Pull-to-sit	Minor head lag	Marked head lag
Tongue fasciculations without other cranial nerve deficits	Unlikely	Very likely
Ophthalmoparesis	Present in brainstem disease	Present in some myopathic diseases
Ptosis	Present in some brainstem diseases	Present in some myopathic and neuromuscular junction diseases
Weakness	Mild to moderate	Severe
Antigravity movements	Present	Absent usually
Arthrogryposis	Less common	More common
Muscle atrophy	None to mild	Moderate to severe

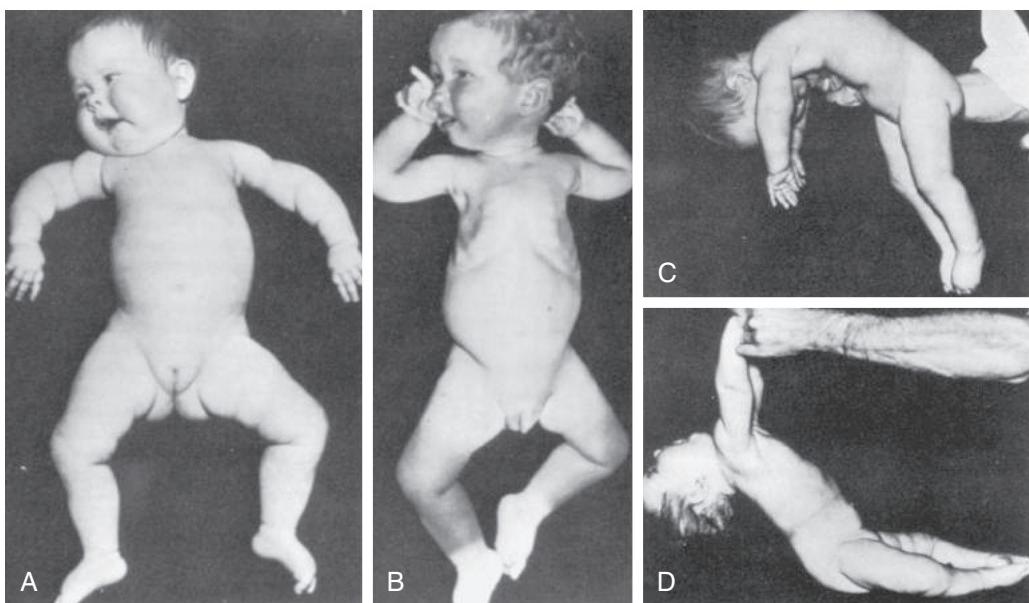
FIGURE 29.3 Normal postural responses in a 5-month-old infant showing that the elbow does not extend beyond the midline on joint extensibility testing *(A),* the head and body in the same plane (no head lag) on pull-to-sit with resistance resulting in flexed elbows and knees *(B),* and lack of a slip-through feeling with resistance against the examiner's hands, good maintenance of head control, and extension of the head and legs with the steppage reflex *(D).* An infant with hypoxic-ischemic encephalopathy who was initially hypotonic at the time of delivery was noted to be hypertonic at 8 months with a normal ventral suspension response as evidenced by the ability to keep the head above horizontal *(C).*


FIGURE 29.4 Spinal muscular atrophy I (Werdnig-Hoffman disease): characteristic postures. *A,* A 6-week-old infant with severe weakness and hypotonia from birth. Note the frog-leg posture of the lower limbs and internal rotation ("jug-handle") at the shoulders. *B,* A 1-year-old infant with frog-leg posture, external rotation at shoulders, intercostal recession, and normal facial expressions. A 6-week old infant with marked weakness of the limbs and trunk giving the characteristic inverted "U" appearance on ventral suspension *(C)* and pull-to-sit *(D).* (Modified from Volpe JJ, ed. *Neurology of the Newborn.* 5th ed. Philadelphia: Saunders; 2008: 770-771.)

and the presence of head lag inappropriate for age suggests hypotonia (see Figs. 29.4D and 29.5C).

Axillary suspension. The response to axillary suspension allows assessment of generalized and shoulder girdle tone. The infant is held under the arms, lifted, and suspended from the axillae without the thorax being grasped. In infants with normal tone and strength, the shoulder girdle muscles exert enough strength to allow the infant to be suspended without slipping through the examiner's grasp. In addition, the infant's head is held midline and the legs are held with some flexion at the hips, knees, and ankles (see Fig. 29.3D). The hypotonic infant droops with legs extended and head falling forward, and the absence of resistance of the muscles of the shoulder girdle allows the infant to slip through the grasp of the examiner as the baby's arms fling upward (see Fig. 29.5B).

Ventral suspension. The response to ventral suspension allows assessment of tone of the trunk, neck, and extremities. The examiner holds the infant, who is lying prone. The infant is supported only by the examiner's hand on the abdomen. A normal infant holds the head erect and the back straight and holds the extremities with some flexion at the elbows, hips, knees, and ankles (see Fig. 29.3C). A full-term neonate makes intermittent attempts to hold the head straight, maintains the back straight, and can flex the limbs. The hypotonic infant droops in the examiner's palm, as if in the shape of an inverted "U," with the head and legs dangling limply (see Fig. 29.4C).

TABLE 29.5	Grading Muscle Strength
0: No contraction	
1: Minimal contraction only	
2: Moves in horizontal plane but not against gravity	
3: Moves against gravity but not against resistance	
4: Moves against gravity and minimal resistance	
5: Moves against gravity and full resistance	

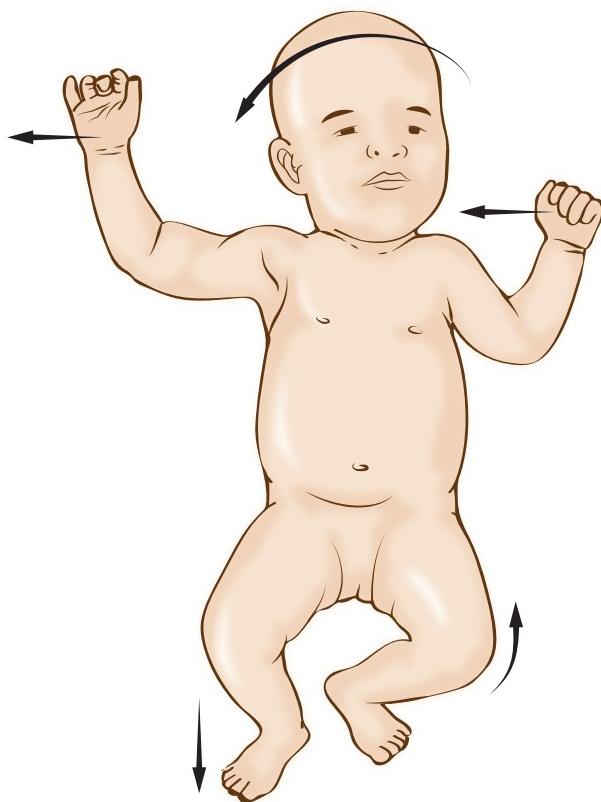
FIGURE 29.5 An 18-month-old infant, with an undiagnosed pure motor neuron disorder with severe axial more than appendicular weakness, delays in motor milestones, and respiratory insufficiency, has internal rotation of upper arm and frog-leg position *(A),* a slip-through appearance on axillary suspension *(B),* and a prominent head lag on pull-to-sit traction testing *(C).*


FIGURE 29.6 Asymmetric tonic neck reflex. Normally present from birth to 2 months. Turning head to 1 side when supine elicits extension of arms and leg ipsilateral to side that head is turned and flexion of opposite arm and leg. Persistence beyond 2 months might suggest abnormal development of contralateral motor cortex.

◆ Diagnostic Approach

A careful perinatal history is obtained to identify possible features suggestive of perinatal **hypoxic-ischemic brain injury**. The infant who has a neurologic dysfunction attributable to perinatal asphyxia should have demonstrated evidence of an acute encephalopathy during the neonatal period (disturbance of consciousness, poor feeding, seizures, autonomic dysfunction).

A computed tomographic (CT) study or magnetic resonance imaging (MRI) of the head is helpful to identify evidence of brain malformation, intrauterine infection, hypoxic brain injury, intracranial hemorrhage, or hydrocephalus. If the history suggests seizures, an electroencephalogram (EEG) should be obtained.

An **ophthalmologic evaluation** may detect evidence of ocular malformation (cataracts, microphthalmia, optic hypoplasia), evidence of intrauterine infection (chorioretinitis), or retinal/macular abnormality (retinitis pigmentosa, cherry-red spot) (see Chapter 32).

In some cases, requesting a hearing evaluation or brainstem auditory evoked response may be appropriate. A lumbar puncture is necessary only if acute or chronic (intrauterine) meningitis is suspected.

Fig. 29.1 summarizes the approach to the hypotonic newborn. After a thorough history and careful physical examination, it should be determined whether the infant has signs of encephalopathy. A CT scan or MRI of the head is obtained to detect any anatomic abnormalities. If the scan does not reveal an abnormality and if the neonate exhibits increased reflexes and tone over time, a diagnosis of static encephalopathy can be made. If hypotonia persists, anterior horn cell disease, congenital myopathy, or NMJ disease should be considered (see Tables 29.1 and 29.3).

If the baby is not encephalopathic, the practitioner should determine whether a syndrome (Prader–Willi or Down) is present. Is the motor-sensory level consistent with myelodysplasia or spinal cord injury? In addition, causes of **arthrogryposis multiplex congenita** must be considered (Table 29.6).

If the baby is markedly weak, the examiner should check to see whether the mother is also weak (proximal muscle weakness, ptosis, ophthalmoparesis) or whether she displays myotonia (on hand grip or to percussion). If either is true, then transplacental-derived **transient neonatal myasthenia gravis** or **myotonic dystrophy**, respectively, is a possibility (Table 29.7). If neither is the case, then myopathy (Table 29.8), congenital (genetic) myasthenia, infant botulism (Table 29.9), or anterior horn cell disease must be considered (see Table 29.2).

Common Disorders

Hypoxic-ischemic encephalopathy. Brain injury resulting from asphyxia, hypoxia, or ischemia is an important cause of neonatal neurologic morbidity. Tissue oxygen deficiency is presumed to underlie the neurologic injury caused by hypoxic-ischemic insults. An oxygen deficit may be incurred by either hypoxemia or ischemia. **Hypoxemia** is defined as diminished oxygen content of blood. **Ischemia** is characterized by reduced blood perfusion in a particular tissue bed. Hypoxemia and ischemia often occur simultaneously or in sequence. Ischemia is likely to be the more important of these 2 insults.

Asphyxia denotes an impairment in gas exchange, which results not only in a deficit of oxygen in blood but also in an excess of carbon dioxide and thereby acidosis. Furthermore, sustained asphyxia usually results in hypotension and ischemia, which is consistent with the likely predominant importance of ischemia as the final common pathway to brain injury. Asphyxia is the most common clinical insult resulting in brain injury during the perinatal period.

Evidence of hypoxic-ischemic injury to the neonatal nervous system is reflected by a constellation of signs noticed early after birth. The asphyxiating event or events may occur at any point in the antepartum, intrapartum, or postpartum periods. On the basis of admittedly imprecise historical data, it has been concluded that insults sustained by the fetus during the antepartum period account for approximately 20% of cases of hypoxic-ischemic encephalopathy (HIE). Maternal cardiac arrest or hemorrhage leading to transplacental and fetal hypotension represents such prenatal insults. Intrapartum events, such as placental abruption, uterine rupture, and traumatic delivery, may account for 35% of cases of HIE. In an additional 35% of infants displaying signs of HIE, markers of intrapartum fetal distress and antepartum risk, such as maternal diabetes, intrauterine growth restriction, or maternal infection, are found. Postpartum difficulties, such as cardiovascular compromise, persistent fetal circulation, and recurrent apnea, account for approximately 10% of HIE cases. Postpartum difficulties are found more commonly in premature than in full-term infants. Therefore, for at least 65% of cases of neonatal HIE, difficulties of the intrapartum period alone do not explain the encephalopathy.

Recognition of neonatal HIE requires careful observation and examination of the newborn in the context of a detailed history of pregnancy, labor, and delivery. Newborns who have sustained hypoxic-ischemic insults severe enough to cause permanent neurologic injury usually demonstrate abnormalities on neurologic examination. Indeed, a combination of low Apgar scores, fetal acidosis or distress, and abnormal neurologic examination findings help define HIE. Nonetheless, if the hypoxic-ischemic damage has occurred well in advance of parturition, it may be asymptomatic in the neonate.

Mild HIE (stage 1) may be characterized by hyperalertness or by mild depression of the level of consciousness, which may be

TABLE 29.6 Major Causes of Arthrogryposis Multiplex Congenita

Site of Major Pathologic Findings	Disorder
Cerebrum, brainstem, cerebellum	• Microcephaly • Cortical migrational disorders: lissencephaly-pachygyria (e.g., Zellweger syndrome), polymicrogyria, agenesis of the corpus callosum, schizencephaly • Pontocerebellar hypoplasia (type 1) • Dentato-olivary dysplasia • Cytomegalovirus infection • Leptomeningeal angiomatosis • Encephaloclastic processes: porencephalies, hydranencephaly, multicystic encephalomalacia • Hydrocephalus
Spinal cord	• Cervical spinal atrophy • Lumbosacral meningomyelocele • Sacral agenesis
Anterior horn cell	• Spinal muscular atrophy type 1 • Spinal muscular atrophy with respiratory distress type 1
Peripheral nerve	• Charcot–Marie–Tooth disease
Neuromuscular junction	• Congenital myasthenic syndromes • Maternal autoimmune myasthenia (rare)
Muscle	• Congenital myotonic dystrophy • Congenital muscular dystrophies • Congenital myopathies (nemaline myopathy, myotubular myopathy, core myopathy) • Distal arthrogryposis syndromes (types 1–10)
Intrauterine/maternal factors	• Amyoplasia (vascular compromise to fetus or placenta during embryogenesis) • Lack of space: multiple pregnancies, uterine abnormality (bicornuate uterus, uterine fibroid) • Fetal alcohol syndrome with contractures • Intrauterine tumors • Amniotic fluid leakage • Disruption (bands) • Maternal illnesses: infections, untreated SLE, metabolic imbalances • Maternal medications (curare, muscle relaxants) • Maternal injuries in the 1st trimester
Joint and connective tissue abnormalities	• Chondrodysplasia • Congenital contractural arachnodactyly • Marfan syndrome

SLE, systemic lupus erythematosus.

TABLE 29.7 Clinical Features of Congenital Myotonic Dystrophy

Clinical Feature	% of Cases Exhibiting Feature
Hypotonia	100
Muscle atrophy	100
Transmission via mother	100
Intellectual disability in survivors	100
Facial diplegia	100
Feeding difficulties	92
Respiratory distress	88
Hyporeflexia or areflexia	87
Arthrogryposis	82
Polyhydramnios	80
Reduced fetal movements	68
Edema	54
Premature birth (<36 wk)	52
Elevated right hemidiaphragm	49
Neonatal mortality	41
Infant death in siblings	28

From Volpe JJ, ed. *Neurology of the Newborn*. 5th ed. Philadelphia: Saunders; 2008:802.

accompanied by uninhibited Moro and brisk deep tendon reflexes, signs of sympathetic activity (dilated pupils), and a normal or only slightly abnormal EEG. Typically, these symptoms last less than 24 hours. **Moderate HIE (stage 2)** may be marked by obtundation, hypotonia, diminished number of spontaneous movements, and seizures.

Infants with **severe HIE (stage 3)** are ill for more than 24 hours and are comatose. In addition, they are markedly hypotonic and display bulbar and autonomic dysfunction. The EEG is abnormal and may demonstrate a burst-suppression pattern or seizures, or it may be isoelectric.

Neonates with moderate or severe HIE may show variation in level of consciousness during the 1st days after birth. Initially, depression of level of alertness may appear to improve after the first 12-24 hours after birth. However, specific signs of improving alertness such as visual fixation or following are lacking. In addition, other persistent or progressive neurologic deficits, as well as functional deterioration of other extraneural systems, are inconsistent with a true improvement in neurologic state. Coma may persist, supervene, or even progress to brain death by 72 hours of life. If the infant survives 72 hours without losing all cerebral function, a variable amount of improvement may be observed.

Diffuse hypotonia accompanied by a lack of movement constitutes the most frequently observed motor deficit found early in the course of neonatal HIE. By the end of the 1st day, patterns of weakness that reflect the distribution of cerebral injury from a generalized hypoxic-ischemic insult may emerge. Affected full-term infants may demonstrate quadriparesis with predominant proximal limb weakness. This pattern of weakness derives from ischemia in the watershed or parasagittal region of the brain, which corresponds to the border zones of circulation between the anterior and the middle cerebral arteries and the middle and the posterior cerebral arteries. Affected premature infants may have weakness primarily in the lower extremities because of perinatal ischemic injury of motor fibers serving the legs. These fibers lie dorsal and lateral to the external angles of the lateral ventricles. Focal injury resulting from focal ischemia (stroke) may result in focal deficits reflective of the vascular territory in which the injury has occurred. These patterns are relatively subtle. As many as 70% of infants with moderate or severe HIE experiences seizures by the end of the 1st day of life.

TABLE 29.8	**Specific Congenital Myopathies: Distinguishing Clinical Features**	
Subcategory	**Distinguishing Clinical Features**	**Associated Genes:**
Central core disease	• Facial weakness mostly with *RYR1* • Ophthalmoparesis and ptosis with *RYR1* • High incidence of malignant hyperthermia with *RYR1* • Severe axial/respiratory weakness out of proportion to limb weakness with *SEPN1* • Prominent early fixed kyphoscoliosis with *RYR1* • Rigid spine in older childhood with *SEPN1* • High incidence of club feet, pes cavus, foot drop, and distal hand/foot muscle atrophy with *RYR1*	*RYR1, SEPN1, TTN, MYH7, CCDC78*
Nemaline myopathy	• Prominent facial weakness • Severe bulbar weakness, feeding difficulties, and respiratory compromise in neonatal period or early infancy in some	*ACTA1, NEB, TPM3, TPM2, TNNT1, CFL2, KBTBD13, KLHL40, KLHL41, LMOD3*
Centronuclear myopathy	• Prominent facial weakness • Prominent ophthalmoparesis and ptosis (in infancy) • Prominent bilateral ptosis • Severe bulbar weakness, feeding difficulties, and respiratory compromise in neonatal period or early infancy • Infant that is long for age with elongated hands/feet • High incidence of neonatal/infantile death with *MTM1* • High incidence of club feet, pes cavus, foot drop, and distal hand/foot muscle atrophy with *DMN2*	*MTM1* (causes myotubular myopathy), *DNM2, BIN1, RYR1*
Congenital fiber type disproportion	• Severe axial/respiratory weakness out of proportion to limb with *SEPN1* • Rigid spine in older childhood with *SEPN1*	*TPM3, RYR1, TPM2, SEPN1, ACTA1*

RYR1, ryanodine receptor 1; *SEPN1*, selenoprotein N 1; *TTN*, titin; *MYH7*, myosin heavy chain 7; *CCDC78*, coiled-coil domain-containing protein 78; *ACTA1*, alpha-actin-1; *NEB*, nebulin; *TPM3*, tropomyosin 3; *TPM2*, tropomyosin 2; *TNNT1*, troponin T1; *CFL2*, cofilin 2; *KBTBD13*, Kelch repeat and BTB/POZ domains-containing protein 13; *KLHL40*, Kelch-like 40; *KLHL41*, Kelch-like 41; *MTM1*, myotubularin; *DNM2*, dynamin 2; *BIN1*, bridging integrator 1; *LMOD3*, leiomodin 3.

Focal and multifocal ischemic brain injury may occur during the perinatal period. Such injury, most often infarction, occurs in a vascular distribution. Prenatal cerebral infarctions have been identified by intrauterine ultrasonography. In one autopsy study of neonates, 32 of 592 (5%) infants had cerebral infarctions. Among neonates surviving only a few hours after birth, several had infarctions with subacute or chronic histologic characteristics, indicating that the ischemic insult occurred before parturition. Focal seizures are the heralding sign of neonatal stroke. Although clinical signs corresponding to the area of infarction are expected, they may be absent. Neonatal strokes may follow uneventful deliveries and may occur in otherwise normal-appearing infants. Stroke may also accompany asphyxia, coagulopathy, polycythemia, and sepsis. A predilection for these ischemic lesions to occur in the territory of the middle cerebral artery, especially the left, has been noted and remains unexplained.

A direct relationship between motor and cognitive deficits at 1 year of age and the severity of acidosis observed at birth in asphyxiated and symptomatic neonates has been described. The extent of these sequelae is dependent not only on the occurrence of asphyxia but also on its duration. The 3 stages of HIE also correlate with outcome at 1 year of age. Those neonates with mild (stage 1) HIE or those who demonstrate moderate (stage 2) HIE for less than 5 days usually develop normally. Persistence of moderate encephalopathy or appearance of severe (stage 3) HIE is associated with seizures and motor and cognitive delay during follow-up. Children with mild HIE as neonates tend to be free of handicap in motor, cognitive, and school performance. Greater impairment of performance in each of these developmental spheres is found among children who exhibited moderate or severe neonatal HIE.

The likelihood of long-term neurologic sequelae after HIE is increased by the presence of neonatal seizures. The EEG may provide valuable prognostic information after the occurrence of seizure. Interictal background abnormalities, such as a burst-suppression pattern, persistently low voltage, and electrocerebral inactivity, are highly correlated with poor outcome. Conversely, infants with normal EEGs or those revealing only maturational delay have much more favorable prognoses.

Neuroimaging is useful in determination of prognosis. Head ultrasonography has shown that severe periventricular intraparenchymal echodensities followed by evidence of tissue injury (cyst formation) are correlated with later motor and cognitive deficits in premature infants. MRI performed early in the neonatal course of hypoxic-ischemic brain injury provides useful prognostic information. Most infants with MRI evidence of basal ganglia "hemorrhage," periventricular leukomalacia, or multicystic encephalomalacia after asphyxia ultimately demonstrate neurodevelopmental abnormalities. Diffusion-weighted imaging (DWI) reveals evidence of neonatal brain injury earlier than T1 and T2 weighted pulse sequences. Indeed, DWI reveals focal injury when standard MRI and CT are normal (Fig. 29.7).

Brain malformations. Brain malformation can arise as a result of a chromosomal disorder, as a component of a multiple malformation syndrome, or as an isolated abnormality. When associated with a chromosomal disorder or multiple malformation syndromes, the other associated features are the primary clues to diagnosis. In isolated brain malformation, the primary features are microcephaly (in most cases)

and cognitive and motor developmental impairment. The MRI scan can detect abnormalities of development of the hemispheric structures (agenesis of the corpus callosum, holoprosencephaly), abnormalities of cortical cellular migration (lissencephaly, pachygyria), and cerebral heterotopias as well as brainstem and cerebellar malformations (e.g., Joubert syndrome).

Uncommon Disorders

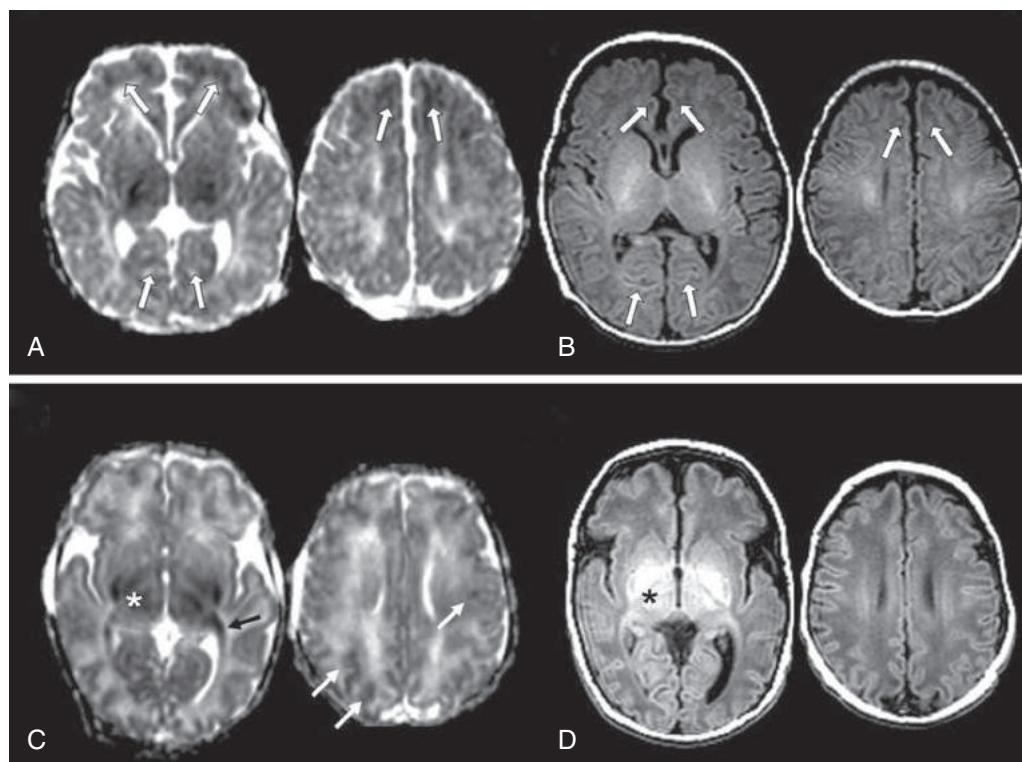
Progressive encephalopathies of infancy. Progressive encephalopathies of infancy account for a small number of children with persistent hypotonia (see Chapter 24). These disorders are recognizable by a progressive deterioration of neurologic function and by diagnostically specific clues. The infant's development is normal for some time and then plateaus; this is followed by developmental regression with loss of previously acquired skills. Hypotonia is a feature of many of these disorders, at least at some point during the course of the illness. Some disorders feature hypotonia as the result of the combination of CNS injury and an associated polyneuropathy (Krabbe disease and metachromatic leukodystrophy). Progressive disorders that may be associated with hypotonia include neonatal adrenoleukodystrophy, mannosidosis, fucosidosis, Gaucher disease types 2 and 3, GM_1 gangliosidosis, infantile neuroaxonal dystrophy, infantile Refsum disease, Krabbe disease, metachromatic leukodystrophy, mucolipidosis type IV, and Tay–Sachs disease. The diagnosis of these disorders is based on recognition of clinically suggestive clues and on results of specialized biochemical and molecular genetic testing. If such a disorder is


FIGURE 29.7 *A* and *C,* Predominant patterns of brain injury in newborns with hypoxic-ischemic brain injury. These apparent diffusion coefficient maps performed on day 3 of life and (*B* and *D*) T1 weighted images performed on day 10 of life are typical of the 2 major predominant patterns of brain injury seen in term newborns with hypoxic-ischemic encephalopathy. *A,* In the "watershed" pattern, areas of restricted diffusion are seen in the parasagittal regions *(arrows). B,* One week later, very subtle hyperintensities can be seen in the same areas on the T1 weighted images *(arrows). C,* In the "basal nuclei" predominant pattern, the areas that show restricted diffusion are the thalami and basal ganglia *(white star)* bilaterally. In this example, part of the optic radiation is also affected *(black arrow). D,* On day 10, the injury in the thalami and basal ganglia *(black star)* appears as T1 hyperintensities bilaterally.

suspected, the infant should be referred to appropriate genetic and neurologic specialists.

Mitochondrial diseases. Mitochondrial diseases often affect both the brain and muscle and clinically manifest as hypotonia, probably as a combination of both cerebral dysfunction and myopathy (Tables 29.10 and 29.11). The diagnosis is based on recognition of clinical symptoms, presence of lactic acidosis, presence of ragged red fibers on muscle histologic examination, and mitochondrial abnormalities identifiable on a muscle electron microscopic examination (Fig. 29.8). The diagnosis of many mitochondrial diseases is possible by specific mitochondrial DNA testing. Other inborn errors of metabolism may produce hypotonia by central mechanisms (organic acidurias, hyperammonemia) or by interfering with muscle metabolism (Table 29.12).

Brain malformation syndromes. **Miller–Dieker syndrome** is characterized by severe **lissencephaly** ("smooth brain" with agyria), severe developmental impairment, hypotonia early in life, and hypertonia with age. The facial changes include bitemporal hollowing, upturned nares, thin vermilion border, and small jaw. Fluorescence in situ

---

TABLE 29.10 Clinical Spectrum of Mitochondrial Disease

Nervous System
- Hypotonia
- Failure to thrive
- Motor regression
- Stroke (nonvascular)
- Dementia
- Episodic encephalopathy (elevated cerebrospinal fluid lactate)
- Intellectual disability
- Neuropathy (axonal, demyelinating, or sensory ganglionopathy)
- Ophthalmoparesis (slowly progressive)
- Ptosis (slowly progressive; little diurnal variation; asymmetric at onset)
- Optic atrophy
- Retinitis pigmentosa (perimacular; vision usually spared)
- Ataxia
- Central apnea
- Epilepsy (focal or multifocal myoclonus; status epilepticus; triggered by sodium valproate)
- Migraines
- Sensorineural hearing loss (asymmetric; young onset; partial recovery possible)

Heart
- Cardiomyopathy
- Conduction block or arrhythmia

Skeletal Muscle
- Myopathy (proximal, symmetric weakness; myalgia)
- Exercise intolerance
- Episodic rhabdomyolysis

Other
- Lactic acidosis
- Recurrent bowel obstruction (pseudoobstruction)
- Short stature
- Diabetes (young onset; nonobese)

---

hybridization–detectable microdeletions of 17p13.3 in the *PAFAH1B1* and *YWHAE* genes cause 80% of de novo mutations, whereas the remaining 20% are inherited from a parent with a balanced chromosomal rearrangement.

Muscle-eye-brain diseases (**MEB**) are an expanding category of congenital muscular dystrophies with eye abnormalities and an assortment of brain malformations including cobblestone lissencephaly type II, focal pachygyria, polymicrogyria, pontocerebellar hypoplasia, and occipital encephalocele. These diseases are characterized by hypotonia in infancy due to a concomitant muscular dystrophy and CNS disease and variable degrees of intellectual disability. **Walker–Warburg syndrome** is the most severe form of MEB, usually resulting with early demise. Genes associated with MEB are increasing rapidly: *POMT1*, *POMT2*, *POMGnT1*, *FKTN*, *FKRP*, *LARGE*, *ISPD*, *GTDC2*, *B3GALNT2*, *B3GNT1*, *TMEM5*, *POMK*, *DPM1*, *DPM2*, *DPM3*, *DOLK*, *GMPPB*, and *DAG1*.

HYPOTONIC OLDER CHILD

◆ Clinical Evaluation

Posture and Strength

Observation of the child's spontaneous posture may suggest the presence of weakness. Muscle strength can be observed as the child performs functional tasks, including pulling to sit spontaneously from a prone position, arising to stand from a sitting or lying position, standing on 1 leg independently, hopping, walking, running, and climbing stairs. The **wheelbarrow maneuver** can be used to functionally assess strength in the upper extremities. In the child older than 5 years, manual muscle testing can be performed if the child is cooperative (see Table 29.5). The examiner evaluates each muscle group independently, comparing the child's muscle strength in resistance to the examiner's strength. The child with muscle weakness has difficulty performing motor tasks and may exhibit unusual postures (lordosis) or toe walking, and on manual muscle testing, may be easily overcome by the examiner's strength.

Passive Tone

Passive muscle tone is more consistent during the waking hours in the child than in the infant. The major joints should be moved through their range of motion and the extent of resistance noted. Flapping the distal extremities provides a useful clue. Briskly lifting the lower extremity at the knee while the patient lies supine is a useful test of muscle tone. In the normal child, the foot briefly drags along the examination table and then rises with the leg. In the hypertonic child, the leg remains extended stiffly at the knee. In the hypotonic child, the lower leg hangs limply and the foot drags as the knee is raised.

Joint Extensibility

The hypotonic child demonstrates hyperextensibility of joints, especially at the elbows, wrists, knees, and ankles. Examination of the small muscles of the fingers may also be helpful (Fig. 29.9).

◆ Diagnostic Approach

The diagnosis of a particular neurologic disorder depends on the location of the lesion (i.e., which part of the nervous system is impaired or abnormal), the patient's age, and whether the condition is progressive or static (see Tables 29.1 to 29.3). Fig. 29.10 outlines an algorithm for determining the cause of muscle weakness in a child.

Anatomic Localization

The initial approach is to identify the location of dysfunction along the axis of the nervous system. Disorders of the cerebral cortex

TABLE 29.11 Select Mitochondrial Disorders with Hypotonia Classified by Clinical Phenotype and Genotype

Clinical Phenotype	Associated Mutations	Mode of Inheritance	Common Clinical Features
MELAS syndrome (mitochondrial encephalopathy, lactic acidosis, and strokelike episodes)	tRNA point mutations: • m.3243A>G in tRNA^{Leu} (~80% of cases) • m.3217T>C in tRNA^{Leu} (~7.5% of cases) • m.13513G>A encoding NADH-ubiquinone (<15% of cases) • m.3252A>G in tRNA^{Leu} (<5% of cases) • Multiple other mtDNA point mutations	Maternal	• Cardinal—strokelike episodes, intermittent encephalopathy, T2/FLAIR abnormalities on brain MRI that do not respect vascular territory, lactic acidosis • Other—hearing loss, diabetes, short stature, gastrointestinal issues
MERRF syndrome (myoclonic epilepsy with ragged red fibers)	tRNA point mutations: • m.8344A>G in tRNA^{Lys} (>80% of cases) • m.8356T>C in tRNA^{Lys} • m.8363G>A in tRNA^{Lys} • m.8361G>A in tRNA^{Lys} • Multiple other mtDNA point mutations	Maternal	• Cardinal—myoclonus, proximal weakness, generalized epilepsy, ataxia • Other—multiple lipomatosis, hearing loss, cognitive impairment, neuropathy
KSS (Kearns–Sayre syndrome)	Single large mtDNA deletion (1.1-10-kb) • m.8470_13446del4977 (deletion of 4977 base pairs; most common) • Multiple other mtDNA deletions	Sporadic	• Cardinal—multisystemic disease with progressive external ophthalmoplegia, pigmentary retinopathy, cardiomyopathy before age 20 yr • Other—short stature, proximal muscle weakness, hearing loss, dementia, ataxia, multiple endocrinopathies (diabetes, hypothyroidism, hypoparathyroidism, hypogonadism
CPEO (chronic progressive external ophthalmoplegia)	Single large mtDNA deletion (1.1-10 kb) • m.3243A>G in tRNA^{Leu} (most common; same as MELAS) • Multiple other mtDNA point mutations • Multiple mtDNA deletions caused by mutations in the following nuclear genes: *SLC25A4* encoding ANT1, *C10orf2* encoding twinkle, *POLG1* encoding mtDNA polymerase, *POLG2, OPA1*	Sporadic Maternal Autosomal dominant	• Cardinal—skeletal muscle disorder with ptosis, ophthalmoparesis, +/− proximal muscle weakness
Leigh syndrome (subacute necrotizing encephalomyelopathy)	mtDNA mutations: • m.8993T>G or m.8993T>C in *MT-ATP6* (~10% of cases) • Multiple other mtDNA point mutations • m.8470_13446del4977 (deletion of 4977 base pairs; also seen in KSS) Nuclear gene mutations resulting in respiratory chain complex deficiencies: • Complex I: *NDUFV1, NDUFS1, NDUFS2, NDUFS3, NDUFS4, NDUFS7, NDUFS8, NDUFA1, NDUFA2, NDUFA10, NDUFA9, NDUFA12, NDUFAF2, NDUFAF5, NDUFAF6, FOXRED1* • Complex II: *SDHA, SDHAF1* • Complex III: *BCS1L, UQCRQ, TTC19* • Complex IV: *SURF1, COX10, COX15, SCO2, NDUFA4, PET100, LRPPRC*	Maternal Sporadic Autosomal recessive	• Hypotonia, spasticity, movement disorders (chorea), cerebellar ataxia, neuropathy, bilateral basal ganglia lesions, seizures, lactic acidosis, psychomotor retardation/regression especially with illness between 3-12 mo of age • Hypertrophic cardiomyopathy
NARP (neurogenic muscle weakness, ataxia, retinitis pigmentosa)	• m.8993T>G or m.8993T>C in *MT-ATP6* (50% of cases)	Maternal	• Proximal neurogenic muscle weakness, sensory neuropathy, seizures, ataxia, pigmentary retinopathy, learning difficulties, dementia with onset usually in childhood
Mitochondrial DNA depletion syndrome	• Homozygous or compound heterozygous mutations in *TK2* (thymidine kinase 2), a mitochondrial deoxyribonuclease, resulting in mitochondrial depletion	Autosomal recessive	• Hypotonia, proximal muscle weakness, axial weakness, respiratory insufficiency, marked clinical variability with death in infancy to early adulthood due to respiratory insufficiency

FLAIR, fluid-attenuated inversion recovery; GI, gastrointestinal; MRI, magnetic resonance imaging; mtDNA, mitochondrial DNA; NADH, nicotinamide adenine dinucleotide, reduced form; tRNA, transfer RNA.

TABLE 29.12 Metabolic Diseases That Affect Muscle

Name(s)	Enzyme Deficiency	Clinical Features	Diagnostic Testing
Glycogen storage disease type II (Pompe disease)	α-1,4-Glucosidase (GAA enzyme)	• Infantile-onset Pompe—poor feeding, motor delay and hypotonia with weakness, respiratory difficulties, cardiac issues (short P-R interval with wide QRS complex, cardiomegaly, LV outflow obstruction, cardiomyopathy) • Late-onset Pompe—limb-girdle pattern of weakness, respiratory insufficiency without clinical heart disease • GAA enzyme replacement therapy available	• Measure α-glucosidase (GAA) enzyme activity on dried blood spot to screen • Confirm via *GAA* gene sequencing demonstrating biallelic mutations for definitive diagnosis • Baseline elevated CK (~10× normal) in infantile-onset form; baseline CK may be normal in adult-onset form • Muscle biopsy may show vacuoles (lysosomes) and glycogen accumulation with positively staining PAS; 20–30% of patients with adult-onset form may not show specific changes on biopsy
Glycogen storage disease type IIIa (Debrancher deficiency, Cori disease, Forbes disease)	Amylo-1,6-glucosidase	• Ketotic hypoglycemia, hepatomegaly, hyperlipidemia, elevated liver enzymes, cardiomyopathy in childhood, limb-girdle pattern of weakness in 20s–30s	• Baseline elevated CK (2–20× normal) • Triglycerides, cholesterol, and liver enzymes are elevated • *AGL* gene sequencing demonstrating biallelic mutations for definitive diagnosis
Glycogen storage disease type IV (Brancher deficiency, Andersen disease)	Glycogen branching enzyme (GBE)	• Fatal perinatal neuromuscular subtype—fetal akinesia, polyhydramnios, fetal hydrops • Congenital neuromuscular subtype—hypotonic newborn, respiratory distress, dilated cardiomyopathy, death in infancy • Childhood neuromuscular subtype—chronic progressive myopathy, dilated cardiomyopathy	• Demonstrate deficiency of GBE in the liver, muscle, or skin fibroblasts • *GBE1* gene sequencing demonstrating biallelic mutations for definitive diagnosis
Glycogen storage disease type V (McArdle disease)	Myophosphorylase	• Exercise-induced muscle cramps and pain, especially early in exercise, that improve with rest or lower intensity ("2nd-wind phenomenon") • Recurrent myoglobinuria +/− rhabdomyolysis	• Baseline elevated CK (>5× normal) • *PYGM* gene sequencing demonstrating biallelic mutations for definitive diagnosis • Quantitative or qualitative (stain) on muscle biopsy shows virtual absence of enzyme activity • Subsarcolemmal glycogen accumulation on muscle biopsy on LM (either PAS-positive or vacuoles on H&E) and EM
Glycogen storage disease type VII (Tarui disease)	Phosphofructokinase	• Classical form—muscle aching, cramping, exercise intolerance, myoglobinuria, nausea/vomiting after intense exercise, starting in childhood; hemolytic anemia • Late-onset form—cramps, myalgia, mild proximal weakness in adulthood • Infantile form—hypotonia, arthrogryposis, intellectual disability, fatal in infancy	• Baseline elevated CK • *PFK* gene sequencing demonstrating biallelic mutations for definitive diagnosis
Glycogen storage disease VIII (phosphorylase kinase [PhK] deficiency)	Phosphorylase b kinase Phosphorylase a1 kinase	• Exercise intolerance, cramps, myoglobinuria, progressive muscle weakness in childhood to adulthood • Hepatomegaly, growth retardation, fasting ketosis and hypoglycemia • Same as above but X-linked and very rare	• Baseline elevated CK • PhK enzyme activity reduced in muscle • *PHKA1* gene sequencing or/and *PHKB* gene sequencing demonstrating biallelic mutations for definitive diagnosis
Glycogen storage disease IX (phosphoglycerate kinase deficiency)	Phosphoglycerate kinase	• Myopathic form—muscle weakness, pain, cramping, especially with exercise with myoglobinuria +/− rhabdomyolysis	• Baseline mildly elevated CK • *PGK1* gene sequencing demonstrating biallelic mutations for definitive diagnosis
Glycogen storage disease X (Phosphoglycerate mutase deficiency)	Phosphoglycerate mutase	• Strenuous exercise intolerance, cramps, myoglobinuria	• Baseline mildly elevated CK • *PGAM2* gene sequencing demonstrating biallelic mutations for definitive diagnosis
Glycogen storage disease XI (lactate dehydrogenase deficiency)	Lactate dehydrogenase	• Exercise intolerance, cramping, recurrent myoglobinuria	• Normal CK between attacks • *LDHA* gene sequencing demonstrating biallelic mutations for definitive diagnosis

TABLE 29.12 Metabolic Diseases That Affect Muscle—cont'd

Name(s)	Enzyme Deficiency	Clinical Features	Diagnostic Testing
Systemic primary carnitine deficiency	Solute carrier family 22 (sodium-dependent carnitine transporter)	• Childhood myopathic form—hypotonia, dilated cardiomyopathy that could result in death, proximal muscle weakness in early childhood (2–4 yr) • Adult form—fatigability	• Baseline CK elevated • Reduced plasma carnitine levels • Increased lipid deposition on muscle biopsy • *SLC22A5* gene sequencing demonstrating biallelic mutations for definitive diagnosis
Carnitine palmitoyltransferase II deficiency	Carnitine palmitoyltransferase II (CPT II)	• Myopathic form—recurrent myalgia and myoglobinuria after prolonged exercise, cold, or fasting; weakness during attacks; onset from childhood to adulthood • Severe infantile form—liver failure, cardiomyopathy, seizures, hypoketotic hypoglycemia, myopathy before 1 yr of age (rare)	• Normal CK between attacks • CPT II gene sequencing demonstrating biallelic mutations for definitive diagnosis • Muscle biopsy can be normal

CK, creatine kinase; EM, electron microscopy; H&E, hematoxylin and eosin; LM, light microscopy; LV, left ventricular; PAS, periodic acid–Schiff.

FIGURE 29.9 Hyperlaxity at the distal interphalangeal joints in a 9-year-old girl with a congenital myopathy.

commonly cause hypotonia in infants and children. Some progressive neurologic disorders affect both the brain and peripheral nerves (metachromatic, Krabbe disease, adrenoleukodystrophies, and some mitochondrial disorders). Other progressive disorders may affect both brain and muscle (MEB, neonatal myotonic dystrophy, and some mitochondrial disorders).

Sometimes disturbance of function at one site conveys a predilection for injury to another site in the nervous system. Children with congenital muscle weakness (congenital myopathy) are likely to have had severe respiratory impairment at birth that resulted in secondary anoxic injury to the brain. Because hypotonia is nonspecific with regard to localizing the site of nervous system dysfunction, the evaluation of the child with hypotonia must begin with a search for other clues that might identify the location of the abnormality.

Is the Problem a Systemic Disorder?

Systemic disorders are a common cause of generalized hypotonia in infants and even in toddlers and children (see Table 29.1). Hypotonia is commonly seen in association with sepsis and other infections, heart failure, failure to thrive, hypercalcemia, renal failure, hypothyroidism, acidosis, hypoxia, hyperammonemia, hypoglycemia, rickets, scurvy, amino and organic acid disorders, severe malnutrition, and other chronic disorders. This observation warrants a careful search for a systemic or metabolic abnormality in children with hypotonia, particularly (but not exclusively) when the onset of hypotonia is acute (Fig. 29.11). Most of these disorders cause hypotonia by causing a disturbance of cerebral cortex function.

Frequently overlooked causes of hypotonia are those that are not traditionally considered neurologic disorders. **Connective tissue disorders** often produce a clinical picture similar to those of neurologic causes of hypotonia in infancy and early childhood, with associated delay of developmental milestones with joint hyperextensibility disproportionate to the extent of weakness and in the absence of other neurologic abnormalities or microcephaly (velocardiofacial syndrome, achondroplasia, Marfan syndrome, Ehlers–Danlos syndrome). In several congenital disorders, hypotonia is a regular feature as a result of a combination of abnormalities of neurologic, muscle, and connective tissue function, including Sotos syndrome, Prader-Willi syndrome, Angelman syndrome, Noonan syndrome, Rett syndrome, and Smith–Lemli–Opitz syndrome.

Diagnostic Considerations

Any child with hypotonia and weakness should be evaluated for a systemic disorder. Laboratory evaluation, such as electrolyte measurements, renal function tests, thyroid function tests, and acid-base balance assessment, should be considered. Laboratory evaluation should also be considered for uncommon metabolic disorders in children with chronic hypotonia, especially those with other neurologic findings and those with recurrent bouts of lethargy, episodic severe hypotonia, vomiting, or acidosis. Appropriate metabolic screening tests include plasma and urine amino acid quantification, urine organic acid quantification, and measurements of blood ammonia, blood lactate, and pyruvate.

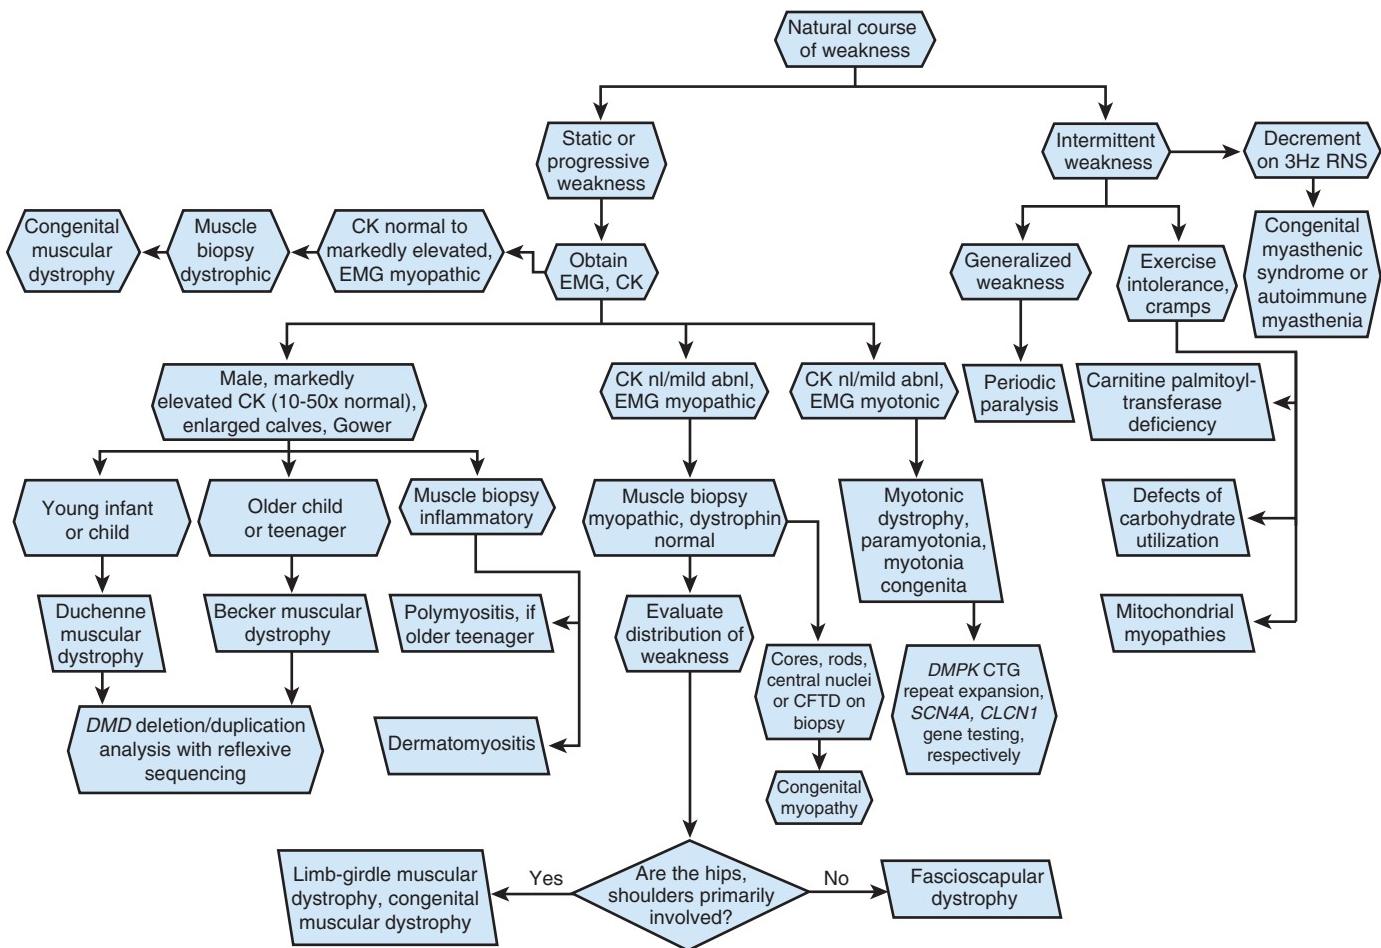
Karyotyping and a chromosomal microarray should be done for any hypotonic child who additionally demonstrates microcephaly,


FIGURE 29.10 Diagnostic approach to the child with muscle disease. abnl, abnormal; CFTD, congenital fiber type disproportion; CK, creatine kinase; CTG, cytosine-thymine-guanine; DMD, Duchenne muscular dystrophy; EMG, electromyography; nl, normal; RNS, repetitive nerve stimulation.

growth retardation, congenital malformations, dysmorphism, global developmental delay, or features of specific disorders (Down or Prader–Willi syndromes).

If unusual neurologic or dysmorphic features are present, specific disorders, such as Rett syndrome, Angelman syndrome, Prader–Willi syndrome, Noonan syndrome, Sotos syndrome, and fragile X syndrome, must be considered.

Common Disorders

Down syndrome. The child with Down syndrome generally has recognizable features, including microcephaly, up-slanted palpebral fissures, epicanthal folds, flat nasal bridge, protuberant tongue, excess posterior nuchal skin, and simian palmar creases (see Chapter 25). Hypotonia and associated weakness are almost constant findings. As the child grows, the muscle strength generally improves, but the hypotonia persists.

The diagnosis is established by karyotype analysis showing trisomy 21.

Prader–Willi syndrome. Prader–Willi syndrome manifests in early infancy with marked hypotonia and virtually no other identifiable symptoms. As the child grows, the phenotypic features become more apparent, including microbrachycephaly, almond-shaped palpebrae, short stature, and small hands and feet. At 3-6 years of age, the child has a disorder of appetite that results in ravenous food-seeking behaviors, impaired satiety, and eventual marked obesity. Weakness associated with the disorder is most prominent in the

neonate and older infant and gradually lessens, whereas the hypotonia persists.

DNA methylation analysis (detects >99% of cases) is the only technique that accounts for paternal deletion, maternal uniparental disomy, and imprinting defect. Seventy to 75% of affected children have deletion of chromosome 15q11-q13 of paternal origin, and 20-25% have maternal disomy. Because the clinical findings are nonspecific during the early months, such testing should be performed in any neonate or infant with hypotonia of unknown cause.

Uncommon Disorders

Metabolic disorders. Metabolic disorders that are associated with hypotonia include the following (see Tables 29.1, 29.11, and 29.12):
- Amino acid and organic acid disorders
- Lowe syndrome
- Peroxisomal disorders (infantile Refsum syndrome, infantile adrenoleukodystrophy, Zellweger syndrome)
- Acyl coenzyme A dehydrogenase deficiencies
- Storage disorders (mannosidosis, Krabbe disease, sialuria, mucolipidosis type IV, Tay–Sachs disease)

Neurologic disorders. Neurologic disorders associated with hypotonia are often recognizable by unusual neurologic features:
- Angelman syndrome: awkward gait, inappropriate laughter, and seizures. DNA methylation analysis reveals that ~80% have abnormal methylation in the maternally inherited 15q11.2-q13 locus, the same chromosome that is affected in Prader–Willi syndrome.

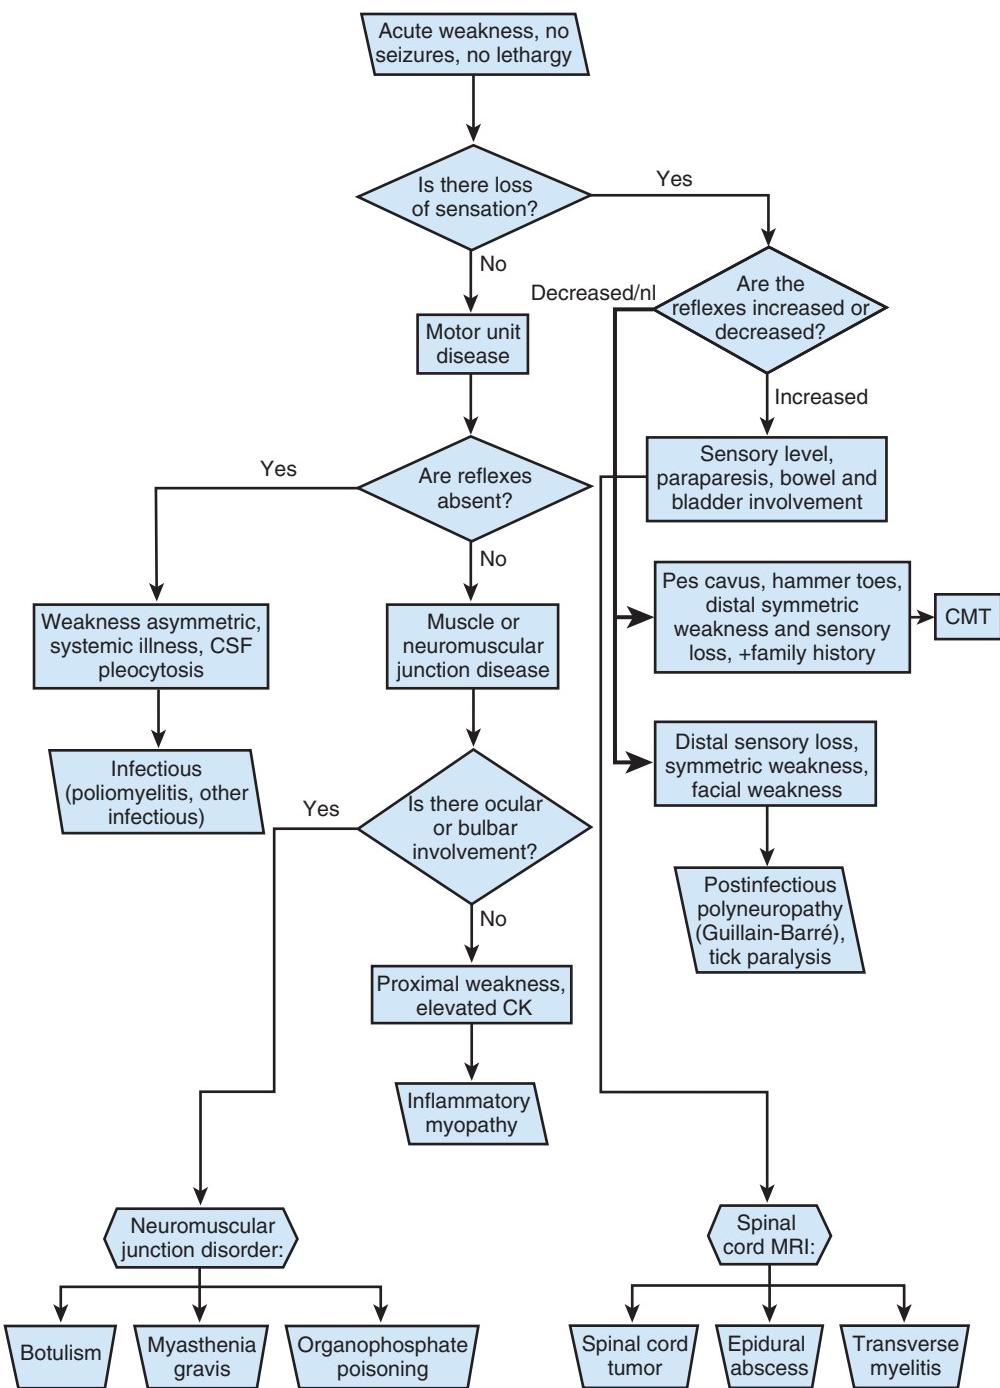
(See *Nelson Textbook of Pediatrics,* p. 610.)


FIGURE 29.11 Diagnostic approach to the child with acute weakness. CSF, cerebrospinal fluid; CK, creatine kinase; MRI, magnetic resonance imaging; nl, normal; CMT, Charcot–Marie–Tooth disease.

- Rett syndrome: autism, loss of hand use, characteristic wringing hand movements

  Congenital malformation syndromes. Congenital malformation syndromes are recognizable by their characteristic features:
- Sotos syndrome: macrocephaly, macrosomia, down-slanted palpebrae, mild ventriculomegaly
- Noonan syndrome: short stature, down-slanted palpebrae, ear abnormalities, congenital heart disease, wide-spaced nipples and shield chest, pectus deformities
- Lowe syndrome: cataracts, aminoaciduria, hypotonia

Connective tissue disorders. Connective tissue disorders associated with hypotonia, and particularly with joint hyperextensibility, can also generally be recognized by their associated symptoms:
- Stickler syndrome: micrognathia, Pierre Robin cleft palate
- Velocardiofacial syndrome: congenital heart disease, micrognathia, hypocalcemia, T cell disorders, cleft palate
- Achondroplasia: disproportionate short stature, risk of brainstem compression
- Ehlers–Danlos syndrome: skin bruising and scarring, skin hyperelasticity, smooth skin, joint hypermobility

- Marfan syndrome: tall stature, long, thin arms and fingers, ectopic lens, blue sclera, aortic dissection, mitral valve prolapse
- Osteogenesis imperfecta: fractures

Is the Problem in the Cerebrum or Cerebellum?

Several clues suggest that hypotonia is caused by an abnormality of cerebral function. The presence of associated symptoms attributable to dysfunction of the cerebral cortex is the most useful:

- Acute impairment of consciousness
- Acute or chronic impairment of cognitive abilities (mental status examination or poor school grades, respectively)
- Seizures

Delayed language and social development are typical of chronic problems. The presence of microcephaly or macrocephaly is also an important clue. The presence of brisk reflexes, clonus, an asymmetric tonic neck response, and the Babinski sign suggests possible cerebral cortical dysfunction. The presence of dysmorphism or of congenital malformations suggests the possibility of a cerebral malformation. Congenital ocular malformations (e.g., microphthalmia or optic hypoplasia) are frequently associated with congenital brain malformation.

The presence of hypertonia mixed with signs of hypotonia strongly suggests a cerebral origin. This may seem paradoxical, but it is often overlooked that many children with cerebral causes of hypotonia have signs of hypertonia as well. This may occur as an evolutionary phenomenon in the development of spasticity; cerebral palsy is often characterized by hypotonia in infancy with later development of spasticity. In some children with cerebral dysfunction, the coexistence of hypotonia and hypertonia is persistent. Thus, an infant with hypotonia of the neck and trunk musculature who also exhibits scissoring of the lower extremities or persistent fisting of the hands (typical signs of hypertonia) can be presumed to have cerebral dysfunction.

Signs of cerebellar dysfunction (ataxia, nystagmus, titubation, dysmetria, and impairment of coordination) are often useful diagnostic clues. The cerebellum helps maintain normal muscle tone, and diseases of the cerebellum typically are associated with some degree of hypotonia.

Is the Problem in the Spinal Cord?

Classically, spinal cord dysfunction produces spastic weakness of all 4 extremities or paraparesis of the lower extremities (Tables 29.13 to 29.15). However, particularly after acute injury to the spinal cord and in some chronic disorders of the spinal cord, hypotonia may be the prominent motor sign. The typical associated findings of hyperreflexia, clonus, Babinski signs, and sensory loss (with a sensory level) are important clues, as is the disparity between the weakness and sensory impairment of the extremities in contrast to the normal strength and function of the head and neck.

Spinal cord injury resulting from birth trauma is frequently overlooked as a cause of hypotonia in the newborn. A history of a lengthy or difficult (breech or vertex) delivery should suggest spinal cord injury, and care should be taken not to falsely attribute motor dysfunction in these infants to anoxic brain injury. The bones of the cervical spine are *normal*, but MRI demonstrates the cord lesion. This diagnosis should never be missed because neurosurgical intervention is often required. To make matters more confusing, many neonates with spinal cord injuries also have anoxic encephalopathy because of the traumatic nature of the delivery.

Finally, the extent to which the hypotonia of neonatal hypoxic-ischemic injury is caused by hypoxic injury to the spinal cord has not yet been fully elucidated. Any child with suspected spinal cord injury should undergo MRI.

Common Disorders

Meningomyelocele. Meningomyelocele is a congenital malformation of the spine, spinal cord, and overlying meninges, that affects 1 in 500 to 1 in 2000 liveborn infants, with some degree of geographic variation of incidence. The spinal defect is obvious at birth, except in milder abnormalities that are covered by skin. The degree to which the lower extremities are hypotonic and flaccid depends on the location of the spinal defect. The presence of an Arnold-Chiari malformation and associated hydrocephalus must be sought in every affected patient.

TABLE 29.13	**Spinal Cord Syndromes**	
Site	**Mechanism**	**Manifestation**
Complete—upper cord (above T10)	Space-occupying lesion Trauma	Flaccid symmetric weakness, paralysis, loss of sensation below lesion, areflexia (in spinal shock), reflexes return and are ↑ after recovery from spinal shock, distended bladder, positive Babinski sign, positive Beevor sign*
Conus medullaris (T10–L2)	Space-occupying lesion Trauma	Symmetric weakness, paralysis, ↑ knee deep tendon reflexes, ↑ ankle deep tendon reflexes, positive Babinski sign, spastic bladder and sphincter disturbance
Cauda equina (below L2)	Space-occupying lesion Tethered cord (?) Trauma	Asymmetric weakness, loss of lower extremity deep tendon reflexes, sensory saddle perineum sensory loss, no Babinski sign, distended atonic bladder with urinary retention and overflow incontinence and decreased rectal tone
Anterior cord	Flexion-rotation force from anterior dislocation or compression fracture of vertebral body (+/− ischemia of anterior spinal artery)	Weakness and reduced pain and temperature sensation
Central cord	Hyperextension injury; tumor, hemorrhage, syringomyelia	Flaccid weakness of arms (lower motor neuron lesion) with strong and spastic lower extremities (upper motor neuron lesion) Sacral sensation with bowel and bladder partially affected
Posterior cord	Hyperextension (fractures of posterior vertebra)	Significant ataxia (loss of proprioception); strength and pain and temperature sensations may be spared or less affected
Brown-Séquard syndrome	Laceration (stabs), lateral space-occupying lesions: hemisection	Strength, position, and vibration sensations are affected on the side of the lesion; pain and temperature sensation are affected on the contralateral side

*Beevor sign, superior displacement of umbilicus in paraplegia during attempts to lift shoulders off an examining table.

Modified from Piña-Garza. *Fenichel's Clinical Pediatric Neurology: A Signs and Symptoms Approach*. 7th ed. Philadelphia: Saunders; 2013.

Patients with meningomyelocele have elevated amniotic fluid α-fetoprotein, and antenatal diagnosis is possible.

Transverse myelitis. Transverse myelitis is a common cause of acute hypotonia and weakness. As with any spinal cord lesion, the localization is suggested by an identifiable motor-sensory level and by impairment of bowel and bladder function. Reflexes are characteristically depressed at the onset of the disease and then become exaggerated with clonus and Babinski signs. The diagnosis is made with MRI and lumbar puncture; signal intensity of the cord segment involved is abnormal on MRI, and mild pleocytosis and elevated cerebrospinal fluid protein levels are present.

Uncommon Disorders

An **epidural spinal abscess** may manifest in a manner similar to transverse myelitis, except with more back pain and local tenderness. **Spinal cord tumor** (primary or metastatic) usually manifests with subacute onset of spastic weakness of the extremities but occasionally manifests

TABLE 29.15 Motor Involvement in Spinal Cord Lesions

Affected Cord Segment	Motor Involvement
C1–C4	Paralysis of neck, diaphragm, intercostal muscles, and all 4 extremities
C5	Spastic paralysis of trunk, arms, and legs; partial shoulder control
C6–C7	Spastic paralysis of trunk and legs; upper arm control; partial lower arm control
C8	Spastic paralysis of trunk and legs; hand weakness only
T1–T10	Spastic paralysis of trunk and legs
T11–T12	Spastic paralysis of legs
L1–S1	Flaccid paralysis of legs
S2–S5	Flaccid paralysis of lower legs; bowel, bladder, and sexual function affected

From Swartz MH. *Textbook of Physical Diagnosis: History and Examination*. 2nd ed. Philadelphia: WB Saunders; 1994:496; modified from Fenichel GM. *Clinical Pediatric Neurology: A Signs and Symptoms Approach.* 2nd ed. Philadelphia: WB Saunders; 1993:262.

as hypotonia (see Table 29.13). Rapid diagnosis with MRI and medical or neurosurgical intervention is essential.

Is the Problem in the Motor Unit?

The functional unit of the anterior horn cell, peripheral nerve, NMJ, and muscle fiber makes up the motor unit. Disorders that affect the motor unit produce a common clinical picture characterized by preservation of cognitive function and alertness, absence of seizures, characteristically diminished or absent muscle stretch reflexes, and hypotonia. **Muscle atrophy** is frequently associated with motor unit disorders, but it can also occur in cerebral causes of hypotonia.

It is not always easy to determine which component of the motor unit is abnormal (anterior horn cell, peripheral nerve, NMJ, or muscle), but the following guidelines are useful.

Anterior horn cell disease is suggested by hypotonia, weakness, absence of reflexes, and fasciculations. The presence of **fasciculations** of muscle usually cannot be appreciated in infants because of the presence of subcutaneous fat. Fasciculations might be seen on the tongue, but they must be distinguished from normal quivering movements. Muscle enzymes are usually normal but can sometimes be mildly to moderately elevated, and nerve conduction studies are usually normal (Table 29.16). The electromyogram (EMG) may demonstrate fibrillations and large motor unit potentials that are reduced in number.

Diagnostic Considerations

The patient is examined for distribution of weakness, reflexes, and the presence of tongue fasciculations. Creatine kinase (CK) levels and an EMG are obtained, and a lumbar puncture is performed when an acute infectious polyradiculoneuritis is suspected.

Common Disorders

Anterior horn cell disease. Spinal muscular atrophy (SMA) is characterized by degeneration of anterior horn cells in the spinal cord (Table 29.17). SMA type I (Werdnig–Hoffman disease) is the prototype for the spinal muscular atrophies and is inherited as an autosomal recessive trait. Manifestations begin early in life and even occasionally

TABLE 29.16	**Typical Electrophysiologic Features of Nerve and Muscle Diseases**				
	Motor Nerve Conductions	**Sensory Nerve Conductions**	**F Response**	**H Reflex**	**Needle Electromyography**
Myopathy (dystrophic, inflammatory)	Normal	Normal	Normal	Normal	• Spontaneous activity: fibrillation potentials and positive sharp waves (muscle membrane irritability) • Volitional activity: small-amplitude myopathic units
Myopathic (mitochondrial, congenital myopathy)	Normal	Normal	Normal	Normal	• Spontaneous activity: usually none • Volitional activity: small-amplitude, short-duration units with rapid recruitment
Axonal neuropathy	• ↓ Amplitude • Normal or mildly slow conduction velocities	↓ Amplitude	Normal	Normal	• Spontaneous activity: fibrillation potentials and positive sharp waves (muscle membrane irritability) especially in distal muscles • Volitional activity: large-amplitude, long-duration units with reduced recruitment
Demyelinating neuropathy	• Markedly slow conduction velocities • Prolonged latencies • ↓ or normal amplitude	• Prolonged latencies • ↓ Amplitude or no response	Delayed or absent	Delayed or absent	• Spontaneous activity: usually none • Volitional activity: large-amplitude, long-duration units with reduced recruitment
Radiculopathy	Normal or ↓ amplitude	Normal	Delayed or absent	Delayed or absent if S1 is involved	• Spontaneous activity: fibrillation potentials and positive sharp waves (muscle membrane irritability); fasciculations • Volitional activity: large-amplitude, long-duration units with reduced recruitment
Motor neuron disease	Normal or ↓ amplitude	Normal	Normal	Normal	• Spontaneous activity: fibrillation potentials and positive sharp waves (muscle membrane irritability); fasciculations • Volitional activity: large-amplitude, long-duration units with reduced recruitment

in the prenatal period (e.g., decreased fetal movements, congenital contractures, polyhydramnios caused by poor swallowing, poor respiratory effort at birth). Neonates and young infants experience progressive weakness and hypotonia, which result in poor head and body control and a flaccid, motionless, extended posture with alert facies (see Fig. 29.4). Fasciculations may be noted in the tongue, over muscles with little subcutaneous fat, and as a fine tremor of the outstretched fingers. Bilateral paralysis of the diaphragm may be present before loss of deep tendon reflexes or detection of muscle weakness.

Genetic analysis shows that 95-98% of individuals have a homozygous deletion of survival motor neuron 1 (*SMN1*) gene, but 2-5% are compound heterozygotes for a deletion coupled with a point mutation in *SMN1*. If *SMN1* mutations are confirmed, then a reflexive *SMN2* copy number analysis should be performed to help prognosticate since more copies of *SMN2* gene confer a milder phenotype (see Table 29.17). The *SMN2* gene differs from *SMN1* by 1 nucleotide base pair in exon 7 and 90% of the time expresses a nonviable gene product but 10% of the time accidentally expresses a functional *SMN1* protein. If genetic

test results are positive, no further evaluation is necessary. If mutation tests are negative, a more traditional evaluation—including serum CK levels, EMG, muscle and brain MRI, and muscle biopsy—is pursued.

Neuropathies. Neuropathies are characterized by hypotonia, weakness, and diminished or absent reflexes (Tables 29.18 and 29.19). Neuropathies may be primarily motor or sensory, and the child's symptoms may be either acute or chronic weakness or discomfort caused by paresthesias and dysesthesias. The pattern of weakness in most neuropathies is in a **distal-to-proximal gradient** with foot deformity and atrophy resulting in pes cavus and hammer toe deformities. **Pes planus** may be a common feature in a neuropathy during infancy or early childhood due to low tone with high-arched feet developing as the patient ages. In chronic sensory neuropathies, the child may sustain injuries (e.g., burns or even fractures) that are unnoticed. Autonomic symptoms associated with some neuropathies include orthostatic hypotension, gastrointestinal dysmotility, and abnormalities of sweating. In general, the reflexes in neuropathies are diminished disproportionately to the extent of muscle weakness; that is, the reflexes

TABLE 29.17	**Spinal Muscular Atrophy (SMA): Clinical and Genetic Characteristics**				
Phenotype	**Age of Onset**	**Natural Age of Death**	**Highest Motor Milestones**	**Other Findings**	***SMN2* Copy Number**
SMA 0	Prenatal	2–6 mo	None achieved	• Arthrogryposis • Facial diplegia • Decreased fetal movements • Polyhydramnios • Breech presentation • Respiratory failure in early infancy	
SMA I (Werdnig–Hoffman)	<6 mo	Usually ≤2 yr, but may survive longer	Sitting with support	• Prominent tongue fasciculations • Mild joint contractures • Facial weakness • Poor suck and swallow • Small bell-shaped chest • Paradoxical breathing	1-2
SMA II	6–18 mo	70% alive at age 25 yr	Independent sitting when placed	• Legs more affected than arms, with failure to sit alone by 9–12 mo and stand by 1 yr • Postural hand/finger tremor • Lose ability to sit independently by mid-teens	2; sometimes 3
SMA III (Kugelberg–Welander)	>12 mo	Normal	Independent ambulation	• Legs more affected than arms, manifesting as difficulty walking • Distal then proximal contractures	≥3
SMA IV	2nd or 3rd decade	Normal	Walking during adulthood	• May lose ambulation with time	3-4

may be markedly reduced or absent, whereas the muscle strength is only mildly diminished. Nerve conduction studies (NCS) and EMGs demonstrate slowing of nerve conduction velocities and features that suggest either primary axonal involvement (fibrillations, normal or mildly slow nerve conduction velocity) or demyelination (marked slowing of nerve conduction velocity) (see Table 29.16).

Guillain–Barré syndrome (GBS) is an acute demyelinating polyneuropathy that frequently follows an upper respiratory tract infection or an illness with diarrhea, especially those caused by *Campylobacter*. The disorder is characterized by ascending motor weakness and areflexia. The weakness is usually symmetric, ascends and progresses over various periods (usually 1–2 weeks), and may cause serious respiratory compromise by producing weakness of the respiratory muscles. Therefore, all patients must be tested for respiratory function (negative inspiratory forces and vital capacity). Children complain of difficulty walking, rising from the floor, climbing stairs, and become irritable and refuse to bear weight. More commonly than adults, children present with acute-onset ataxia with multiple falls and poor balance stemming from sensory disturbance with milder weakness. Children often have more paresthesias and discomfort than their adult counterparts with neck, back, leg, and buttock pain in at least 50% of cases, presumably mimicking a radiculopathy due to nerve root inflammation. The triad of **ophthalmoplegia, areflexia, and ataxia** without overt weakness characterizes **Miller–Fisher syndrome (MFS)**, a variant of GBS. Autonomic nervous system involvement may produce hypotension or hypertension and bradyarrhythmias or tachyarrhythmias. Therefore, due to the risk of respiratory and autonomic dysfunction, all patients suspected of having GBS should be monitored in the intensive care unit or other telemetry setting with high-frequency nursing care. In addition to an abnormal nerve conduction velocity, the cerebrospinal fluid protein level is usually elevated out of proportion to the white cell count (**cytoalbuminologic dissociation**) after the 1st week of illness, indicative of an inflammatory process occurring within the CSF space. Postgadolinium enhancement of edematous nerve roots and

peripheral nerves as seen on MRI in the cervical and lumbosacral regions can be seen in ~95% of children with GBS and is suggestive, although not specific for, the disease.

Dejerine-Sottas syndrome (DSS) is an umbrella term for severe, infantile-onset Charcot–Marie–Tooth (CMT) disease regardless of inheritance pattern manifesting with hypotonia. Patients exhibit moderate-to-severe motor delays, foot deformities with pes cavus and hammer toes, claw-hand deformities, respiratory insufficiency, and early-onset scoliosis that may need surgical correction. Nerve biopsy shows axons without evidence of myelination and onion-bulb formation. Nerve dysfunction may be axonal or demyelinating and inheritance may be autosomal recessive or autosomal dominant. Mutations in the following genes are associated with the DSS phenotype: *MPZ*, *EGR2*, *PMP22*, *PRX*, *NEFL*, *MFN2*, and *GDAP1*.

Muscle and neuromuscular junction disorders. NMJ disorders must be differentiated from muscle diseases. Both are characterized by hypotonia and weakness; however, reflexes may be impaired in myopathies but are usually preserved in NMJ disorders. In myopathies, the degree of muscle weakness is usually more pronounced than the extent of loss of reflexes, just the reverse of the case observed in neuropathies. Disorders of the NMJ are identifiable by a history of diurnal fluctuations (worse symptoms later in the day) and acute episodes of worsening. In NMJ disorders and most myopathies, weakness is most prominent in the proximal muscles and the sensory examination is normal. Laboratory testing and studies performed show a normal CK level and normal motor and sensory nerve conduction velocities, but a decrementing response to 3-Hz repetitive nerve stimulation in NMJ disorders (Fig. 29.12). The needle EMG may be normal or appear myopathic if the NMJ disorder is severe, resulting in static weakness.

Myopathies. **Duchenne and Becker muscular dystrophy** (**DMD** and **BMD**) are X-linked recessive disorders caused by mutations in the *DMD* gene encoding dystrophin. DMD is characterized by the absence of dystrophin in muscle, whereas BMD has a partially functional protein product. The genetic difference between the 2 phenotypes is

based on the concept of the "reading frame rule," in which mutations that cause DMD are "out-of-frame" resulting in a premature termination of translation with subsequent degradation, while mutations that cause BMD are "in-frame" due to a partly functional, albeit truncated, protein. The distribution of DMD mutations is described in Table 29.20. Using Fig. 29.13, one can easily determine if a deletion or duplication results in an in-frame or out-of-frame mutation.

Some boys have mild delays in their motor and/or cognitive milestones, but most have normal early milestones and do not come to clinical attention until 2-5 years of age when they are noted to be

TABLE 29.20	**Distribution of DMD Mutations**
Deletions	65%
Duplications	7%
Single-point mutations	20%
Small insertions/deletions	7%
Splice site or intronic mutations	<1%

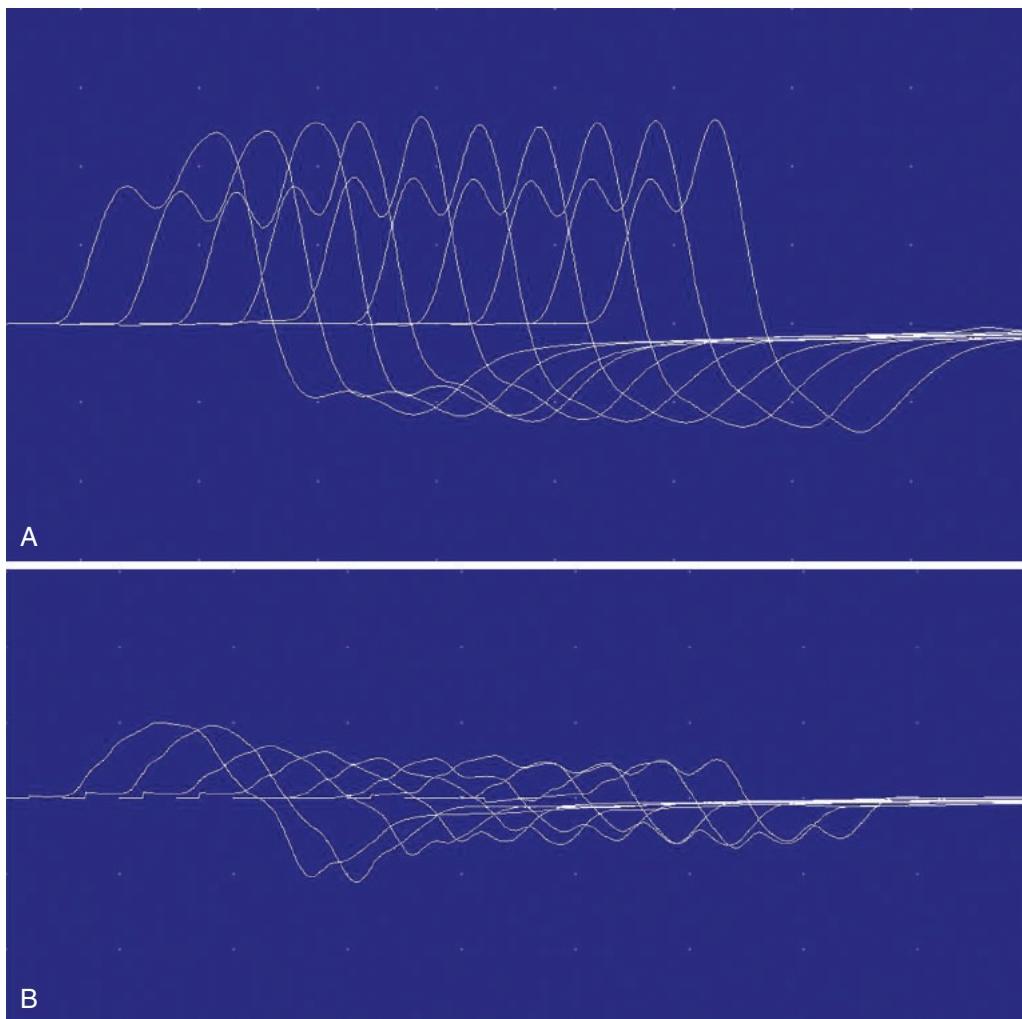
DMD, Duchenne muscular dystrophy.


FIGURE 29.12 Repetitive nerve stimulation (RNS) at a rate of 3 Hz in a 15-year-old female with ptosis and generalized weakness diagnosed with seropositive myasthenia. RNS of a clinically strong muscle, the abductor digiti minimi, shows no decremental response *(A);* however, when performed on a clinically weak muscle, the trapezius, a decremental response of 44% between the 1st and 5th responses *(B)* is seen.

slower in walking or running, rising from the floor, or climbing stairs compared to their peers. The classic maneuver employed to rise from the floor is a **Gower sign**, indicative of proximal hip extensor weakness and is typically seen by 3 years of age (Fig. 29.14). The characteristic toe-walk with Trendelenburg gait (waddling) in a hyperlordotic boy with enlarged calves is usually seen by 5-6 years of age. Early in the disease, there is usually **calf pseudohypertrophy** because of a proliferation of fat and collagen and even some muscle hypertrophy giving a herculean appearance in a small subset of patients. However, atrophy of all muscles occurs with age. Language and cognitive abnormalities are seen in many patients.

With time, proximal muscle weakness makes ambulation difficult, and the patient requires a wheelchair. With the standard use of steroids, the age of wheelchair dependence ranges between 9-14 years. Respiratory muscle failure develops by late adolescence. The pulmonary insufficiency may be aggravated by thoracic kyphoscoliosis. Another possible complication is cardiomyopathy. Most affected patients die by 25-35 years of age.

BMD has marked clinical heterogeneity with a variable age of onset ranging from childhood to adulthood. These patients also have calf pseudohypertrophy and eventually exhibit a Gower maneuver with variable degrees of proximal muscle weakness. Other phenotypes in

BMD include isolated quadriceps weakness, childhood cramps-myalgia syndrome, exercise-induced myoglobinuria, and asymptomatic elevated CK levels (rare). Childhood-onset weakness typically results in loss of ambulation in the 3rd or 4th decade. Cognition is usually normal but cardiomyopathy occurs frequently in this population and rarely may be the heralding symptom.

The diagnoses of DMD and BMD is suspected from the history (including the family history), physical examination findings, and an elevated serum CK (often 10,000-30,000 IU/L). Genetic testing via *DMD* deletion/duplication with reflexive sequencing analysis confirms the diagnosis. Although muscle biopsy is no longer necessary in DMD, it may still be useful in certain cases of BMD (Fig. 29.15).

Myotonic dystrophy is a common muscle disorder of childhood that is distinct in that it causes primarily a distal distribution of muscle weakness and is associated with myotonia, a phenomenon characterized by persistent muscular contraction with apparent delay in relaxation of muscles. A child with **myotonia** has difficulty releasing a ball after gripping it tightly or letting go of a doorknob. Myotonia usually is present by age 10 years, but significant distal muscle weakness is not usually evident until the end of the 2nd decade. In **congenital myotonic dystrophy**, the newborn infant has severe generalized

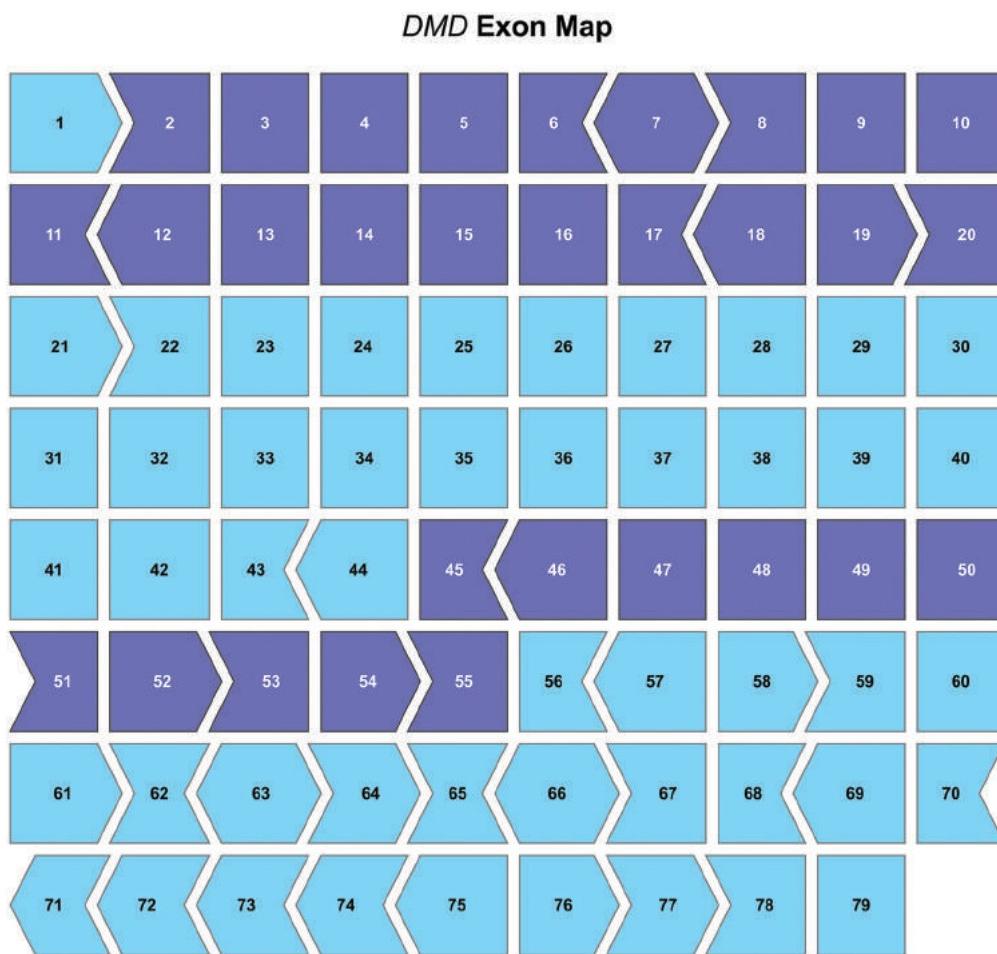
DMD Exon Map


FIGURE 29.13 An exon schematic diagram of the *DMD* gene used to determine the impact of deletions or duplications on the reading frame. The *DMD* gene has 79 exons. Exons colored in purple represent regions of "hot spots" in which a high frequency of mutations occurs across the general population. The primary hot spot is exons 45-55 and the secondary is 2-20. If all 3 base pairs of a codon end within an exon, then a vertical border is used to depict the exon. If either 1 or 2 base pairs of a codon are located in the next exon, then an angled border is drawn. Therefore, a deletion/duplication of a particular exon or exons may result in alteration of the reading frame. For example, deletion of exon 50 results in an out-of-frame mutation because the right-sided "edge" of exon 49 does not align the left-sided "edge" of 51, whereas a deletion of both exons 50 and 51 results in an in-frame mutation because the right "edge" of exon 49 aligns the left "edge" of 52.

hypotonia and weakness, often with swallowing and sucking difficulty, facial diplegia, a down-turned tented mouth, moderate-to-severe intellectual disability, and congenital joint contractures (talipes equinovarus, arthrogryposis) (Fig. 29.16). Usually there is a history of polyhydramnios and reduced fetal movements in utero.

This is a slowly progressive disorder with multisystemic involvement, including the development of cataracts, premature male-pattern baldness, facial muscle atrophy resulting in a "hatchet face" appearance, cervical kyphosis, cardiac arrhythmias, diabetes, pilomatrixomata, increased risk of thyroid cancer, thyroid dysfunction, gastrointestinal dysmotility, and testicular atrophy. EMGs in children reveal the characteristic myotonic discharge ("dive bomber") but an EMG in the neonatal period may not show this characteristic finding. Gene testing demonstrating the cytosine-thymine-guanine (CTG) trinucleotide repeat expansion in the *DMPK* gene of chromosome 19q13.3 establishes the diagnosis.

Congenital myopathies are a genetically and clinically heterogeneous category of myopathies (see Table 29.8). This category of myopathy has characteristic muscle biopsy findings that may guide in narrowing the genetic differential diagnosis. Specific muscle pathologic features are distinguished by the presence of cores, nemaline rods, central nuclei, or congenital fiber type disproportion (CFTD) (Fig. 29.17). **Centrally placed nuclei** are usually large in relation to the myofiber, present in a disproportionate number of fibers, and may be centrally placed along the length of the fiber. **Cores** are areas devoid of oxidative enzyme activity, best seen on oxidative stains such as nicotinamide adenine dinucleotide or ATPase. **Nemaline rods** are red, purple, or blue inclusions best seen on Gomori trichrome stain and vary per fiber, by fiber type, and in their distribution within the myofiber. **CFTD** refers to the relative atrophy of type 1 fibers by 35-40% compared to type 2 fibers in the absence of other structural changes such as rods, cores, and central nucleation.

Neuromuscular junction disorders. Myasthenia gravis is caused by the presence of antiacetylcholine receptor antibodies that produce a neuromuscular blockade at the level of the NMJ.

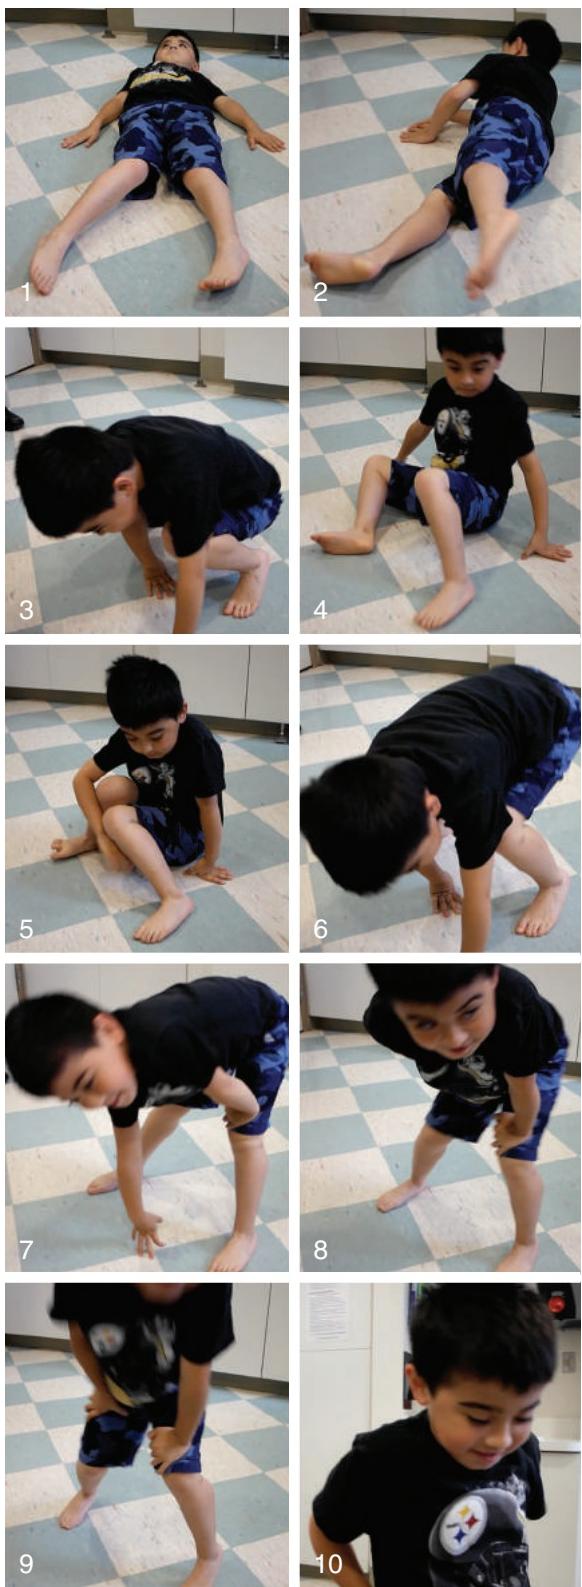
Transient neonatal myasthenia is caused by transplacental transfer of antiacetylcholine receptor antibodies in infants born to mothers with this disease. These patients usually demonstrate generalized


FIGURE 29.14 The Gower maneuver in a 7-year-old boy with Duchenne muscular dystrophy: the sequence of postures used in getting up from the ground. *1,* Lying prone. *2-4,* Getting onto the hands and knees. *5-6,* Legs and arms extended and legs brought as close as possible to the arms. *7,* Hand placed on the knee. *8,* Both hands on the knees, knees extended. *9,* Hands moving alternately up the thighs, "climbing up himself." *10,* Erect posture.

hypotonia and difficulty feeding a few hours after birth. Otherwise, they are alert, and pupils are reactive. Complete recovery in 4-6 weeks is the rule. Anticholinesterase therapy may be needed for a few days to a few weeks after birth.

Infantile (autoimmune) myasthenia is less common than transient neonatal myasthenia. Symptoms include acute-onset ophthalmoparesis, ptosis, and respiratory and feeding difficulties in a previously healthy infant with worsening symptoms later in the day. Demonstrating a decrementing response on repetitive nerve stimulation and a good response to a short course of steroids makes the diagnosis. Childhood autoimmune myasthenia has a high rate of seronegativity (36-50%), higher rates of pure ocular form, higher remission rates, and affects males and females equally. Distinguishing between autoimmune and genetic forms of myasthenia can be challenging in the infant. Treatment includes long-acting cholinesterase inhibitors such as pyridostigmine. Prednisone is useful because of the autoimmune nature of the disease.

Congenital myasthenic syndrome is a rare set of disorders stemming from many genetic defects causing either defective release of acetylcholine (presynaptic), lack of acetylcholinesterase or abnormal clustering of acetylcholine receptors (synaptic), or abnormal acetylcholine receptor response (postsynaptic). Clinically, all congenital myasthenic syndromes are seronegative for acetylcholine receptor antibodies and can manifest ophthalmoparesis, ptosis, and feeding and respiratory difficulties, making them indistinguishable from the autoimmune variety (Fig. 29.18).

Infantile botulism is caused by the germination of *Clostridium botulinum* organisms in the infant's gastrointestinal tract with local endogenous toxin production. Toxin is absorbed into the circulation and eventually inhibits the release of neuronal acetylcholine in the peripheral nervous system.

Infantile botulism is common between the ages of 2 and 6 months of life; many affected infants are breast-fed and may have a prior history of constipation. The sources of *C. botulinum* include honey, corn syrup, soil, and dust. Manifestations include lack of fever, poor feeding (poor sucking and swallowing), constipation, a weak cry and smile, hypotonia, ptosis, mydriasis, ileus, bladder atony, and hypotonia (see Table 29.9). Respiratory arrest and inappropriate antidiuretic hormone secretion may ensue. There is a descending paralysis, as symptoms are usually first noted in the face and bulbar region.

Food-borne botulism is manifested after ingestion of preformed toxin in poorly canned foods. Affected children have nausea and vomiting with dilated pupils, diplopia, dysphagia, dysarthria, dry mouth, and hypotonia.

The diagnosis of infant botulism is confirmed by recovery of the organism or the toxin from stool, blood, or food.

STROKE IN CHILDHOOD

Stroke is among the top 10 causes of death in childhood. The sequelae are not trivial. In addition to lasting lateralized weakness, learning disabilities, disturbances of language, visual deficits, and seizures may persist.

Brain injury resulting from stroke occurs in 1 of 2 general forms:
1. **Ischemia** consists of inadequate brain or spinal cord perfusion with consequent lack of oxygen or other blood-delivered substances necessary for normal metabolic function.
2. **Hemorrhage** occurs when blood is released into the extravascular cranial space. In this circumstance, focal injury of brain or spinal tissue occurs as a result of pressure exerted by the space-occupying mass of blood.

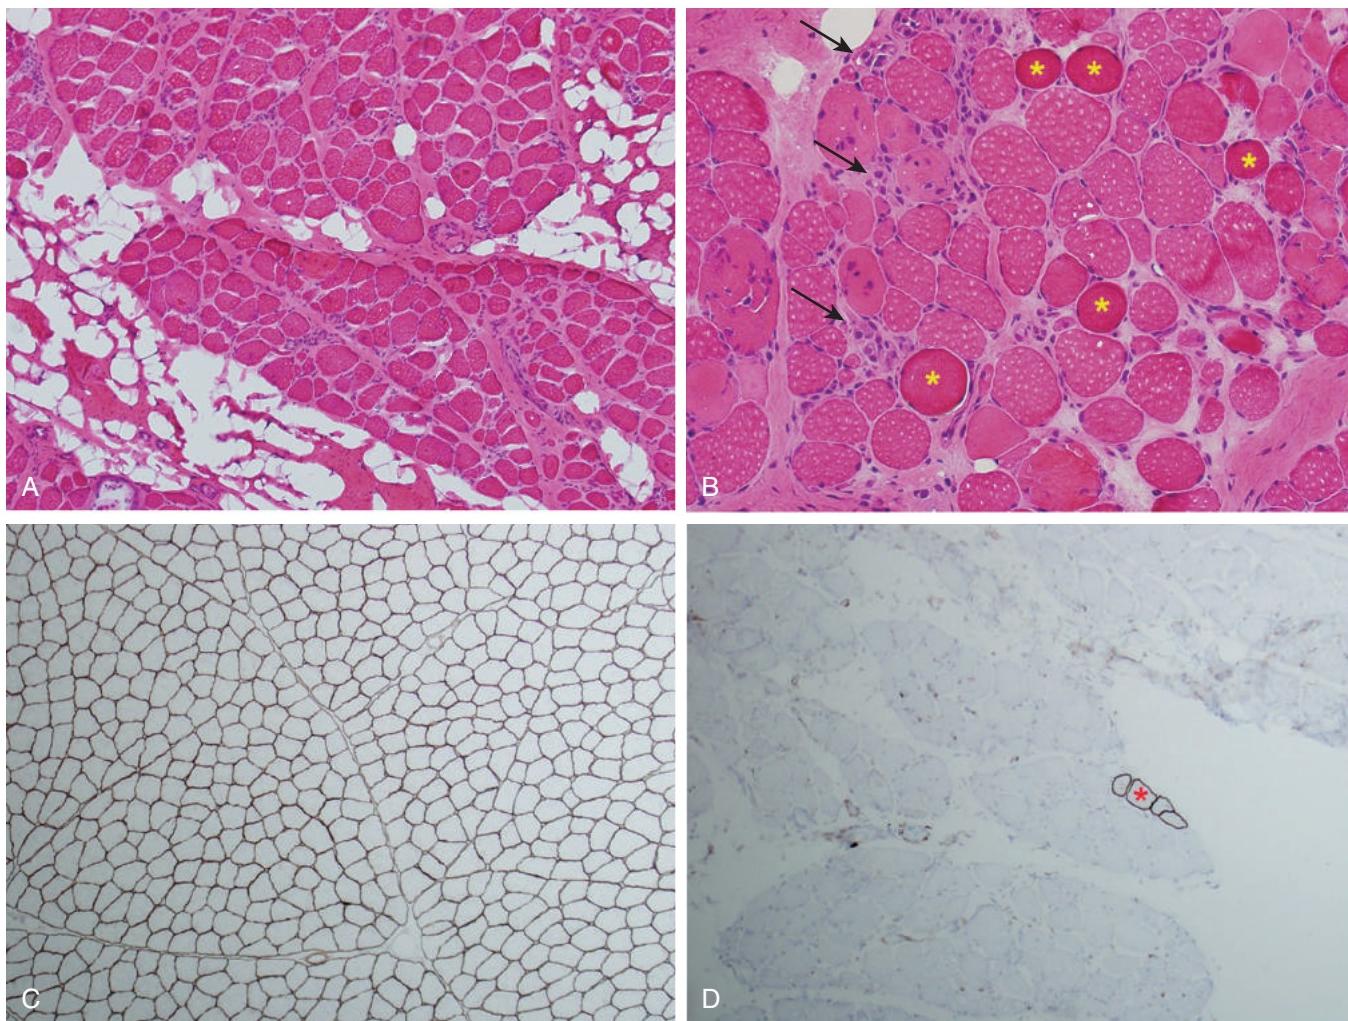
(See *Nelson Textbook of Pediatrics,* p. 2925.)


FIGURE 29.15 Muscle biopsy in Duchenne muscular dystrophy (DMD) showing prominent dystrophic changes consisting of fiber size variation, thick endomysial (around each myofiber) and perimysial connective tissue, increased internal nucleation, and fatty replacement of muscle tissue on hematoxylin and eosin (H&E) *(A)*. Higher magnification on H&E *(B)* shows mild inflammation consisting of myophagocytes consuming degenerating muscle fibers *(arrows)* and hypercontracted fibers *(yellow asterisks)*. Dystrophin immunohistochemistry demonstrates the normal staining pattern outlining the sarcolemma *(C)* in normal muscle, whereas the absence of staining in nearly all the fibers is seen in a DMD patient *(D)*. A few fibers within the muscle, called "revertant fibers" may have their reading frame spontaneously restored, thus enabling them to express dystrophin *(red asterisk)*. (Courtesy Michael Lawlor, MD, PhD, Medical College of Wisconsin, Milwaukee, WI.)

Ischemic injury of the brain occurs as a result of 1 of the 3 mechanisms: embolism, thrombosis, or global cerebral hypoperfusion.

Embolic damage to the brain occurs when material formed at a site in the vascular system proximal to the brain lodges in a blood vessel, thus blocking cerebral perfusion. Emboli originate most commonly from the heart, arising from a thrombus on cardiac chamber walls or from vegetation on valve leaflets. Artery-to-artery emboli are composed of clot or platelet aggregates that originate in vessels proximal to the brain but ultimately come to rest and occlude flow in vessels critical for cerebral perfusion. Systemic vein-to-cerebral artery emboli (paradoxical emboli) are possible in the presence of right-to-left shunts with cyanotic congenital heart disease or a patent foramen ovale.

Thrombosis denotes vascular occlusion caused by a localized process within a blood vessel or vessels. Although atherosclerosis underlies most thrombotic processes affecting adults, it is not common in children. Localized luminal clot formation occurs in polycythemia or in a hypercoagulable state. Alternatively, anatomic abnormalities may lead to clot formation or mechanical obstruction as is found in fibromuscular dysplasia, arteritis (vasculitis), or arterial dissection.

Global cerebral hypoperfusion due to cardiac pump failure (resulting from congenital heart disease or its surgical repair) and systemic hypotension resulting from hypovolemia represent common causes of hypotensive cerebral ischemic injury. With diminished cerebral perfusion, brain injury is more diffuse than the more focal injuries characteristic of thrombotic and embolic cerebral events.

Intracranial hemorrhage arises in 1 of 2 neuropathologic patterns:

1. **Subarachnoid hemorrhage (SAH)** occurs when blood flows from the intracranial vascular bed and onto the surface of the brain to mix with cerebrospinal fluid in the subarachnoid space. The most

FIGURE 29.16 A 6-year-old with congenital myotonic dystrophy with 1975 cytosine-thymine-guanine (CTG) repeats in the *DMPK* gene showing the characteristic elongated facies, left ptosis, and an open, down-turned (tented) mouth with dental malocclusion *(A)*. The tracheostomy scar is evidence of the severe respiratory distress requiring intubation at time of birth. Neonate with congenital myotonic dystrophy *(B)* also with an open, down-turned mouth and frog-leg position of lower extremities. A neonate with congenital myotonic dystrophy with severe respiratory distress and arthrogryposis *(C)*. (*B,* From Johnston H. The floppy weak infant revisited. *Brain Dev.* 2003;25:155-158; *C,* from Echenne B, Bassez G. Congenital and infantile myotonic dystrophy. *Handb Clin Neurol.* 2013;113:1387-1393.)

common source of such intracranial bleeding in early childhood is an **arteriovenous malformation (AVM)**. Ruptured **intracranial aneurysms** also cause subarachnoid hemorrhage, especially in older children.

2. **Intracerebral hemorrhage** denotes bleeding into the parenchyma of the brain. Severity and region of deficits caused by intraparenchymal hemorrhage are determined by the extent and location of bleeding in the brain.

The location, or focality, of the resultant deficit after a stroke depends on whether the event occurred in the cortex, the subcortical areas, the brainstem, or the cerebellum. Although alterations of blood flow result in permanent deficits, some cause only temporary ones. **Transient ischemic attacks (TIAs)** are brief episodes of focal, nonconvulsive neurologic deficit attributable to interruption of cerebral perfusion. As in stroke, the onset is abrupt. By definition, a TIA must last less than 24 hours and in reality lasts only a few minutes, and recovery must be complete.

Progression of symptoms characterizes stroke when the underlying process, either ischemia or hemorrhage, widens its CNS domain with resultant expansion of symptoms and signs. Whether short-lived or permanent, deficits are commonly motor. Loss of strength may occur as a lateralized weakness involving one-half of the body (**hemiparesis**) or as complete loss of strength (**hemiplegia**). Diparesis, or diplegia, involves weakness of the legs and is found primarily in premature infants who have suffered bilateral hypoxic-ischemic brain injury, in

full-term neonates after intracranial hemorrhage that has led to posthemorrhagic hydrocephalus, and in children suffering spinal cord injury below the neck. Involvement of the cerebellum often manifests as gait ataxia or impairment of fine motor coordination. Stroke occurring in the brainstem is reflected by cranial nerve dysfunction in the distribution of the vascular event. If long sensory or motor tracts running between the brain and spinal cord are involved, dysfunction of these systems may be involved.

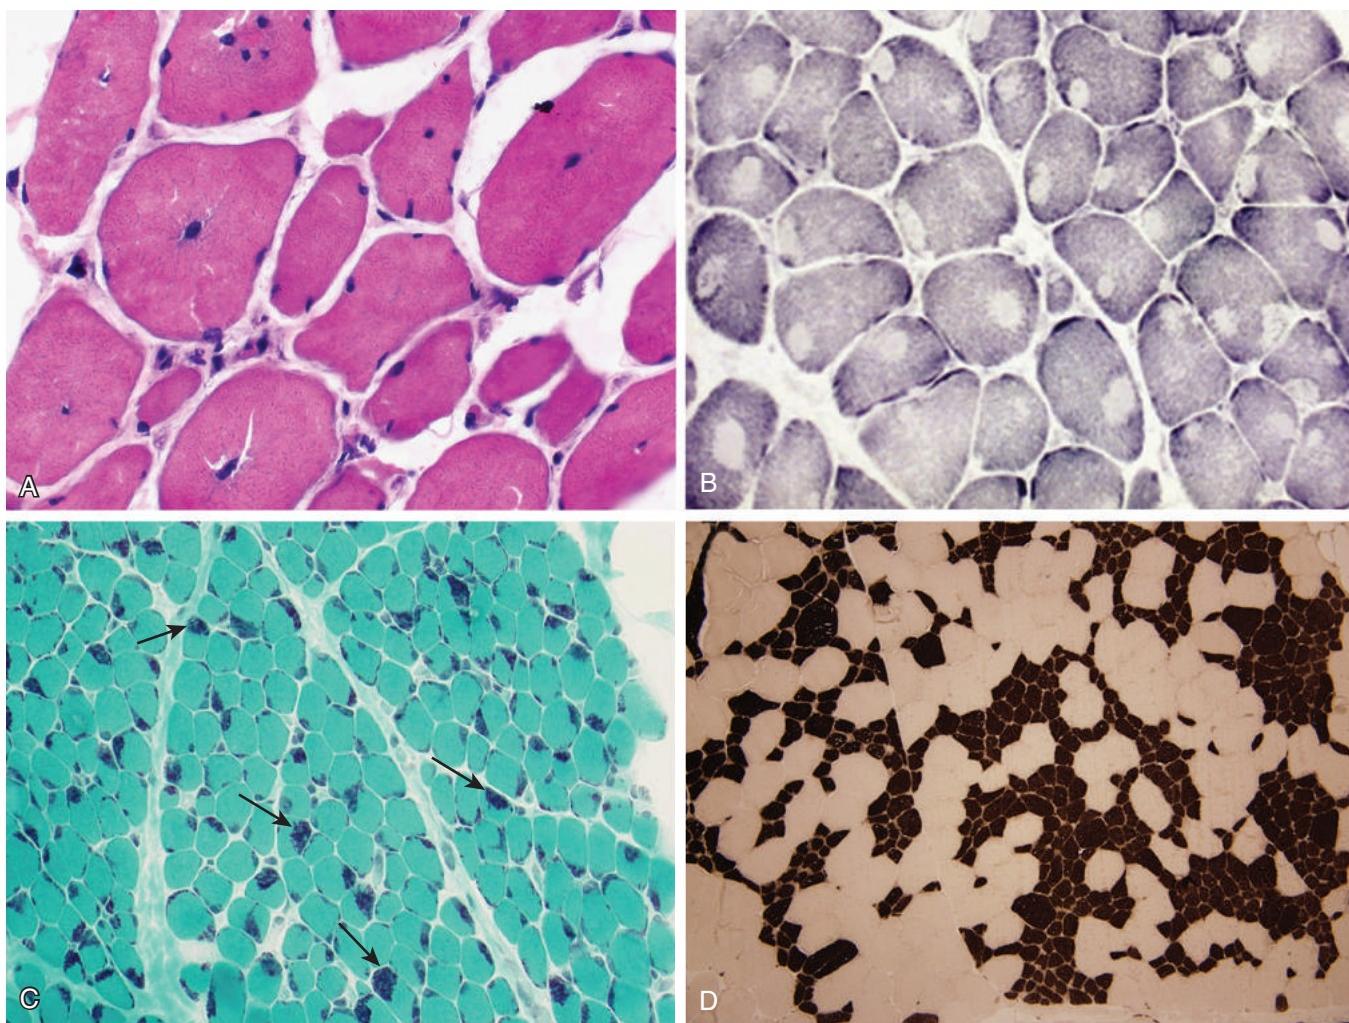
Distinction among the 3 processes underlying stroke—embolism, thrombosis, and hemorrhage—is possible according to clinical features (Table 29.21). **Thrombotic strokes** are usually abrupt and on occasion may be heralded by TIAs. This type of stroke may bear a stepwise tempo, and neurologic symptoms may appear haltingly. The cerebrospinal profile is normal. **Embolic strokes** are infrequently preceded by TIAs. Onset of the episode is abrupt, and neurologic symptoms are manifested immediately. A mild-to-moderate headache may accompany neurologic symptoms. Lumbar puncture yields normal cerebrospinal fluid. **Intracerebral hemorrhage** is frequently marked by headache. Severe headache of sudden onset marks SAH, in particular. Prodromal symptoms generally do not occur. However, previous seizures may suggest the existence of an AVM, whereas previous episodes of headache may be attributable to leaks from intracranial aneurysms. Consciousness is often lost, although it may be regained after a short while. Cerebrospinal fluid is bloody if SAH has occurred or if intraparenchymal bleeding reaches the ventricular system.


FIGURE 29.17 Characteristic Pathologic Changes Seen on Muscle Biopsy in Congenital Myopathies. Centronuclear myopathy is classified based on a centrally placed nucleus *(A)* seen in a disproportionate number of myofibers, on the background of fiber size variability shown here on hematoxylin and eosin (H&E) staining. Core myopathy has well-demarcated centrally or eccentrically placed cores, best visualized on oxidative stains such as SDH *(B)*. Nemaline rods are purple-blue staining rods (few are labeled by *arrows*) best visualized on Gomori trichrome located in a subsarcolemmal position *(C)*. Congenital fiber-type disproportion showing small, dark-staining type 1 fibers (average diameter, 20-40 μm) on ATPase at pH 4.3 relative to the larger, pale-staining type 2 fibers (average diameter, 80–100 μm) *(D)*. SDH, succinate dehydrogenase. (*A,* Courtesy Karra Jones, MD, PhD, University of California, San Diego, San Diego, CA; *B,* from North KN, Wang CH, Clarke N et al. Approach to the diagnosis of congenital myopathies. *Neuromuscular Disord.* 2014;24:97-116, with permission; *C,* courtesy Michael Lawlor, MD, PhD, Medical College of Wisconsin, Milwaukee, WI; *D,* courtesy Chamindra Konersman, MD, Medical College of Wisconsin, Milwaukee, WI.)

The signs of stroke found on physical examination often reflect interruption of the motor pathways extending from cortical upper motor neurons to the spinal cord lower motor neuron, the anterior horn cell. Upper motor neuron motor deficits seen in stroke patients may result from events occurring at any of several levels in the CNS: cerebral cortex, subcortical white matter, brainstem, or spinal cord. Despite the vast neurologic terrain in which stroke may occur, characteristics common to its occurrence at each of these locations can be found. A group of muscles is always involved. Never are individual muscles affected in isolation. The group of muscles affected may initially be flaccid and powerless, but the paralysis is rarely permanently complete.

Spasticity serves as the chronic functional manifestation of upper motor neuron injury caused by stroke. The antigravity muscles, consisting of arm flexors and leg extensors, are most commonly affected. As a result, the arms assume a position of flexion and pronation, whereas legs become extended and adducted. Testing for spasticity involves rapidly moving the relaxed affected extremity in the range of motion of the joint and assessing for freedom of movement. The extremity should then be stretched at higher velocity at which point increased tone is encountered in spasticity and classically referred to as *clasp-knife phenomenon*. Enhancement of deep tendon reflex response has been attributed to the interruption of descending inhibitory pathways as well as to increased activity of the γ neuron reflex loop.

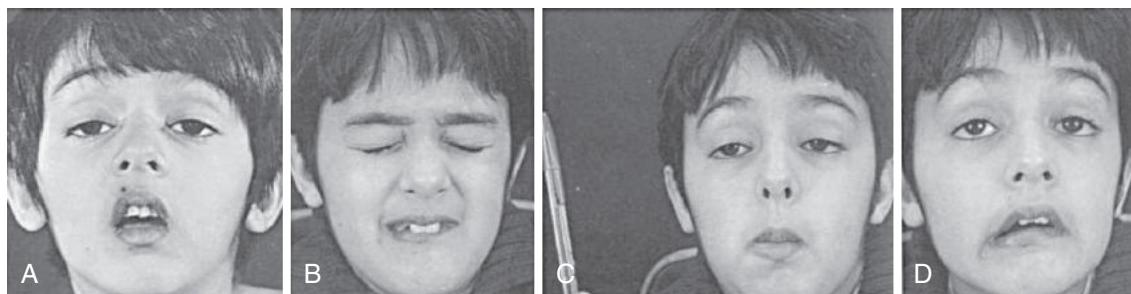
Clonus, repetitive muscle contraction in response to tendon percussion or stretch, further reflects the enhanced response of tendon reflexes resulting from upper motor neuron injury in stroke. Reflex


FIGURE 29.18 **Congenital Myasthenia.** This child was referred at 4 years of age with a history of swallowing difficulty. By 2 years, his walking had not progressed further, and he was unable to run or climb stairs. His parents had also noted some ptosis in the 1st year. On examination, he had obvious ptosis, limited ocular movement, associated weakness of facial movement, an expressionless face, open mouth, and an inability to close the eyes tightly *(A)*. There was general hypotonia with joint laxity. The child got up from the floor with a Gower sign and could not stand on 1 leg or run. A diagnosis of myasthenia was confirmed by demonstrating a response decrement to repeated ulnar nerve stimulation. A definite improvement in the ptosis and his ability to get up from the floor was noted after intravenous edrophonium chloride (Tensilon). He was treated with pyridostigmine and showed a definite improvement, but with time, he needed an increased dosage and frequency. His performance improved after each dose and tended to wane as the next dose became due. He still had a Gower sign on rising from the floor, marked ptosis, external ophthalmoplegia, and facial weakness *(B-D)*. His parents are 1st cousins, and so this is probably a case of autosomal recessive infantile (congenital) myasthenia. (From Dubowitz V. *Muscle Disorders in Childhood*. 2nd ed. London: WB Saunders; 1995:414.)

TABLE 29.21   Stroke in Children: Characteristics of Stroke by Mechanism

Mechanism	Onset	Pace of Deficit Onset	Location	TIAs	Neck Pain	Headache	Impaired Consciousness
Embolism	Sudden	Abrupt	Remote site of origin	Rare	None	Yes	Rare unless infarction is large or involves ARAS or bilateral thalami
Thrombosis	Sudden; may occur during sleep or systemic hypotension	Abrupt; may be stepwise	In situ	Yes	None*	Rare	Unusual
Hemorrhage	Rapid	Abrupt or rapid in progression	In subarachnoid space or in brain parenchyma	None	Yes	Yes	Frequent in SAH and large parenchymal hemorrhages

*Except in carotid dissection with intimal tearing.
ARAS, ascending reticular activating system; SAH, subarachnoid hemorrhage; TIAs, transient ischemic attacks.

elicitation at 1 point, such as at the biceps muscle, may provoke reflex responses in adjacent muscle groups, such as brachioradialis or finger reflexes. Such spread of reflex responsiveness is commonly seen in patients whose upper motor neuron pathways have been injured by stroke.

Children with stroke present similarly to adults with focal neurologic deficits but diffuse features occur more commonly, although not in isolation (Table 29.22). Stroke in children is commonly caused by or related to congenital heart disease, infection, metabolic disorders, hematologic and coagulation diatheses, and collagen vascular disease (Table 29.23). Nonetheless, despite the most thorough evaluation, the cause escapes detection in 25-33% of patients. A pediatric stroke classification system originally proposed by Wraige et al. in 2005 demonstrated that stenoocclusive arteriopathy is the most common cause of arterial ischemic strokes (AISs) (Table 29.24), whereas AVMs were the most common cause of hemorrhagic strokes (Table 29.25). The evaluation of stroke should proceed in a stepwise fashion, with determination of whether the stroke is ischemic or hemorrhagic via cranial CT

or MRI. Subsequent diagnostic testing may include cerebral vessel imaging, echocardiography, and laboratory work-up for prothrombotic and inflammatory states based on history (Fig. 29.19).

The outcome of stroke varies considerably due to differences in etiology, age, management, population studied, and functional outcome measures studied. In general, 5-10% of affected children die, and more than half of the survivors incur a functional or cognitive neurologic deficit.

The clinical presentations and causes of stroke are best considered with respect to each of 3 age groups: neonates, children between 1 and 13 years of age, and adolescents.

NEONATES

Perinatal Ischemic Stroke

The National Institute of Neurologic Disorders and Stroke defines ischemic perinatal stroke as a "focal disruption of cerebral flow secondary to arterial or cerebral thrombosis or embolization between 20

weeks of fetal life through 28th postnatal day" as confirmed by neuroimaging, fetal imaging methods, or neuropathologic studies. Perinatal stroke can be subclassified into fetal (diagnosed before birth), neonatal (diagnosed after birth but before the 28th postnatal day), or presumed perinatal (diagnosed after the 28th postnatal day) ischemic stroke. The causes of stroke in neonates are similar to those in children (Table 29.26).

The incidence of neonatal arterial ischemic stroke (AIS) in term infants is reportedly 1 in 2300 to 1 in 5000 live births. Neonatal AIS occurs more frequently in preterm newborns with an incidence of 7 in 1000 infants born at or before 34 weeks of gestation.

Newborns who incur AIS present 58-68% of the time in the newborn period. Focal seizures are the most common presenting symptom of neonatal AIS, occurring in 69-90% of term newborns (Table 29.27). Onset of seizures after 12 hours of life and focal motor seizures predict an association with stroke compared to HIE. Furthermore, most seizures associated with AIS occur within the 1st 3 days of life. Even though lateralized findings on neurologic examination may

TABLE 29.28   Risk Factors for Perinatal Arterial Ischemic Stroke (AIS)

Type of Risk Factor	Risk Factors
Term Infants with Neonatal AIS	
Maternal	Thrombophilia
	Infertility
	Prolonged rupture of membranes
	Preeclampsia or gestational hypertension
	Smoking
	Intrauterine growth restriction
	Infection
	Maternal fever during delivery
	Smoking
Fetal	Thrombophilia (MTHFR mutation, FVL, prothrombin gene mutation, protein C/S deficiency)
	Congenital heart disease
	Arteriopathy
	Hypoglycemia
	Perinatal asphyxia
	Infection (sepsis/meningitis)
	Need for resuscitation
	Apgar score of <7 at 5 min
Placental	Chorioamnionitis
	Placental infarcts
	Distal villous immaturity
	Placenta weighing <10th percentile
Preterm Infants with Neonatal AIS	
Maternal	Infection
	Gestational bleeding
	Maternal smoking
	Maternal drug use
Fetal	Twin-twin transfusion
	Abnormal fetal heart rate
	Hypoglycemia
	Thrombophilia (MTHFR mutation, FVL)
Presumed Perinatal AIS	
Maternal	Preeclampsia
	Infection
	Gestational bleeding
	Gestational diabetes
	Thrombophilia
Fetal	Congenital heart disease

MTHFR, methylenetetrahydrofolate reductase deficiency; FVL, factor V Leiden deficiency.
Modified from Lehman LL, Rivkin MJ. Perinatal arterial ischemic stroke: presentation, risk factors, evaluation, and outcome. *Pediatr Neurol.* 2014;51:760-768.

be found, they need not be present as hallmarks of cerebral infarction. Furthermore, diminished movement of extremities on the side of the focal seizure may represent a postictal Todd paralysis rather than paresis from upper motor neuron injury caused by cerebral infarction. Initially, other neurologic signs may be absent. However, as the child grows, motor or cognitive impairment may become progressively more apparent during the 1st 1-3 years of life. Preterm neonates with AIS are commonly asymptomatic and are diagnosed on cerebral ultrasound, whereas the most common presentation of presumed perinatal AIS is early hand preference (see Table 29.27).

The cause of the cerebral infarction frequently escapes detection among neonates who have not been subjected to prenatal asphyxia.

Data analyzing risk factors for perinatal AIS are limited and sometimes conflicting, but can be broadly categorized into maternal, fetal, and placental factors (Table 29.28). For unknown reasons, a left hemispheric location (53-64% with an isolated unilateral lesion) has been noted to be the most common area involved in perinatal AIS and exclusive involvement of the middle cerebral artery (MCA) territory is seen in 75-90% of perinatal AIS cases. The location of strokes varies based on age of gestation (Table 29.29). Emboli from the placenta may lodge in cerebral vessels and result in stroke. In addition, congenital

heart defects involving right-to-left shunts through septal defects or through a patent ductus arteriosus serve as settings for embolic stroke in neonates. Coagulopathies caused by congenital defects of coagulation (factor VIII, protein C or S, or antithrombin III deficiency and others) or by sepsis-induced disseminated intravascular coagulation may underlie neonatal embolic stroke. Fetal head trauma during labor and delivery that results in endothelial damage to cerebral vessels occasionally leads to thrombosis and resultant focal ischemia of the brain. Polycythemia and hypotension can each lead to intravascular stasis and abnormalities in flow, resulting in cerebrovascular thrombosis in neonates. Meningitis and encephalitis cause diffuse or localized thrombosis as a result of vascular inflammation, leading to hemostasis and thrombosis.

Evidence of localized dysfunction of brain found on EEG consists of focal, persistent voltage reduction or of marked focal slowing and sharp wave activity. In some instances, EEG evidence of clinically observed seizures may be found. Each of these findings may exist while the EEG remains relatively normal over other regions of the brain. The areas of electrical abnormality should correspond to the affected areas of brain revealed by neuroimaging. Cranial CT demonstrates a low-density region that eventually evolves into atrophy (Fig. 29.20). MRI demonstrates low or isointense signal intensity on T1 weighted images and high signal intensity on T2 weighted images as a result of increased water content in the infarcted region of the brain. DWI reveals the local area of edema before any other neuroimaging procedure and must be performed if the CT and MRI are normal (Figs. 29.21 to 29.24).

TABLE 29.29 Location of Arterial Strokes in Perinatal Arterial Ischemic Stroke Based on Gestational Age

Gestational Age	Location of Arterial Stroke	% of Cases
Full-term neonate	Cortical branch strokes	59
Preterm neonate (overall)	Lenticulostriate (overall)	39
<28–32 wk of gestation	Lenticulostriate	
32–36 wk of gestation	Cortical branch infarcts	

The mortality rate for neonatal AIS is low at 0.16 per 100,000 live births. Stroke recurrence occurs in only 2% of neonates, most of whom have thrombophilia, congenital heart disease, or an arteriopathy. Chronic motor deficits occur in 48-59% of neonates with AIS with MRI evidence of infarction in the basal ganglia, cerebral cortex, and posterior limb of internal capsule in term neonates correlating with long-term hemiparesis. Other long-term sequelae in neonatal AIS include behavioral disorders (attention and/or hyperactivity) (11%) and language delay (21%). About 38-46% of neonates with AIS develop epilepsy as a result of their stroke. Patients with presumed perinatal AIS fare poorer than their neonatal AIS counterparts: Approximately 95% have hemiparesis, 41% require limb casting/splinting, 50% have cognitive/behavioral difficulties, and 38% have epilepsy.

Polycythemia

Neonates are much more commonly polycythemic (central venous hematocrit >65%) than are older children. Polycythemia has been estimated to be present in 1.5% of newborns. It is most commonly encountered in neonates who are born at high altitude, those who are small for gestational age, infants of diabetic mothers, or recipients in twin-twin transfusion syndrome; it may also be seen in neonatal hyperthyroidism or adrenogenital syndrome. Clinical signs of the elevated hematocrit are present in some but not all affected infants and include plethora, acrocyanosis, impaired renal function, poor feeding, apnea, tachypnea, hypoglycemia, and indirect hyperbilirubinemia. Neurologic symptoms include jitteriness, irritability, lethargy, seizures, and focal motor deficits.

Most cases of polycythemia are idiopathic or secondary to acquired abnormalities of fetal oxygen delivery. Nonetheless, other polycythemias bearing autosomal dominant or recessive inheritance patterns have been described. These familial polycythemias are associated with mutant hemoglobins that create abnormalities of oxygen delivery.

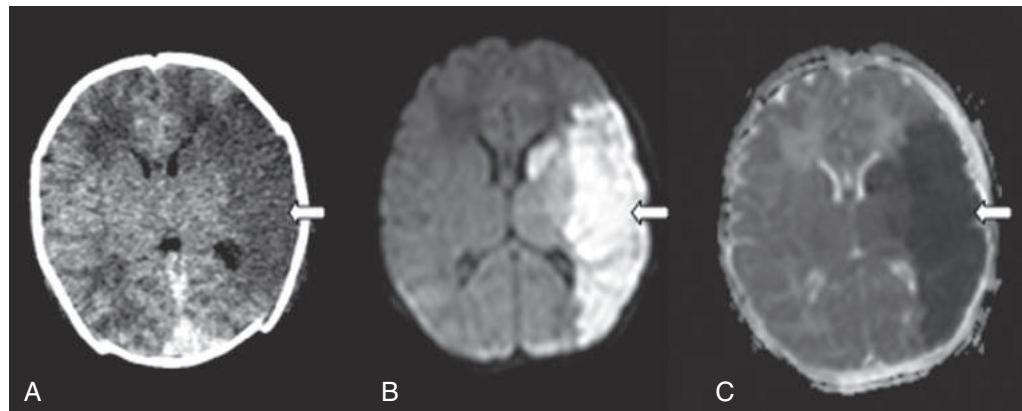
Polycythemia and its resultant hyperviscosity may contribute to stroke in neonates. Inadequate cerebral perfusion and cerebrovascular thrombosis cause cerebral ischemia. Although most of the systemic complications of polycythemia resolve with adequate treatment, neurologic signs frequently do not. Cerebral infarction resulting from polycythemia-related ischemia causes deficits that resolve either slowly


FIGURE 29.20 Neonatal Arterial Ischemic Stroke. Computed tomography (CT) and magnetic resonance imaging (MRI) demonstrate an arterial ischemic stroke in a 1-day-old term infant who presented with a right focal seizure. *A,* An axial CT image reveals hypodensity *(white arrow)* in the left middle cerebral artery (MCA) territory consistent with acute infarction. *B,* Axial MRI diffusion-weighted trace image of the same patient reveals a clearly demarcated area of infarct as a region of hyperintensity *(white arrow)* in the left MCA territory. *C,* Apparent diffusion coefficient map reveals region of signal hypointensity and restricted diffusion *(white arrow)* to match area of signal hyperintensity observed in *(B).* (With permission from Lehman LL, Rivkin MJ. Perinatal arterial ischemic stroke: Presentation, risk factors, evaluation and outcome. *Pediatric Neurol.* 2014;51:760-768.)

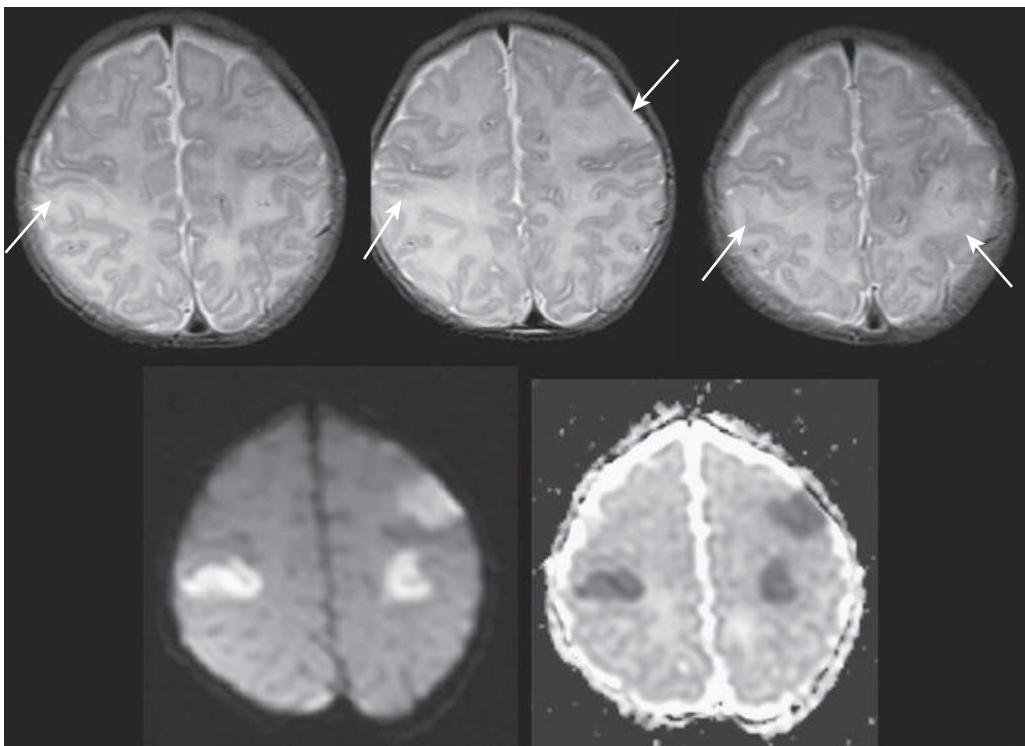

FIGURE 29.22 MR axial T2 weighted images *(top row),* a diffusion-weighted image, and calculated apparent diffusion coefficient (ADC) map *(bottom row)* of a term baby boy who presented with right-sided seizures. MR imaging on day 3 of life showed bilateral multiple acute cortical branch MCA territory infarcts. Note the cortical and white matter signal hyperintensity on T2 weighted images with loss of the normal cortical ribbon in some regions *(arrows in top row).* The diffusion-weighted imaging increases the conspicuity of the lesions; these show restricted diffusion with signal hyperintensity on the diffusion-weighted image *(bottom left)* matched by the low signal on the ADC map *(bottom right).* (With permission from Gunny RS, Lin D. Imaging of perinatal stroke. *Magn Reson Imaging Clin North Am.* 2012;20:1-33.)
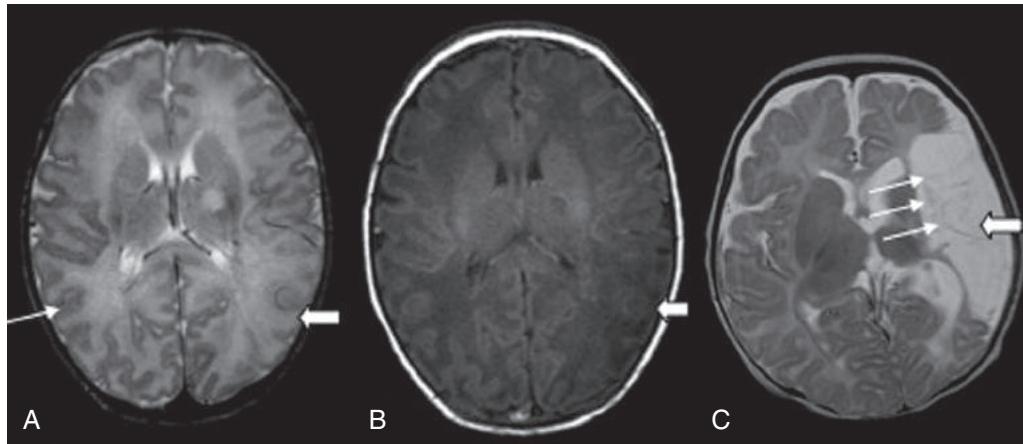

**FIGURE 29.23 Presumed Perinatal Arterial Ischemic Stroke (AIS).** Comparison of magnetic resonance imaging (MRI) appearance of a patient with acute neonatal AIS compared with MRI of a patient with presumed perinatal AIS. *A,* T2 weighted (T2W) axial image obtained in a 1-day-old term infant who presented with seizure reveals hyperintensity *(thick arrow)* in gray matter cortex and underlying white matter with loss of gray and/or white matter differentiation in the left middle cerebral artery territory *(thick arrow)* consistent with acute infarction compared with the normal right side with dark cortex *(thin arrow)* and normal differentiation of the white and gray matter. *B,* T1 weighted axial image, obtained in the same patient at the same time as the image in *(A)*, reveals signal hypointensity in cortical gray matter *(white arrow)* matching the area of hyperintensity observed in *(A)* consistent with a diagnosis of acute neonatal AIS. *C,* T2W image obtained in a 3-month-old infant with an unremarkable neonatal history who presented at 3 months of age with a prematurely appearing right-hand preference reveals an area of hyperintensity and cystic change *(thick arrow)* with cystic septations *(thin arrows)* typical of chronic infarction. (With permission from Lehman LL, Rivkin MJ. Perinatal arterial ischemic stroke: Presentation, risk factors, evaluation, and outcome. *Pediatr Neurol.* 2014;51:760-768.)
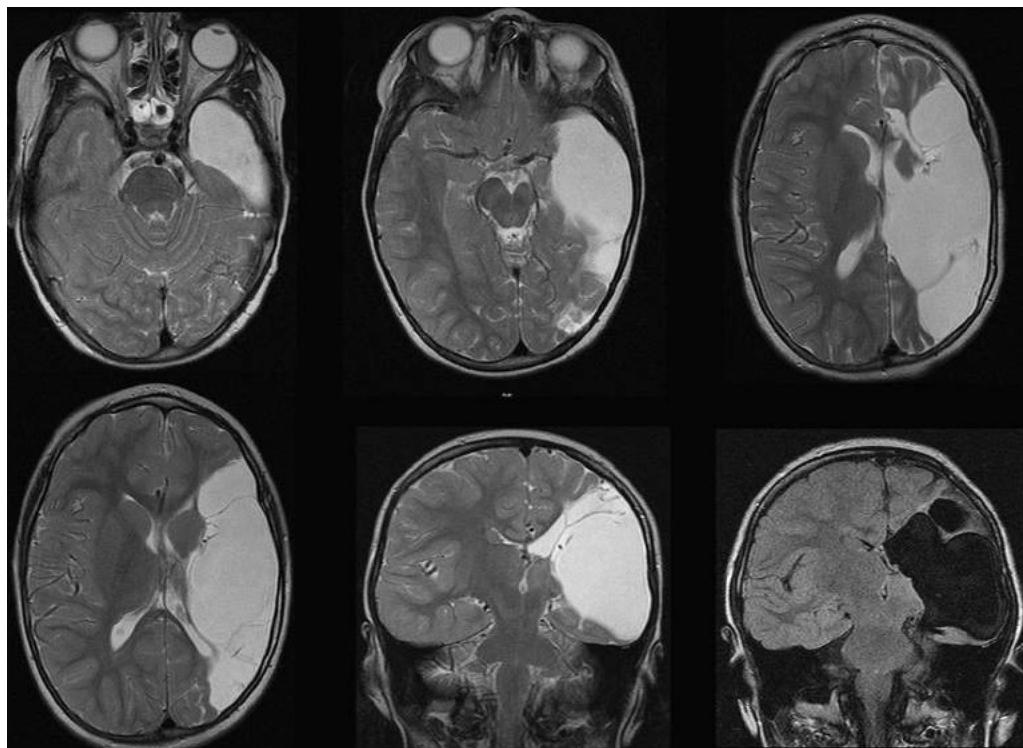

FIGURE 29.24 Presumed Perinatal Arterial Ischemic Stroke (AIS). Magnetic Resonance Imaging of a 5-year-old girl with long-standing right hemiplegia and intractable epilepsy secondary to a left-sided infarct. Note the large area of cystic cavitation in the left temporal (*top left* and *middle* images), frontal (*top right* image), and parietal lobes (*top right* and *bottom left* images) in the extended left middle cerebral artery territory (with some additional anterior choroidal involvement, and atrophy of the left thalamus; *bottom left* image). The left hemicranium is smaller, and there is some expansion of the left calvarial diploic space. There is 3-site involvement of the basal ganglia, superficial cortex, and posterior limb of the internal capsule (*bottom row* images). There is imaging evidence of Wallerian degeneration with atrophy, and signal hyperintensity suggestive of gliosis in the ventral midbrain and pons (*bottom middle* and *right* images). (Modified with permission from Gunny RS, Lin D. Imaging of perinatal stroke. *Magn Reson Imaging Clin North Am.* 2012;20:1-33.)

or not at all. Neurologic sequelae may be present in up to 35% of neonates with symptomatic polycythemia.

If signs of polycythemia are found in a neonate, further evaluation should be undertaken. Venous or arterial hematocrit, rather than capillary hematocrit, should be measured. If the family history and physical examination findings suggest a hereditary polycythemia, hemoglobin electrophoresis should be undertaken. Routine hemoglobin electrophoresis does not elucidate high oxygen-affinity hemoglobinopathies in all cases. If clinical suspicion is high, the heat instability test for unstable hemoglobins and oxygen dissociation assays can be utilized. Neuroimaging should be used to assess for cerebral infarction.

Neonatal Cerebral Sinovenous Thrombosis (CSVT)

Full-term neonates are the most frequently affected age group in the pediatric population for CSVT with an estimated incidence of 40.7 per 100,000 live births per year. Thrombosis may occur in cerebral veins that conduct deoxygenated blood from the parenchyma to the dural sinus system. These sinuses—the sagittal, straight, transverse, cavernous, and petrous—then convey the blood to the jugular veins. Occlusion of flow anywhere in these venous conduits leads to ischemia, infarction, and even hemorrhage.

Pathophysiology of CSVT is similar to perinatal AIS with the inherited thrombophilias being just as likely to cause venous infarctions as they do arterial (Table 29.30). Infection, dehydration, polycythemia, congenital heart disease, and extracorporeal membrane oxygenation (ECMO) have also been implicated. Five percent of all infants on ECMO have evidence of CSVT. The lesions associated with cerebral venous thrombosis include thrombosis in the deep or superficial veins, venous infarction, and hemorrhage. The hemorrhage that typically accompanies CSVT is a result of the increased venous/capillary hydrostatic pressure due to the presence of the clot causing extravasation of fluid and red blood cells.

The only signs may be lethargy and focal or generalized seizures. Other common symptoms include apnea and poor feeding (see Table 29.22). The features of slowly developing focal motor deficits, headache, and cranial nerve dysfunction found in older children with cerebral venous thrombosis are seldom observed.

Neuroimaging reveals the venous stasis best if magnetic resonance phase imaging, which detects blood flow, or magnetic resonance venography is performed, as well as conventional T1 and T2 weighted imaging (Fig. 29.25). An unenhanced CT may show a hyperdense, expanded "dense triangle" or "cord sign." An enhanced CT venogram may aid in the detection of the "empty delta" sign indicating a nonenhancing thrombus within the lumen of the vein (Fig. 29.26). Outcomes of CSVT include severe neurologic deficits in 19-38% of cases including death, but 45% have normal development.

TABLE 29.30 Risk Factors for Neonatal Cerebral Sinovenous Thrombosis	
Type of Risk Factor	**Risk Factors (Estimated % of Cases)**
Maternal	Preeclampsia
	Diabetes
Fetal	Acute neonatal illness (61–84%)
	Infection
	Meningitis
	Dehydration
	Congenital heart disease
	Thrombophilia (same as in arterial; 15–20%)
	ECMO
	Complicated delivery
	Polycythemia

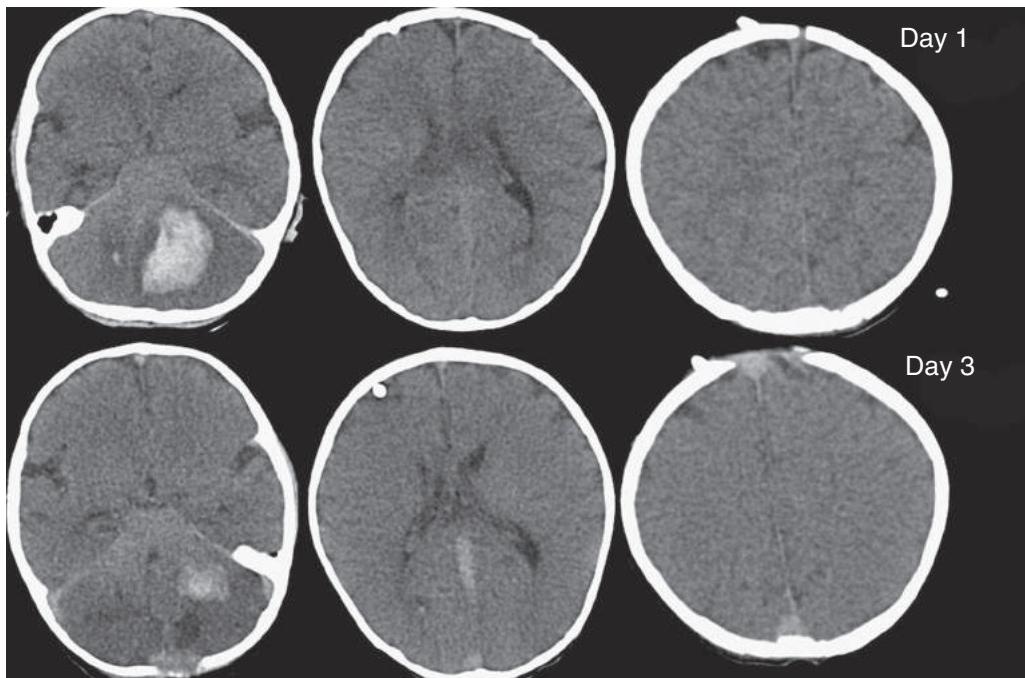
ECMO, extracorporeal membrane oxygenation.


FIGURE 29.25 Neonatal Cerebral Sinovenous Thrombosis. Computed tomography (CT) scan *(top row)* in a 6-week-old infant with acute cerebellar hemorrhages causing marked cerebellar swelling presumed to be secondary to idiopathic thrombocytopenic purpura. A CT scan the day after the posterior fossa hematoma resection *(botttom row)* shows there is new acute thrombus in the straight sinus, torcular, and superior sagittal sinus. (With permission from Gunny RS, Lin D. Imaging of perinatal stroke. *Magn Reson Imaging Clin North Am.* 2012;20:1-33.)
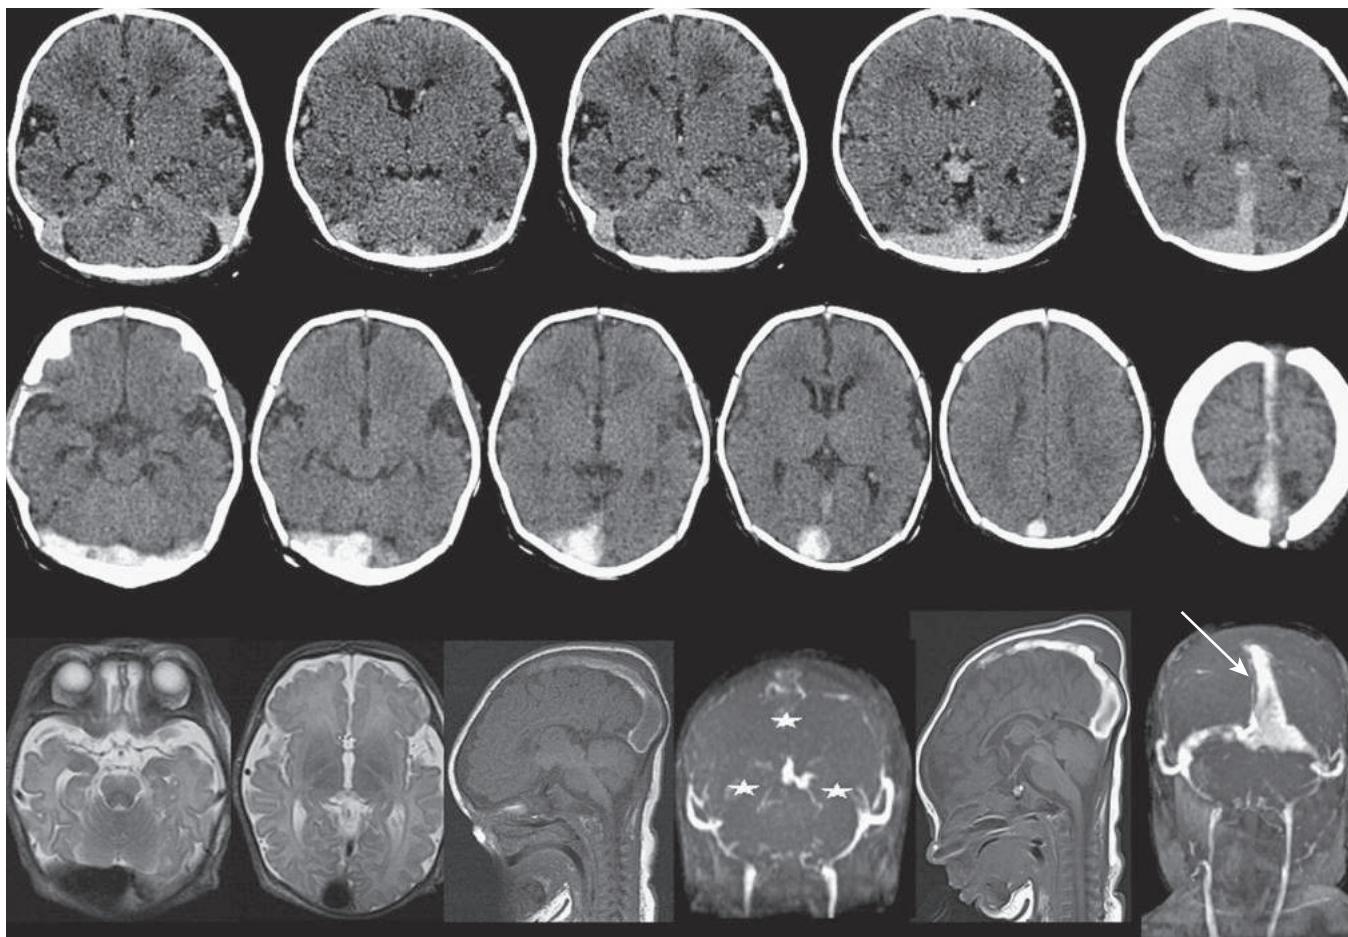

FIGURE 29.26 Neonatal Cerebral Sinovenous Thrombosis. A term male neonate was hypotonic at birth with poor respiratory effort requiring resuscitation. Initial computed tomography (CT) *(top row)* on day 2 of life shows diffuse brain edema with expanded and hyperdense transverse and sagittal sinuses, torcula, and internal cerebral veins as well as the cerebral cortical veins. CT performed on day 9 *(middle row)* shows resolution of the cerebral edema, increased density of the thrombus within the transverse sinus, torcula, and superior sagittal sinus. Magnetic resonance (MR) imaging on day 9 *(bottom left,* images 1–4) shows mild diffuse cerebral atrophy but no focal venous infarcts, with a persistent thrombus and no flow on the MR venography (*stars*). Follow-up MR imaging on day 15 (*bottom right,* images 5 and 6) shows the evolution of thrombus signal intensity to methemoglobin. Note the effect of T1 shortening within the thrombosed sagittal and transverse sinuses and torcula, mimicking flow within the sinuses *(arrow)*. (With permission from Gunny RS, Lin D. Imaging of peinatal stroke. *Magn Reson Imaging Clin North Am.* 2012;20:1-33.)

Intracranial Hemorrhage in the Neonate

Intracranial hemorrhage occurs in neonates in 1 of 4 different neuro-anatomic distributions: subdural (SDH), subarachnoid (SAH), intra-parenchymal (IPH), or intraventricular (IVH). Whereas SDH occurs more commonly in full-term infants, the other 3 types of hemorrhage are more common in premature infants.

Subdural Hemorrhage

SDH in neonates usually results from head trauma during birth. Thus, factors of labor and delivery promoting the application of increased force on the fetal head are liable to promote SDH. Cephalopelvic disproportion, rigidity of the bony pelvis, prolonged duration of labor, unusual presentations, or the need for prolonged manipulation or forceps application may each generate increased forces on the fetal head and cause SDH. As a result, shearing forces may create tears in the vein of Galen or tears of superficial cerebral veins. If forces are extreme, tears at the junction of falx and tentorium can generate large subdural blood collections in the relatively small posterior fossa,

culminating in compression of the brainstem and cerebellar tonsillar herniation. The incidence of SDH has steadily declined as a result of improved obstetric practice.

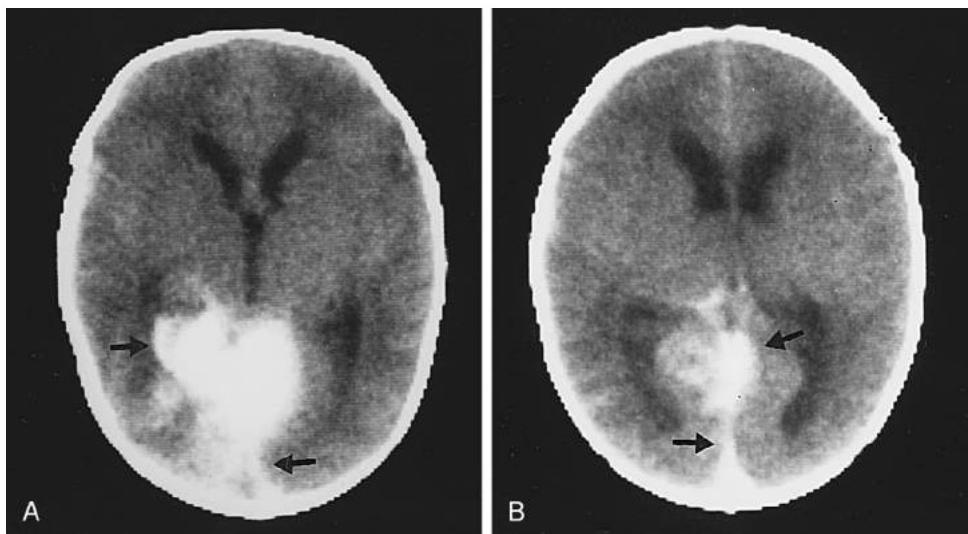
Clinical features of SDH depend on the location and size of the hemorrhage. Tentorial laceration (Fig. 29.27) can cause stupor or even coma. Pupillary and extraocular movement abnormalities are common. Dystonic postures such as retrocollis or opisthotonos are seen. Finally, abnormalities of respiratory pattern regulation such as apneustic or ataxic respirations are seen and signify imminent respiratory arrest. Less severe SDHs in the posterior fossa evolve more slowly and cause less severe brainstem dysfunction. Subdural collections of blood over the cerebral surfaces that result from tears of superficial cerebral veins may be asymptomatic, or may present with subtle symptoms such as irritability. With time the blood may liquefy and draw water into the area by osmotic forces, thus expanding the size of the lesion. If the collection is sufficiently large, seizures occur. Greater pressure may cause oculomotor dysfunction accompanied by pupillary dilation and ablated pupillary light responses.


FIGURE 29.27 *A* and *B,* Generalized tonic seizures, lethargy progressing to coma, and an irregular respiratory pattern were observed in a 1-day-old full-term infant. Computed tomography scan demonstrates a hyperdense lesion emanating from the falx and tentorium *(arrows)* caused by a traumatic tear of the tentorium, which resulted in hemorrhage from the straight sinus.

SDH may escape diagnosis in the 1st few weeks of life and appear later as a chronic subdural effusion; in this situation, the clinician must consider child abuse (see Chapter 26). Such an occurrence is marked by a rapidly enlarging head circumference. There may also be a combination of acute and chronic SDH in cases of child abuse.

Subarachnoid Hemorrhage

Blood can occupy the subarachnoid space in 1 of 2 ways. First, blood may reach the subarachnoid space after hemorrhage has occurred in the cerebral parenchyma or in the periventricular region. Second, SAH may result from disruption of the superficial leptomeningeal arteries or of the fragile vessels bridging the subarachnoid space; disruption of either vascular structure leads to direct bleeding into the subarachnoid space, so-called primary SAH. Primary SAH commonly occurs after hypoxic-ischemic brain insults and after fetal head trauma.

Mild SAH is clinically the most common type, occurring as an occult phenomenon with few if any manifestations. Greater amounts of blood collecting over the convexities may result in focal motor deficits and seizures. Large SAH accumulating over the convexities has been associated not only with seizures but with infarction of underlying cerebral cortex. The presence of accompanying infarction is indicated by the occurrence of focal seizures. A history of difficult labor and delivery may be associated with large SAH. Cerebral infarction in the setting of SAH has been observed more commonly in full-term infants than in premature infants.

When SAH is mild, the neurologic outcome can be good. Even in cases of SAH accompanied by an infrequent seizure or cerebral infarction, the prognosis is often favorable. Adverse consequences appear to be more dependent on the severity of any underlying intrapartum trauma or hypoxic-ischemic brain injury.

Intraparenchymal and Intraventricular Hemorrhage

IPH of the brain occurs in both full-term and preterm infants. **Cerebral hemorrhage** in the absence of IVH occurs most commonly in full-term infants. Hemorrhage into the parenchyma of the cerebral hemispheres can be caused by head trauma, vascular malformation (Fig. 29.28), coagulopathy, thrombocytopenia, tumor, or infarction. A common cause of prenatal, intrapartum, and postnatal hemorrhage is alloimmune thrombocytopenia, caused by acquired antiplatelet antibodies when a mother becomes sensitized to paternal antigens on fetal platelets. Maternal immune thrombocytopenia may also affect the fetus, producing thrombocytopenia in utero. However, the incidence of neonatal cerebral hemorrhage is much lower in immune thrombocytopenia than in alloimmune thrombocytopenia. Vitamin K deficiency should be considered for breast-fed full-term neonates who present with intracranial hemorrhage. In the absence of recognized coagulation or anatomic abnormalities, cerebral hemispheric IPH has been attributed to hemorrhagic infarction. In premature infants, parenchymal hemorrhage most often occurs in conjunction with severe IVH (Fig. 29.29). Hemorrhage from the friable, unsupported germinal matrix leads to accumulation of intraventricular blood, and often ventricular distention. These events, in turn, cause impairment of blood flow in the medullary veins located in the periventricular white matter, preventing blood drainage into the greater cerebral venous system. Eventually, the periventricular venous congestion leads to ischemia and a resultant venous infarction.

Developmental outcome in full-term infants with IPH depends on the location and extent of the underlying cause. The occurrence of posthemorrhagic hydrocephalus or of moderate-to-severe asphyxia is predictive of abnormal outcomes, including motor impairment or cognitive delay. In premature infants, the simultaneous occurrence of IVH with IPH carries high risk for major motor deficits and marked cognitive impairment.

Evaluation of Stroke in Infants

Head ultrasonography detects areas of increased echogenicity in the cerebral cortex. In especially severe cases of ischemia, increased echogenicity of injured subcortical structures such as the thalamus and basal ganglia can be appreciated. Ischemic cortical injury involving the territory of the middle cerebral artery (frontal and parietal lobe regions surrounding the central sulcus) is better revealed by ultrasonography than are other vascular territories. The principal advantages of cranial ultrasonography are its easy portability to the patient's bedside and its lack of radiation exposure to the infant.

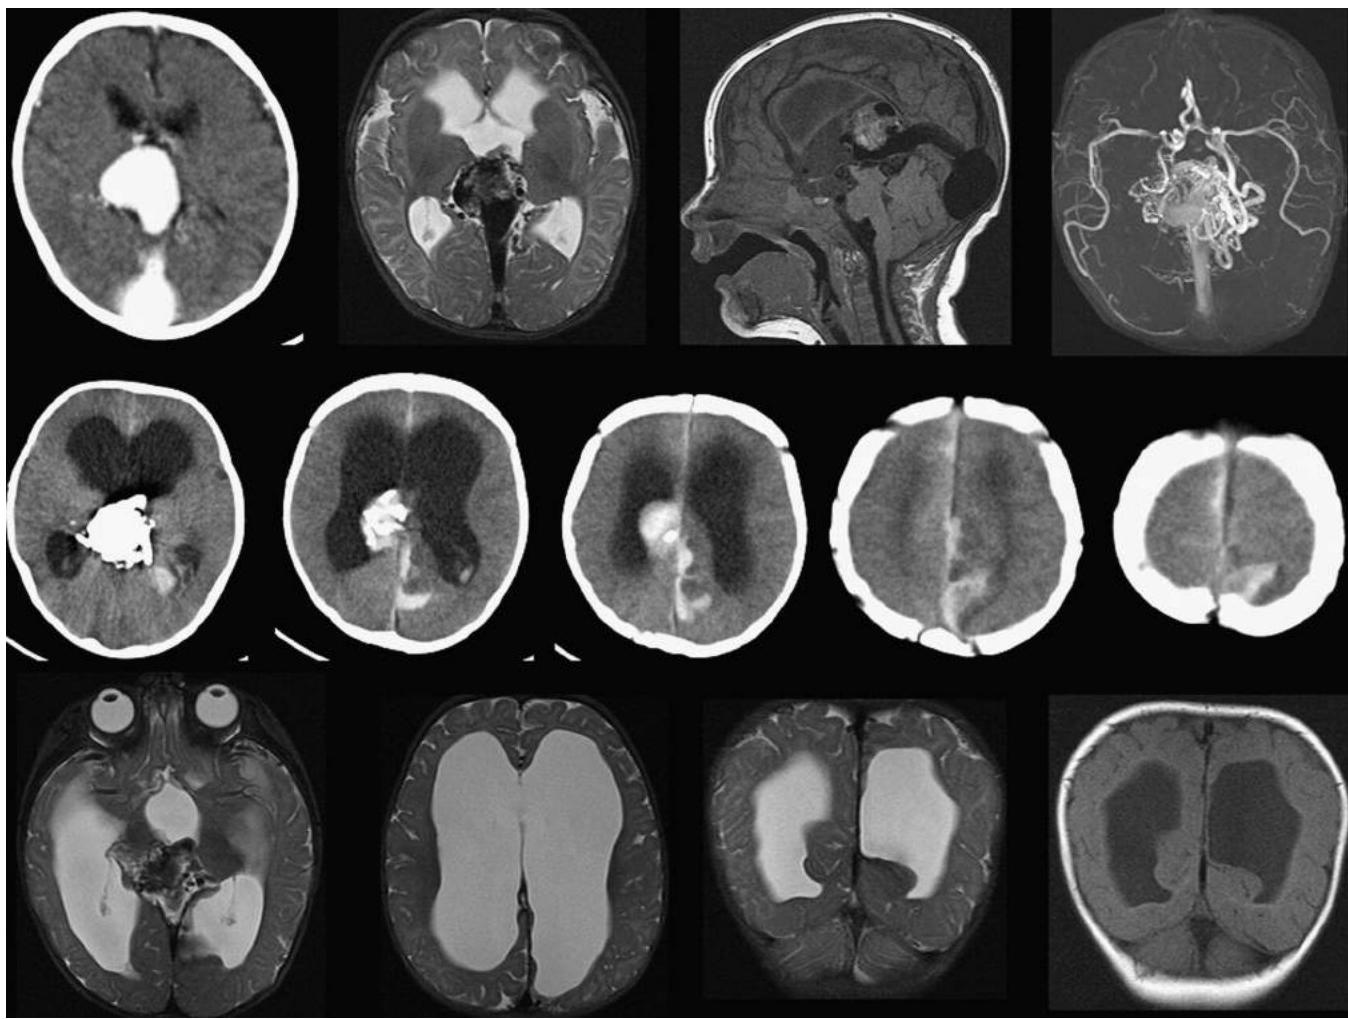
CT of the brain is particularly useful for evaluation of full-term infants after a suspected cerebral insult. Diffuse injury appears as abnormal generalized attenuation throughout the cerebral parenchyma with a loss of the distinction between gray and white matter;


FIGURE 29.28 Neonatal Vein of Galen Malformation and Intraventricular Hemorrhage. A 5-day-old female born at 38 weeks was noted to be drowsy with poor feeding. She had signs of cardiac failure. A computed tomography (CT) scan *(top left)* demonstrates vein of Galen aneurysmal malformation, which was partly treated by transarterial glue embolization without complication but with significant residual arteriovenous shunting (MR images, *top row*). Following a 2nd embolization procedure, there was acute clinical deterioration with signs of raised intracranial pressure *(middle row)*. CT shows acute intraventricular hemorrhage and hydrocephalus, and a left parieto-occipital lobe low-density lesion (*middle*, images 1-3) with adjacent subarachnoid and subdural hematoma (*middle*, images 4-5). Some linear hyperdensity was believed to be due to thrombus within the persistent falcine sinus (*middle*, images 4-5). Follow-up imaging shows maturation of the focal left parieto-occipital lesion in keeping with an infarct *(bottom row)*, which is probably venous in origin. (With permission from Gunny RS, Lin D. Imaging of pediatric stroke. *Magn Reson Imaging Clin North Am.* 2012;20:1-33.)

this abnormality may represent cerebral edema. Focal and multifocal brain injury is readily detected by cranial CT.

MRI scans obtained within the first 4 days of life in full-term infants with signs of severe HIE reveal white matter abnormalities and indistinct gray matter–white matter junctions on T2 weighted images. **DWI** can identify areas of recent infarct even earlier than conventional T1 and T2 weighted images. Subsequent images can show chronic changes such as cerebral atrophy, paucity of white matter, delayed myelination, and ventriculomegaly. MRI has proved useful in documenting delay of myelination, a sequela to perinatal ischemic white matter injury not readily discerned with CT. This additional capability has provided a potential explanation for subtle motor deficits found in children who have ischemic brain injury in the perinatal period. MRI also detects neonatal hypoxic-ischemic injuries of basal ganglia not well detected by either head ultrasonography or CT. Moreover,

MRI with venography is the procedure of choice in the neonatal period for identification of venous thrombosis.

Laboratory testing for the wide variety of etiologic factors underlying stroke should be conducted. The causes include infection, liver dysfunction, coagulopathy, prothrombotic states, organic and amino acid inborn errors of metabolism, urea cycle disorders, and mitochondrial abnormalities.

CHILDREN AGED 1-13 YEARS

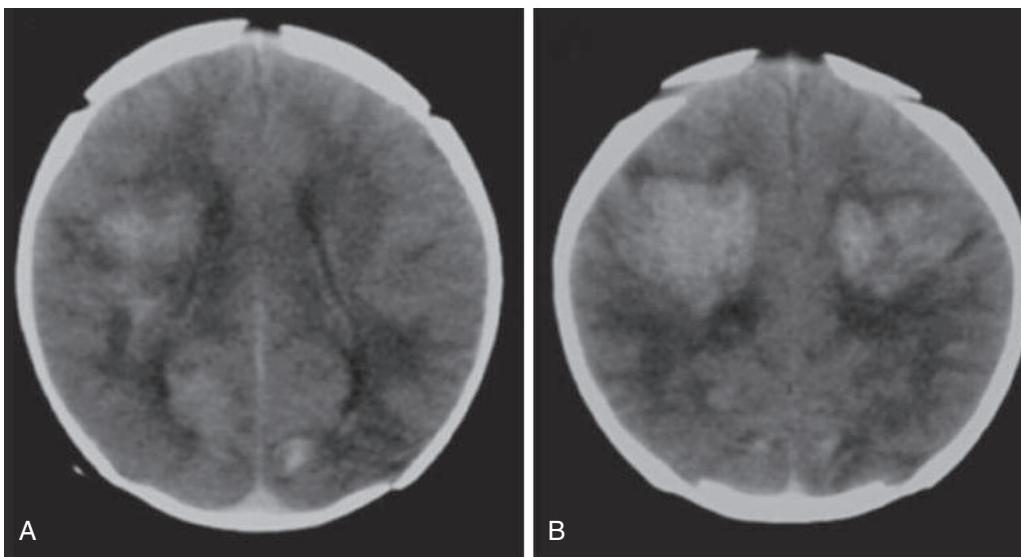
When stroke occurs in children, focal symptoms are reported and corresponding localized deficits are noted on the neurologic examination, which correlate anatomically with the involved region of the CNS (see Table 29.22). Lateralized weakness often signifies injury to the contralateral hemisphere, including the regions governing movement. Such


FIGURE 29.29 Neonatal Intraventricular and Intraparenchymal Hemorrhages. A term baby delivered by Cesarean section for thick meconium and late decelerations, Apgar scores of 1, 6, and 8 (at 1, 5, and 10 minutes), presented with neonatal seizures on the 1st day of life. *A* and *B,* Axial head computed tomography images show bilateral frontal, parietal, and scattered occipital hemorrhages in the periventricular and subcortical white matter, the largest in the frontal centrum semiovale. (With permission from Gunny RS, Lin D. Imaging of perinatal stroke. *Magn Reson Imaging Clin North Am.* 2012;20:1-33.)

motor impairment accompanied by cranial nerve dysfunction on the side of the head opposite to the side of extremity weakness suggests brainstem infarction at a location above the pyramidal decussation. Findings of the sensory examination also may be helpful. Preservation of primary sensory modalities provides assessment of spinothalamic axis (pain and temperature) and posterior column (proprioception) integrity. Loss of pain and temperature sensation on one side of the body combined with motor weakness and the presence of proprioceptive deficits on the other side indicate that the cerebrovascular event is in the spinal cord. If the same distribution of motor and sensory disturbances occurs but is accompanied by cranial nerve dysfunction, a brainstem site of injury is likely. Finally, impairment of cortically based sensations such as graphesthesia and stereognosis on one side of the body implies a contralateral hemispheric cause of the observed cortical sensory deficit.

Analysis of language function in the older child may provide help in localizing the region of the cerebrovascular event. Unilateral lesions of the dominant hemisphere involving the frontal lobe immediately anterior to the motor strip supplying the face result in characteristic speech disturbance, Broca aphasia. Broca (nonfluent) aphasia consists of the patient's inability to utter or to write the words or phrases that he or she wishes to express. Although the patient knows the thoughts that he or she wishes to express, the volitional motor function for written or oral expression cannot be mustered. Infarction in the more posterior superior temporal lobe results in an aphasia of a different type, Wernicke aphasia, characterized by marked impairment of auditory comprehension. Comprehension of written matter may be impaired as well. Although the patient remains fluent in speech, language is peppered with unintelligible utterances that are meaningless (neologisms) or are similar but incorrect versions of the intended word (paraphasias). The larger the injury to this region, the more severe is the impairment of language. Speech in most right-handed people and in 50% of left-handed people is governed by the left hemisphere (so-called left hemispheric dominance). The remaining minority share right hemispheric dominance.

The causes of stroke in 1- to 13-year-old children may be considered in 2 general groups: (1) ischemic stroke and (2) intracranial hemorrhage. The ischemic category comprises embolic, thrombotic, and hypotensive causes of stroke. The category of intracranial hemorrhage includes both IPH and SAH.

Ischemic Stroke in Children
Congenital Heart Disease
Congenital heart disease remains the most common diagnosable cause of stroke in childhood. Children with cyanotic congenital heart disease (right-to-left shunts or mixing lesions) face the greatest risk. An embolic stroke constitutes the most common cerebrovascular event. Cardiac defects involving right-to-left shunts allow emboli originating in peripheral venous circulation to bypass their filtration and removal by the pulmonary vascular bed. Thus, emboli entering the heart via venous return may be shunted to the peripheral arterial circulation, only to lodge in the cerebrovascular tree (Fig. 29.30).

Patent foramen ovale contributes significantly to the occurrence of stroke in children. Echocardiographic evaluation of patients who have had stroke reveals patent foramen ovale or evidence of right-to-left shunting in many. Transesophageal echocardiography conducted with Valsalva bubble studies for evidence of direct right-to-left flow is the most useful diagnostic test.

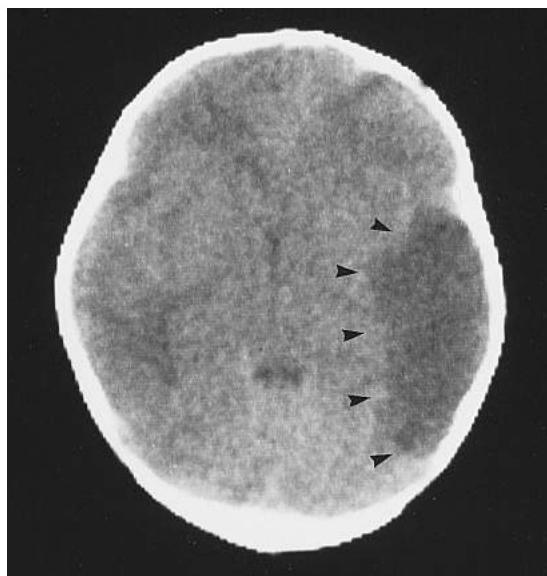
Valvular defects can cause stroke. Mitral valve prolapse may contribute to the occurrence of embolic stroke. Small emboli are dislodged from the abnormal valve leaflets. Mitral valve prolapse has been estimated to underlie 20-30% of strokes in patients younger than 30 years. Echocardiography in both 2-dimensional and M modes proves most helpful in discerning the cardiac valvular abnormality. Rheumatic valvular disease (mitral, aortic), once a common cause of embolic stroke, has become an infrequent cause of childhood stroke. Infected valves in bacterial endocarditis pose a considerable risk for the occurrence of embolic stroke (native, prosthetic, rheumatic, or congenitally abnormal valve). Mitral and aortic valvular vegetations may dislodge and travel distally to occlude cerebral arteries. The most common


FIGURE 29.30 Computed tomography scan of a 3-month-old boy with trisomy 21 and tetralogy of Fallot who, after cardiac catheterization, had focal seizures involving the right side of the face and right arm. Region of hypodensity in the left hemisphere *(arrowheads)* reflects infarction of the left middle cerebral artery territory, most likely caused by embolic occlusion of that vessel.

TABLE 29.31 **Autoimmune Disorders Associated with Central Nervous System (CNS) Involvement**	
Disorder	**CNS Manifestations**
Systemic lupus erythematosus	Migraine headache, seizures, stroke, cerebellar dysfunction, transverse myelopathy, aseptic meningitis, psychosis
Mixed connective tissue disease	Seizures, stroke, cerebellar dysfunction, trigeminal neuropathy
Polyarteritis nodosa	Migraine headache, stroke, subarachnoid hemorrhage, seizures
Granulomatosis with polyangiitis	Migraine headache, subarachnoid hemorrhage, stroke
Takayasu arteritis	Seizure, stroke
Henoch–Schönlein purpura	Headache, stroke, seizures, chorea
Primary CNS vasculitis	Headache, stroke, seizure

organisms found are streptococci and staphylococci (see Chapter 8). Even after vegetations have been successfully sterilized, they may embolize and cause stroke. Emboli from infected valvular vegetations may embolize, travel to the cerebral vasculature, and seed the adventitia of the cerebral vessel. The resultant infection and inflammation result in weakening of the vessel and development of a mycotic aneurysm. Aneurysms may lie dormant for some time before their rupture leads to SAH or IPH and resultant neurologic signs.

Procoagulopathies

Several disorders of coagulation can lead to embolic or thrombotic stroke (see Table 29.23). Adverse consequences of antiphospholipid antibodies have been identified in all age groups. Children, adolescents, and young adults experience the cerebrovascular consequences of these antibodies most often. Antiphospholipid antibodies, including the lupus anticoagulant (LAC), are polyclonal antibodies found in serum that are able to bind to both neutral and negatively charged phospholipids (see Chapter 38). LAC and anticardiolipin antibodies were 1st associated with thrombotic or embolic cerebrovascular events in patients with systemic lupus erythematosus (SLE). Subsequently, patients suffering stroke with no evidence of underlying immune-mediated illness other than the LAC or anticardiolipin antibody were found. The antibody prolongs the partial thromboplastin time (PTT) in vitro but acts as a procoagulant in vivo. A common finding associated with coagulation testing among children with AIS is the presence of anticardiolipin antibody. The presence of these antibodies in a patient who concurrently smokes cigarettes, has findings positive for antinuclear antibodies, or suffers from hyperlipidemia may impart a higher risk for stroke than if the patient carries the antibody alone. The antibody's presence is indicated by a prolonged PTT and a falsely positive serum Venereal Disease Research Laboratory (VDRL) result. The antibody's presence can be conclusively demonstrated functionally and immunologically. Although cerebral infarction and TIAs constitute the most frequently observed neurologic manifestations related to the presence of these antibodies, migraine headache, seizures, and monocular visual disturbances are also associated.

Absence of specific serum proteins that act as inhibitors of coagulation may lead to stroke. Two of these proteins, protein S and protein C, have been associated with thrombotic or embolic cerebrovascular disease. Protein C and its cofactor protein S act as anticoagulants and synergistically attenuate coagulation by deactivating the activated forms of factors V and VIII. Absence of (or resistance to) either of these proteins disrupts the balance of coagulation toward increased spontaneous clotting and can result in stroke. In addition, antithrombin III opposes the action of the activated forms of factors II, IX, X, XI, and XII through the irreversible formation of inactivating complexes with these factors. Deficiencies of proteins S and C as well as of antithrombin III may cause arterial thrombotic or embolic stroke or venous infarction. Although their deficiencies are often congenital, they may be acquired through liver disease or nephrotic syndrome. Factor V Leiden, prothrombin 20210A, and lipoprotein A are all important factors that may contribute to the pathogenesis of AIS. Elevated lipoprotein A, protein C deficiency, and sickle cell anemia increase the risk of recurrent strokes. A screening battery of tests, including prothrombin time, PTT, and specific immunologic and functional testing for the proteins suspected of being deficient is essential for diagnosis. Cranial radiation therapy may induce an occlusive vasculopathy, leading to focal cerebral ischemia.

Autoimmune Disorders

Autoimmune disorders may cause neurologic disturbance and cerebrovascular involvement (Table 29.31). Symptoms of abrupt onset with accompanying deficits referable to the CNS have long been associated with SLE. A CNS vasculitis had been presumed to underlie the CNS manifestations of SLE; however, an autopsy study of patients who suffered from SLE revealed a virtual absence of cerebrovascular inflammation. Rather, small areas of infarction relate to proliferative changes in cerebral arterioles that lead to luminal occlusion. Large areas of infarction are more probably related to LAC-derived thromboembolism or to embolism from the sterile cardiac valve leaflet vegetations associated with SLE (Libman–Sacks endocarditis). Additional causes of CNS illness include thrombocytopenic hemorrhage, steroid-induced pseudotumor or psychosis, and CNS infection.

True **cerebral arterial vasculitis** may be an isolated disease or seen in association with recognizable systemic autoimmune disorders. Isolated angiitis of the CNS may affect small, medium-sized, or large vessels. Multiple regions of infarction are often found on MRI.

Neuropathologic evidence of polymorphonuclear leukocyte or monocyte infiltration leading to intimal proliferation and vessel wall necrosis is found. The inflammation affects blood flow and predisposes to thrombosis.

Stroke may occur in the course of **polyarteritis nodosa**. Involvement of the CNS is found in 20-40% of such patients.

Granulomatosis with polyangiitis (formally known as Wegener granulomatosis), a necrotizing vasculitis of the upper pulmonary system, rarely affects the CNS; stroke is uncommon. When the CNS is affected, extension of sinus or nasal inflammation into the basilar skull frequently has occurred.

Mixed connective tissue disease, which clinically overlaps with polymyositis, SLE, and progressive systemic sclerosis, can involve the CNS. Cranial neuropathy, most commonly trigeminal nerve dysfunction, has been the most frequently cited deficit. Stroke manifesting as sudden-onset hemiparesis and aphasia has been reported in children afflicted with mixed connective tissue disease.

Takayasu arteritis, involving the aorta and its principal branches, has been associated with thrombotic stroke. Inflammation-induced luminal constriction leading to thrombosis is thought to cause cerebral ischemia in children.

Necrotizing arteritis with inflammatory infiltrate has been found in both meningeal and cerebral vessels of children suffering from Henoch–Schönlein purpura. Both fixed and transient deficits may occur in this disorder.

Inflammation of cerebral vessels may also occur in the course of bacterial meningitis. The subarachnoid arteries become immersed in exudate. The vessel wall is affected by the inflammatory process. If this condition proceeds long enough, thrombophlebitis ensues. Vascular occlusion results, with consequent features of stroke.

Metabolic Disorders Causing Stroke

Homocystinuria, a disorder of homocysteine metabolism, can cause thrombotic stroke in children. Abnormal homocysteine metabolism results from 1 of 3 inheritable enzymatic defects. The most striking phenotype results from deficiency of cystathionine synthetase, the enzyme that facilitates the catabolism of homocysteine to cystathionine. This leads to accumulation of not only homocysteine but also methionine. Children affected by this autosomal recessive disorder (Table 29.32) have marfanoid habitus, global developmental delay, lens dislocation, and thromboembolism. Thromboemboli may travel to cerebrovascular beds, causing stroke. Serum hyperhomocystinuria injures the vascular endothelium. The denuded vessel wall then becomes a site for thrombosis. The resulting thrombus may remain at its site of origin or it may embolize to a distal locus. Therefore, stroke may have thrombotic or embolic characteristics. Both arterial and venous infarctions may result. Some patients without homocystinuria but with elevated homocysteine levels may be at risk for vascular morbid conditions, including stroke.

Sulfite oxidase deficiency, another autosomal recessive disorder, results in the accumulation of serum sulfite. The associated phenotype may result from deficiency of either the enzyme or its associated and essential pterin-containing molybdenum cofactor. Intellectual disability, seizures, lens displacement, and acute hemiplegia result. The mechanism of the strokelike episodes has not been fully elucidated. It is possible that ischemic mechanisms are not involved and that direct metabolic neurotoxicity accounts for the sudden onset of deficits resembling those of stroke. Sulfites and S-sulfocysteine accumulate in urine.

Fabry disease, a lipid storage disease attributable to ceramide trihexosidase deficiency, results in accumulation of the sphingolipid trihexoside in the kidneys, vascular endothelium, and corneas. Symptoms

TABLE 29.32	**Genetic Causes of Stroke**

Thrombotic/Embolic Stroke
Homocystinuria or elevated homocysteine levels
Fabry disease
Fibromuscular dysplasia
Procoagulopathies (protein C/S deficiency; antithrombin III; factor V Leiden; prothrombin 20210A mutation; methylenetetrahydrofolate reductase mutations)
Sickle cell anemia

Hemorrhage
Factor VIII deficiency
Factor IX deficiency
Factor XI deficiency
Familial intracranial aneurysm
Sickle cell disease
Familial cavernous angioma
Glanzmann thrombasthenia
X-linked thrombocytopenia

Unknown Mechanism
Familial porencephaly
Organic acidemia
Mitochondrial disorders

Rare Monogenic Disorders
APP, *CST3*, *BRI* genes (autosomal dominant amyloid angiopathies)
NOTCH3 gene (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy [CADASIL])
KRIT1 gene (cavernous angiomas)

become apparent in childhood or adolescence. Angiokeratomas and painful paresthesia often constitute the 1st symptoms. Renal failure follows. However, because of endothelial accumulation of sphingolipid in vessel walls, cerebrovascular occlusion results in stroke. Recurrent stroke is common in this rare X-linked disorder.

The manifestations of **mitochondrial disorders** include recurrent and sometimes catastrophic stroke. The syndrome of mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes (MELAS) manifests in childhood and results from a mutation of mitochondrial DNA. The most common biochemical finding is a deficiency of complex I of the electron transport chain. An elevated serum or cerebrospinal fluid lactate level serves as its chemical signature, and molecular confirmation of the diagnosis can be secured from blood. Although some features of MELAS are shared by other mitochondrial syndromes, hemiparesis of abrupt onset is fairly specific for this syndrome. An excruciating headache resembling migraine may precede the strokelike episodes. Seizures and sensorineural hearing loss are almost always present at some point in the course of the illness. Neuropathologic study of brains from patients with MELAS has shown cystic cavities and necrosis of cortex with relative sparing of white matter.

Other metabolic disorders have been associated with stroke in childhood. Urea cycle defects, especially ornithine transcarbamylase deficiency manifesting in girls, can cause stroke. Deficiency of arginase, another important enzyme of the urea cycle, has been observed in association with hemiparesis and diparesis of subacute onset. Finally, familial lipoprotein disorders, especially those featuring a dearth of high-density lipoprotein or an abundance of triglycerides, have been associated with stroke in children. In most cases, a family history of hyperlipidemia is found.

Moyamoya Disease

Moyamoya disease commonly affects children younger than 15 years and manifests with TIAs or sudden-onset fixed motor deficits. Progressive narrowing and occlusion of the intracranial portion of the internal carotid arteries are characteristic. Endothelial proliferation, fibrosis, and intimal thickening characterize the vascular disease. Resultant proliferation of collateral vessels from the basilar skull circulation creates an intricate latticework of compensatory blood flow. The appearance on angiography is characteristic and consists of a fine vascular network located at the base of the brain. Moyamoya means "hazy" or "puff of smoke" as seen on conventional angiography (Fig. 29.31).

Children usually present with acute hemiplegia as a result of uncompensated occlusion of the internal carotid artery. Because the anatomic abnormality is often bilateral, the hemiplegia may alternate. Disturbance of fine motor function has been observed. Chorea has been reported in association with moyamoya disease. The designation moyamoya syndrome is given when the progressive distal internal carotid artery occlusion occurs as a sequela to a primary disorder such as sickle cell disease, neurofibromatosis, trisomy 21, tuberculous meningitis, and fibromuscular dysplasia. Evidence suggesting a hereditary origin in some cases has been reported in Japan.

Sickle Cell Disease

Acute hemiplegia may be found in children with sickle cell disease (see Chapter 37). Strokes are designated as overt, meaning clinically symptomatic, or silent, in which no symptoms occur but changes are seen on brain imaging. The incidence of overt strokes is 11% in children with HbSS by 20 years and silent strokes occur in up to 37% of children. It may be an isolated event, or it may occur in the setting of a sickle crisis. Sickle cell disease–related cerebral vasculopathy encompasses stroke, TIA, SAH, and moyamoya syndrome. Neurologic signs include hemiparesis, aphasia, and visual disturbances. Neuroimaging studies, particularly MRI, reveal that stroke occurs in watershed distributions between 2 cerebrovascular territories, affecting both the gray and white matter of the cortex. Children with sickle cell disease who have silent infarctions may demonstrate school dysfunction as the only manifestation of neurologic involvement of the disease. These children can demonstrate twice the rate of school difficulties found in children with sickle cell disease without infarctions. Recurrences are common.

The proposed pathophysiologic mechanisms encompass both sickling and progressive stenosis in cerebral vessels. Sickled red blood cells (RBCs) through arteries and capillaries alter the rheology and activate endothelial proliferation in large vessels, ultimately leading to stenosis. Angiography demonstrates large-vessel vasculopathy in the internal carotid arteries and middle cerebral arteries, which on microscopic analysis reveal endothelial proliferation, disruption of the elastic lamina, and microthrombi. Furthermore, there is increased RBC adhesion, endothelial activation, inflammation, and coagulation dysregulation. Cerebral hyperemia thought to be caused by vasodilation has been suggested as a mechanism contributing to the occurrence of watershed infarctions in patients with sickle cell disease.

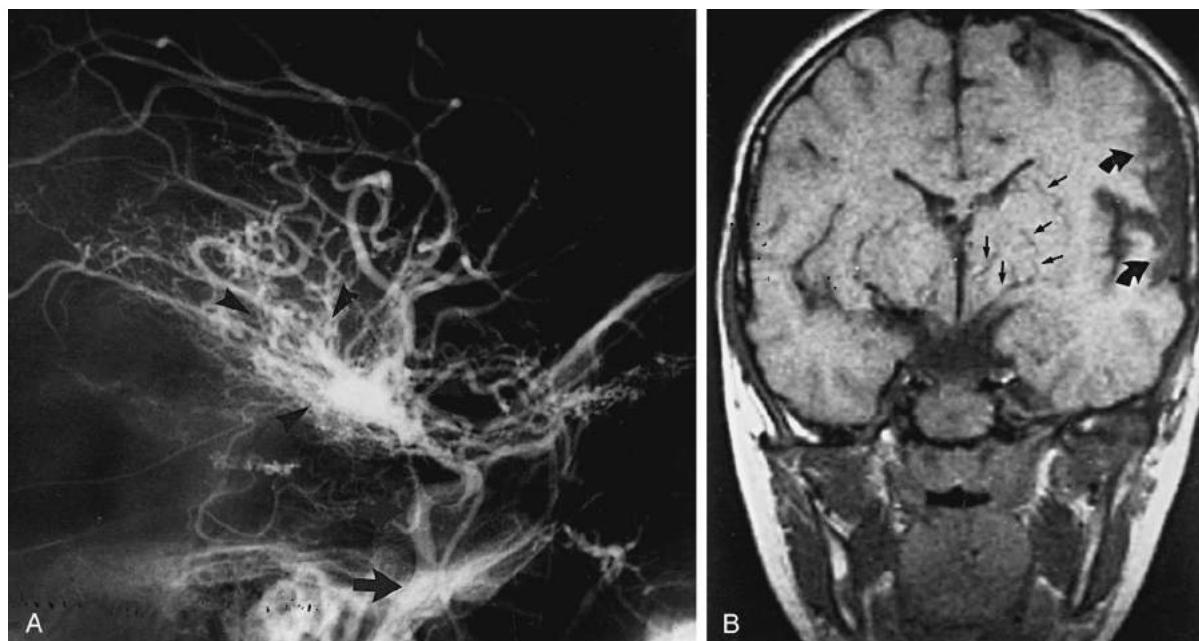
SAH also occurs among children with sickle cell disease. The frequency of SAH is less than that of infarction, occurring in fewer than 2%. The clinical findings of SAH differ from those of infarction in patients with sickle cell disease. Severe headache, vomiting, and alteration in mental state characterize SAH in children with sickle cell disease. Meningeal signs and focal neurologic deficits may be found on examination. Angiography should be performed on all patients to detect any surgically correctable vascular lesion underlying the hemorrhage.


FIGURE 29.31 Sudden onset of right hemiparesis in a 6-year-old boy. *A,* Cerebral angiogram shows the left internal carotid artery *(arrow)* leading to a highly arborized, telangiectatic network of vessels *(arrowheads)* typical of moyamoya disease. The typical middle cerebral artery vascular tree is absent. *B,* Cranial coronal magnetic resonance imaging scan shows region of low signal in the middle cerebral artery territory and denotes infarction *(curved arrows)*. Flow voids in the basal ganglia *(straight arrows)* are radiographic manifestations of the basilar collateral circulation typical of this vascular anomaly.

(See *Nelson Textbook of Pediatrics,* p. 1065.)

Intracranial Hemorrhage
Coagulopathies

The hemophilias (A and B) are X-linked disorders that may result in intracranial bleeding. Bleeding may occur in either intraparenchymal or subarachnoid locations. Hemophilia A arises from factor VIII deficiency. Patients with this disorder may experience intracranial bleeding in association with head trauma. Unfortunately, spontaneous intracranial bleeding not associated with head trauma also occurs. The risk of spontaneous bleeding rises with the severity of factor VIII deficiency.

Hemophilia B derives from a deficiency of factor IX. Intracranial bleeding is seen less frequently among these patients than among patients with hemophilia A. Hemophilia B is encountered much less frequently than hemophilia A, and this difference may account for the less frequent observation of intracranial bleeding. Clinical symptoms depend on the intracranial location of the hemorrhage. If the bleeding occurs in the subarachnoid space, symptoms of severe headache, nuchal rigidity, and meningismus are found. Mental status is frequently altered. If bleeding occurs within brain parenchyma, focal features, including hemiparesis, may be found.

Thrombocytopenia

Severe thrombocytopenia rarely leads to cerebral hemorrhage, especially if the cause is idiopathic (immune) thrombocytopenic purpura. Thrombocytopenia caused by bone marrow failure (drug-induced suppression, aplastic anemia, malignancy) may pose a greater risk. Significant risk of intracranial hemorrhage is thought not to occur until the platelet count is less than 20,000/mm^3. Small petechial hemorrhages into white matter are thought to be more common than are large parenchymal hemorrhages.

Causes of thrombocytopenia include idiopathic immune thrombocytopenic purpura, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, infection, and malignancy (replacement of bone marrow or drug-induced suppression). The features of these underlying causes dominate the clinical picture (see Chapter 38).

Vascular Malformations

AVM of the brain is the most common cause of intracranial hemorrhage in preadolescent children. The malformation represents a developmental anomaly that manifests with hemorrhage much more frequently in children than in adults. The AVM consists of dilated vascular channels, some of which reveal the highly muscularized walls of arterioles. Gliotic neural tissue resides in and among the vascular branches of the malformation. It is more common in boys. The most frequent presenting events associated with AVM in children are seizures and hemorrhage. Most AVMs reside in the cerebral hemispheres; 10% arise in the posterior fossa.

The clinical features of AVM hemorrhage consist of those found in IPH. Focal features depend on the area of brain in which the bleeding has occurred. A higher mortality rate has been observed in children than in adults harboring hemorrhagic AVMs. The risk of hemorrhage from an unruptured AVM is approximately 3% per year. The introduction of MRI has led to better localization of the malformation (Fig. 29.32).

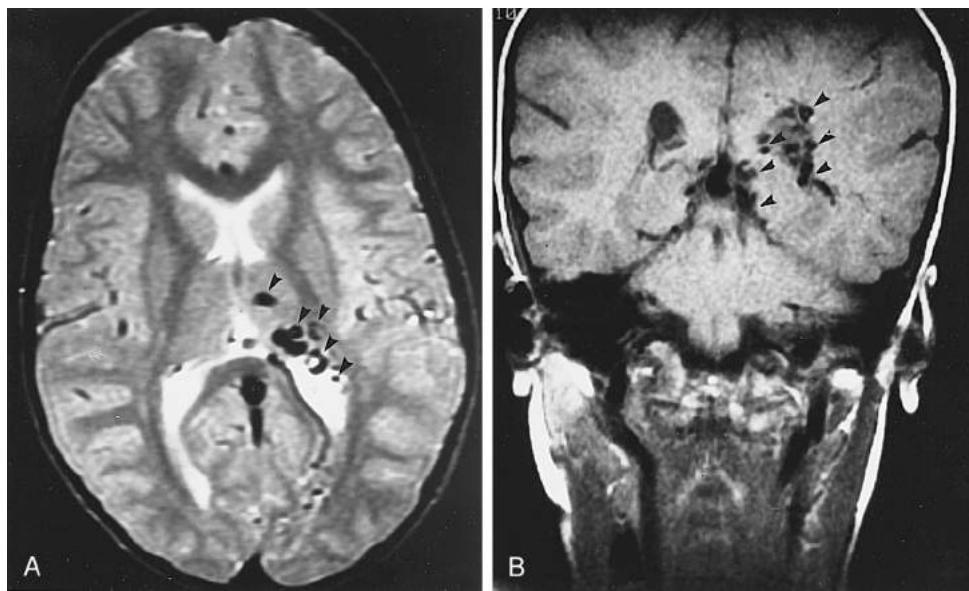
Intracranial aneurysms constitute the most common cause of intracranial bleeding in all patients younger than 20 years and are more frequent in boys. The most common site of aneurysmal bleeding in children is along the intracranial portion of the internal carotid artery. The vertebral and basilar arteries are other common sites of intracranial aneurysm in children. In addition, intracranial aneurysms discovered in children tend to be larger than those found in adults. Although most aneurysms constitute vascular developmental anomalies, other causes exist, including mycotic aneurysms associated with bacterial endocarditis (Fig. 29.33). Acquired cerebral artery aneurysms have been reported in children infected with the human immunodeficiency virus. Intracranial aneurysms are found with increased frequency among patients suffering from polycystic renal disease, those with aortic coarctation, and those with Ehlers–Danlos syndrome in comparison with the general pediatric population. Intracranial aneurysms have been noted to exist in close association with AVMs in some pediatric cases.


FIGURE 29.32 Cranial magnetic resonance imaging scan of a 6-year-old girl with recurrent headache. *A,* Axial view demonstrates flow voids deep in the left hemisphere near the lateral ventricle *(arrowheads),* consistent with arteriovenous malformation. *B,* Coronal view through parietal lobes also demonstrates numerous flow voids *(arrowheads)* indicative of arteriovenous malformation.
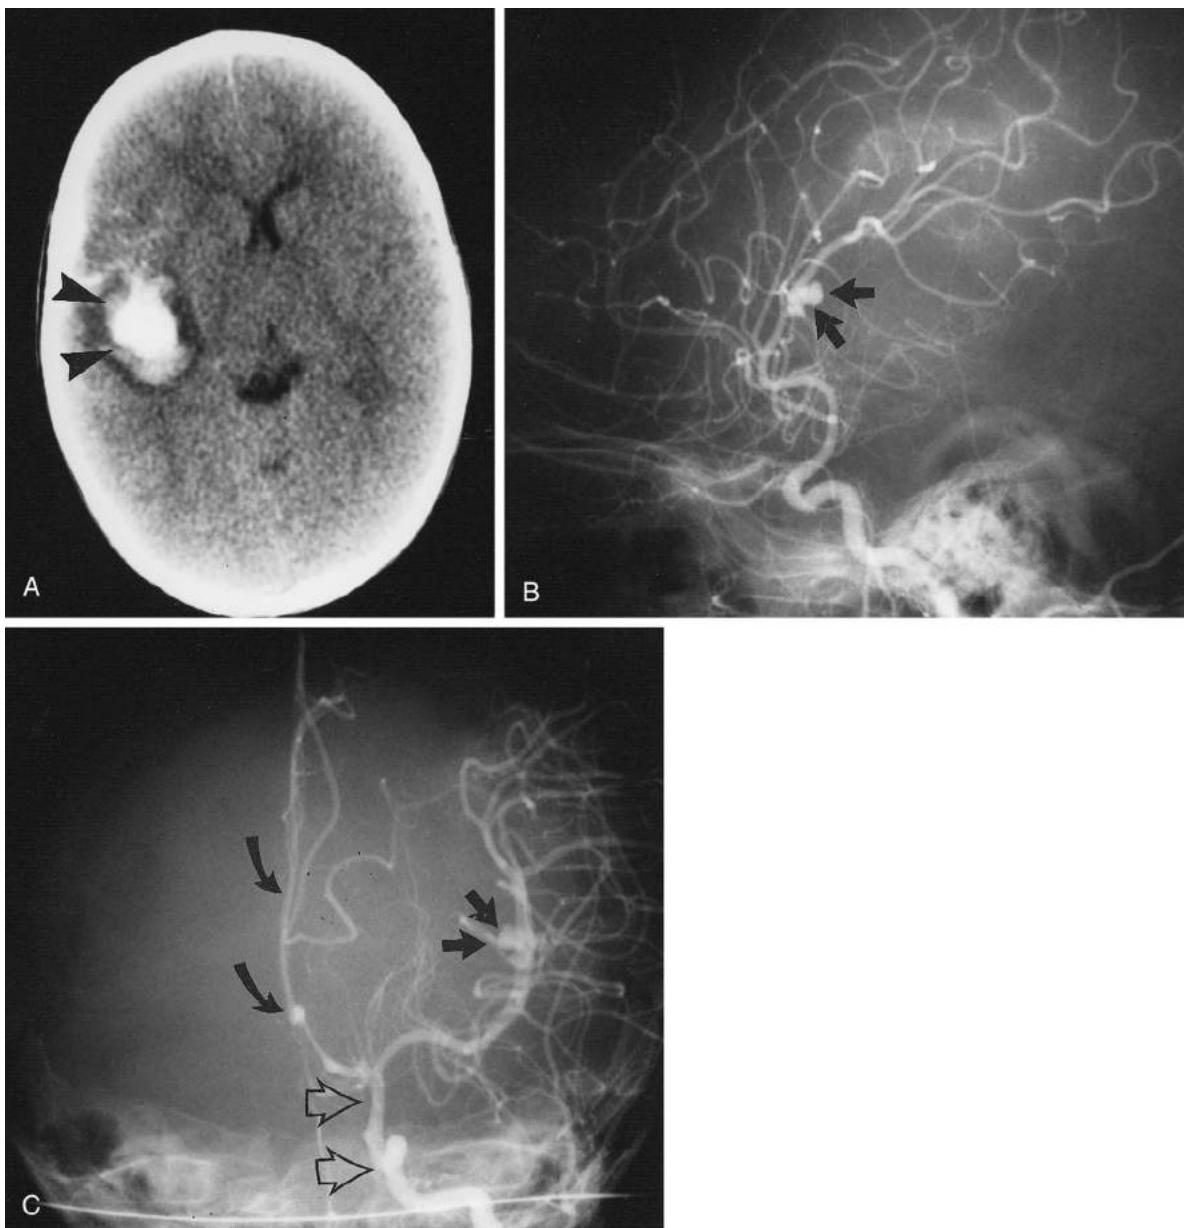

FIGURE 29.33 Mycotic Cerebral Aneurysm Hemorrhage. *A,* A cranial computed tomographic scan reveals a hyperdense area in the left temporal lobe *(arrowheads)* representing intraparenchymal hemorrhage. *B,* Cerebral angiography in a lateral view shows a lobulated structural abnormality representing the mycotic aneurysm, most probably residing in the middle cerebral artery tree *(arrows). C,* An anteroposterior angiographic view confirms the location of the aneurysm in the middle cerebral artery *(straight arrows)* located laterally rather than in the more medial anterior cerebral artery *(curved arrows).* The internal carotid artery *(open arrows)* gives rise to both the anterior and the middle cerebral arteries.

All affected patients should be studied with angiography after aneurysmal bleeding. Patients should be closely observed for development of hydrocephalus and increased intracranial pressure. Aneurysmal bleeding resulting in significant SAH can precipitate cerebral vasospasm. Vasospasm, in turn, can cause a secondary cerebral infarction. Vasospasm occurs most commonly 7-10 days after the aneurysmal bleeding. Prophylaxis is the most effective treatment for vasospasm. Maintenance of blood pressure through intravascular volume expansion has been shown to reduce the incidence of posthemorrhagic vasospasm.

The syndrome of posterior fossa brain malformations, facial hemangiomas, arterial anomalies, coarctation of the aorta, and cardiac and eye defects (**PHACE**) is a constellation of disorders. CNS malformations affect the posterior fossa and include Dandy–Walker malformation, arachnoid cysts, cerebellar hypoplasia, and enlarged cisterna magna. Vascular anomalies include brachiocephalic artery and aortic arch anomalies (coarctation of aorta), cerebrovascular arterial hypoplasia, aneurysms, stenosis and aberrancies, and progressive occlusive arterial disease leading to stroke.

Evaluation of Stroke in Children

Neuroimaging provides the foundation of evaluation. Intracranial blood is rapidly seen with CT. The early stages of ischemic stroke, however, are detected with difficulty. MRI provides evidence of

ischemia in the early stages of stroke. Magnetic resonance angiography (MRA) has provided reliable information about the blood flow in and the structure of large intracranial vessels. Small intracranial vessels are poorly seen on MRA, however, and invasive contrast angiography remains the radiologic procedure of choice for full elucidation of the cerebral vasculature (see Fig. 29.19). Laboratory studies helpful in the evaluation of the child who has suffered stroke are determined by the patient's clinical features (Table 29.33).

ADOLESCENTS

The causes of adolescent stroke include those discussed for preadolescent children. Determination of stroke mechanism—embolic, thrombotic, or hemorrhagic—remains important. Nonetheless, stroke among adolescents may also be caused by other entities not commonly found in neonates or preadolescent children.

Fibromuscular Dysplasia

Fibromuscular dysplasia involves arteries throughout the body. First described in renal arteries, the pathologic features of fibromuscular dysplasia have been found in carotid, vertebral, and intracranial arteries. Fibromuscular dysplasia involves irregularly spaced focal zones of fibrous and muscular hyperplasia of the media, disruption of the elastic lamina, and eventration of the media. The constricted regions of vascular fibrosis alternate with regions of luminal dilation to create the characteristic beaded appearance on angiography. Fibromuscular dysplasia is more common in young girls and has been found in adolescents; with carotid involvement, a bruit may be auscultated in the neck. If renal arteries are affected, hypertension may be present. Neurologic symptoms signifying cerebrovascular involvement most commonly consist of TIAs and mild strokes. A thrombotic mechanism is presumed but has never been proven.

Sexual Activity, Oral Contraception, and the Puerperium

Sexual intercourse generates marked increases in systemic blood pressure. Sustained hypertension elevates the risk of hypertensive intracranial hemorrhage. The risk for such a hemorrhage is heightened by the existence of an intracranial aneurysm or arteriovenous hemorrhage.

Oral contraceptives have been associated with stroke in young women. In some series, the combination of migraine headache and concurrent oral contraceptive use has been cited as a risk factor for stroke.

Pregnancy and the postpartum state have been considered periods of hypercoagulability. In addition, venous stasis increases. These 2 factors are believed to promote the occurrence of cerebral venous thrombosis and resultant cerebral venous infarction in pregnant patients and in patients immediately after parturition. Frequently, the initial manifestation is headache. Seizures, either focal or generalized, are common. Acute hemiparesis is the most common focal feature on neurologic examination. Papilledema can appear as intracranial pressure rises caused by resultant venous outflow obstruction in the head. The appearance of these signs or symptoms in a gravid or postpartum adolescent should raise suspicion about the existence of underlying cerebral venous thrombosis. Diagnosis is made with cranial neuroimaging; MRI provides the best noninvasive assessment.

Cocaine Use

SAH can result from cocaine use. The probability of this occurrence is higher in cocaine users with occult intracranial aneurysms or AVMs. Irrespective of the method of cocaine administration, SAH may occur. Cocaine produces tachycardia, hypertension, and vasoconstriction.

TABLE 29.33 Radiologic, Laboratory, and Cardiovascular Assessment of Stroke in Children

Radiologic Assessment

Rapid Detection of Intracranial Blood
Cranial CT
Cranial MRI (also detects extravascular blood but is not as rapidly obtained as cranial CT images)

Detection of Brain Parenchymal Changes Related to Stroke
Cranial MRI, including diffusion-weighted imaging
Cranial CT (reveals changes later in course than MRI)

Detection of Abnormal Vascular Structure
Percutaneous cerebral angiogram (provides the most complete and accurate demonstration of extracranial and intracranial vasculature)
Cranial MRA

Laboratory Assessment

Disturbance of RBC, WBC, or Platelet Number
Hematocrit
Platelet count
WBC count with differential

Disturbance of Coagulation
PT, PTT
Antithrombin III level
Protein C level, protein S level; resistance to protein C assay
Lupus anticoagulant detection, anticardiolipin antibody, antiphospholipid antibody
MTHFR gene mutation, prothrombin 20210A gene mutation analysis

Metabolic Disturbances
Serum electrolytes, glucose
Serum amino acids
Urine organic acids
Serum/CSF lactate and pyruvate
Urine toxicology screen

Disturbance of Hemoglobin
Hemoglobin concentration
Hemoglobin electrophoresis

Inflammatory Disturbances
ESR
ANA, RF
CSF studies: glucose, protein, cell counts, special stains, cultures
Lipid and lipoprotein disturbances
Serum triglycerides
Serum cholesterol; if high, obtain fasting HDL

Cardiovascular Assessment
ECG
Standard and transesophageal echocardiogram

ANA, antinuclear antibodies; CSF, cerebrospinal fluid; CT, computed tomography; ECG, electrocardiography; ESR, erythrocyte sedimentation rate; HDL, high-density lipoproteins; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging; MTHFR, methyltetrahydrofolate reductase; PT, prothrombin time; PTT, partial thromboplastin time; RBC, red blood cell; RF, rheumatoid factor; WBC, white blood cell.

The resultant sudden rise in systemic blood pressure is thought to precipitate SAH. Ischemic lesions have also been found. Nonetheless, intracranial hemorrhage appears to occur more commonly than ischemic infarction.

Causes of Stroke Unrelated to Age

Pharyngeal Infection

Pharyngeal infections have been associated with stroke caused by thrombotic occlusion of the carotid arteries in their cervical course. In childhood, stroke resulting from carotid occlusion more commonly occurs in the intracranial segment of the carotid artery. Infections of the cervical region such as tonsillitis, pharyngitis, cervical lymphadenitis, and necrotizing fasciitis have been found in children experiencing acute hemiplegia. In these instances, angiography has shown occlusion of the internal carotid artery located in its cervical segment. Neuroimaging has demonstrated ischemic infarction of the cortical region served by the middle cerebral artery, which arises from the carotid circulation. It is speculated that the soft tissue infection leads to an inflammatory arteritis. Vessel wall inflammation and direct pressure on the artery then lead to intravascular thrombosis and occlusion. Neurologic symptoms are noted in a patient with evidence of infection: fever, lethargy, sore throat or neck, difficulty swallowing, or cervical lymphadenopathy.

Head and Neck Trauma

Head and neck trauma is an important cause of stroke in children. Neurologic symptoms may be delayed more than 24 hours in their appearance in relation to the time of the inciting trauma. Stroke caused by carotid artery injury has been well documented. Most often, these cerebrovascular events occur after head and neck trauma sustained in motor vehicle accidents, bicycle accidents, fights, or falls. Hemiparesis is a common symptom at presentation if the cause resides in the carotid artery. Carotid angiography reveals internal carotid artery occlusion. The site of occlusion most often exists at the level of the carotid bifurcation. Pathologically, an intimal tear is found with attendant thrombus blocking the arterial lumen. In some cases, arterial dissection is found.

Vertebral artery injury from trauma may cause stroke in children. Traction injuries of the neck appear to cause vertebral artery injury. The vertebral artery is most vulnerable to traumatic injury at its atlantoaxial portion. The resultant strokes occur in the vertebrobasilar portion of the cerebral circulation. Symptoms are referable to the structures receiving blood from this system: brainstem, cerebellum, occipital lobes, and temporal lobes. Clinical symptoms of vertebrobasilar stroke include difficulty swallowing, ataxia, facial weakness, tinnitus, vertigo, anisocoria, extraocular movement palsies, dysmetria, cortical blindness, and mental status changes. Because both the long sensory and the motor tracts course through the brainstem, symptoms of general sensorimotor impairment may be found. Vertebral artery injury in children has been reported in the setting of athletic endeavor or automobile accidents. The resultant vertebrobasilar strokes are caused by thrombosis or vertebral artery dissection.

Migraine Headache

Stroke may occur in the setting of migraine headache. The occurrence of focal motor deficits during a migraine headache denotes **complicated migraine** (see Chapter 28). Acute hemiparesis has been well documented during these episodes and is believed to reflect the involvement of the cerebral circulation derived from the carotid artery. Symptoms such as ataxia, cortical blindness, and cranial nerve dysfunction are correlated with vertebrobasilar circulation involvement. Focal symptoms may be fixed or may occur as TIAs.

Initially, an association between migrainous stroke and discharged emboli from mitral valve prolapse was hypothesized, but studies have not supported the association. Although oral contraceptives confer hypercoagulability thought to predispose to stroke, the postulated additive risk for stroke with migraine headaches and oral contraceptives has been challenged. Angiographic studies on patients with focal deficits consistent with stroke in the setting of migraine headache reveal vasoconstriction of vessels in either the vertebrobasilar or the carotid circulations. The anatomic position of the constricted vessels correlated with the location of the observed deficits. Ischemia provoked by vasoconstriction during prolonged migraine has been hypothesized as the mechanism of stroke in these patients.

SUMMARY AND RED FLAGS

In the neonate and older infant, hypotonia is more commonly associated with systemic diseases that indirectly affect the central nervous system. However, various disorders are related to the nervous system and necessitate immediate attention. Meningomyelocele is usually discovered by prenatal fetal ultrasonography or at birth. Like an encephalopathic infant, any child with an acute neurologic process needs a thorough investigation. Hypotonia and weakness can arise from dysfunction at many potential sites of the nervous system. An accurate diagnosis requires careful anatomic localization.

Ascending motor weakness with absence of deep tendon reflexes that develops over a few days suggests GBS and is a medical emergency. In addition, spine pain, a motor-sensory level, bowel and bladder dysfunction, and upper motor neuron signs strongly suggest a lesion in the spinal cord and constitute a medical and possibly a surgical emergency.

Acute hemiplegia most frequently represents stroke. Because stroke occurs most often in children as a consequence of an underlying process, the clinician should evaluate the patient carefully to determine whether such a predisposing condition exists.

Red flags in children with stroke include manifestations of underlying primary processes (e.g., trauma, medications, inborn errors of metabolism, malignancy, coagulopathy), depressed level of consciousness, a positive family history of early-onset stroke (younger than 30 years), signs of increased intracranial pressure (see Chapter 31), a carotid bruit, hypertension, and the presence of prior TIAs.

Paroxysmal Disorders

Priya Monrad

INTRODUCTION

Paroxysmal neurologic symptoms are often referred to by the generic term "spells"; these paroxysmal events can be neurologic, cardiovascular, or gastrointestinal in origin. Most paroxysmal neurologic symptoms can be properly evaluated, diagnosed, and managed by following a systematic approach. A detailed history will often be sufficient to make the diagnosis or to significantly narrow down the diagnostic differential. A few well-selected tests will then allow the physician to correctly diagnose and treat the child. The physician should aim first to assess for signs of serious or emergent neurologic disease, and second to form a differential diagnosis to guide further investigations and treatment (Fig. 30.1).

◆ History

A careful description of the event or events from beginning to end, including re-enactments by the parents of any unclear physical symptoms, is critical.

Pertinent questions include:

- Was this the first such event, or have there been multiple events?
- Is there a single type of event, or multiple events?
- What was the child doing at the time of each spell—were they awake, asleep, playing, or sitting quietly?
- If they were asleep, how long had they been asleep, or what time of day or night did the spell occur?
- If abnormal tone or movements were involved, was the child rigid or limp, and which limbs were involved? Were the movements rhythmic and synchronous, or were they alternating, migratory, or stop-start?
- If the child was unresponsive or had alteration of awareness, what did the parents do to ascertain their level of responsiveness? Did the parents try touching them to regain their attention, or merely call their name?
- How long did the event last, and how did the child behave afterward?
- Did the child describe any symptoms prior to the onset of the actual event, or was there any abnormal behavior that the parents witnessed prior to the event?
- Were there any signs or symptoms of illness associated with the spell? Were any fevers documented?
- Has there been any behavioral, developmental, or academic regression since the start of the events?
- Is the child developmentally normal? If not, has the child's development always been abnormal, or was there a regression at some point?
- Were there any problems during pregnancy or the delivery?
- Has the child ever had a significant head injury or central nervous system (CNS) infection?

- Is there any family history of similar events, or any other neurologic disorders?

Parents frequently record videos of these spells on their mobile devices, which are ideal for the physician to review.

◆ Physical Examination

The physician should compare vital signs, including blood pressure and head circumference, to previous measurements if possible. Elevated blood pressure can be indicative of pain, anxiety, increased intracranial pressure, or hypertensive encephalopathy. Hypotension may suggest syncopal events or sepsis. Dramatic increases in head circumference in infants may indicate intracranial pathology.

A general physical examination, including the cardiopulmonary and abdominal examinations, should be performed; abnormalities may indicate a nonneurologic cause for spells. **Dysmorphic** features or **cutaneous** findings can provide clues toward an underlying syndrome.

An **ophthalmologic** examination can be as simple as obtaining a red reflex and observation of eye movements in young children. Eye movements may be observed by having the patient track a moving object or toy; abnormalities such as deviation, nystagmus, or new-onset limitations in range of motion may indicate a structural cause for the spells such as hydrocephalus or a mass lesion. In cooperative older children, the physician should attempt a funduscopic examination. **Papilledema** is a clue to increased intracranial pressure but unfortunately is only readily appreciable after 2-3 weeks of increased intracranial pressure; it will not be present with acute disturbances leading to increased intracranial pressure.

The child will provide important information about their **mental status** and **developmental status** through simple conversation. Conversations about toys, school, or family members in the room can provide information about orientation, aphasia, dysarthria, and fund of knowledge for age. If there are any questions about whether any facial asymmetry is new-onset, parents may be able to provide old photographs; most people have some degree of facial asymmetry at baseline that may only be noticed after a frightening event causes the parents to observe the child more closely.

Muscle strength can be ascertained by manual testing in a cooperative older child, or observing natural play or strength of resistance to examination in a younger child. If a child can easily perform age-appropriate actions such as crawling, walking, running, climbing, or grabbing for objects, and strongly resists examination, they are fairly likely to have grossly normal strength in their major muscle groups. **Tone** can be checked by passively moving the patient's limbs, or suspending an infant in your hands to check if they start to slide through your grip. Low tone (hypotonia) can also be detected by observing gait or observing how the child sits; "W"-sitting (sitting with knees together and heels outside of their hips) may be another clue. Low strength

Did the child have a seizure?

No — Yes

No:
Benign paroxysmal
    vertigo
Breath holding
Cough syncope
Famical choreoathetosis
Hereditary chin trembling
Shuddering attacks
Narcolepsy
Night terror
    pseudoseizures
Rage attack
Benign myoclonus of
    infancy
Tics

Initial Seizure
Fasting blood sugar,
    calcium, metabolic
    studies dictated by
    history and physical:
    EEG, CT scan, MRI,
    CSF examination

Recurrent Seizures
Drug compliance?
Improper dose?
Incorrect drug?
Metabolic disorder?
Underlying structural lesion?
Drug interaction?
CNS degenerative disease?
Intractable seizures?

Studies and Examination

Abnormal
Symptomatic seizures
Treat underlying cause
    (hypoglycemia, urea
    cycle abnomality,
    meningitis. temporal
    lobe tumor, etc.)
Antiepileptic drugs if
    necessary

Normal
Isolated flrst seizure
    with normal EEG
Negative family history
No continuous drug
    treatment
Close observation
Prescribe rescue
    medications (rectal
    diazepam) for
    seizures longer than
    5 min

Normal (except EEG)
Consider drug therapy

Follow-up

Good Control
Regular follow-up
Antiepleptic drug levels
    monitor toxicity (CBC,
    liver function,
    behavioral, learning)
EEG as indicated

Poor Control
Consider hospitalization
Prolonged EEG
    recording and video
    monitoring for
    possible epilepsy
    surgery candidacy
Readjust medication
Reconsider underlying
    pathology with
    reinvestigation with
    CT or MRI
Frequent follow-up

FIGURE 30.1 Approach to the child with a suspected convulsive disorder. CBC, complete blood count; CNS, central nervous system; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalography; MRI, magnetic resonance imaging.

(weakness) should be distinguished from hypotonia or ataxia; an example of normal strength but low tone might be an infant with motor delays and head lag who vigorously opposes examination; a child with normal strength but ataxia might vigorously oppose examination but cannot accurately reach to push away the examiner.

A normal physical examination does not rule out the presence of a neurologic disorder, but generally indicates a disorder that does not require immediate intervention and that more time can be spent carefully evaluating all diagnostic possibilities. In children with baseline neurologic abnormalities, such as children with cerebral palsy, knowledge of their base line physical examination, abilities, and behavior is critical in deciding how urgently they need to be evaluated further. Parents can be very helpful in determining a child's baseline behavior in this case.

RED FLAGS

After obtaining a history of the events, the presence of "red flags" in the history or examination should strongly prompt referral to the emergency room:

Increased Intracranial Pressure or Large Intracranial Mass

- Hypertension and bradycardia
- 3rd or 6th nerve palsy; anisocoria, ptosis, diploplia
- Forced-seeming and persistent downward deviation of both eyes (tonic downward gaze deviation)
- Papilledema
- Severe vomiting that is exquisitely positional (i.e., strongly provoked by the transition from lying to sitting)
- Engorged scalp veins
- Bulging fontanel or split cranial sutures in an infant
- Presence of a ventriculoperitoneal shunt (VP shunt) with any of the above symptoms should prompt concern about shunt malfunction

Ongoing Status Epilepticus

- Waxing and waning responsiveness after a convulsive seizure has ended, particularly with periods of complete unresponsiveness
- Persistent eye deviation after a convulsive seizure has ended

- Persistent tachycardia after a convulsive seizure has ended
- Persistent confusion or delirium, even if the child is able to speak and walk

Stroke or Complicated Migraine

- Focal weakness or numbness, particularly if accompanied by slurred speech or confusion (if the spell is remote and the patient has returned to a normal baseline, suggest expedited referral to a neurologist)

Meningitis

- Fever
- Nuchal rigidity
- Positive Kernig or Brudzinski signs
- Bulging fontanel

The following red flags should prompt an urgent or even emergent referral to a pediatric neurologist, including direct communication with a neurologist for proper triaging:

- Infantile spasms
- Clusters of abdominal "crunches" or "startles," particularly when the child is falling asleep or waking up from sleep
- Developmental plateau or regression
- Loss of visual attentiveness

Any developmental regression in infants or toddlers that has been present for more than 1 month (or sooner, for dramatic or progressive regressions) is concerning; change in handedness after 4-5 years of age is also a red flag.

PAROXYSMAL SPELLS OF ALTERED BEHAVIOR OR MOVEMENT

Paroxysmal neurologic symptoms can have neurologic, psychiatric, pulmonary, cardiovascular, or gastrointestinal causes. For this reason, during the investigation of a paroxysmal event, generic terms such as "spells," "convulsions," or "altered mental status" are more appropriate to use rather than "seizures," which implies a very specific etiology and may falsely eliminate diagnostic possibilities. Witnesses may use terms such as "grand mal," "petit mal," or even "generalized tonic-clonic" (GTC) to describe events; these descriptors should not be taken at face value or thought to only describe epileptic seizures.

EPILEPTIC SEIZURES

An epileptic seizure is a paroxysmal alteration in behavior, motor function, and/or autonomic function occurring in association with excessive synchronous neuronal activity in the CNS. Seizures may be considered "provoked" or "unprovoked," referring to whether they were precipitated by an acute cause such as illness, concussion, metabolic derangement, or toxic ingestion. The term "symptomatic" refers to whether the seizures represent a symptom of a known chronic disorder, such as a structural, genetic, or metabolic abnormality. *Epilepsy* is a disorder in which there are *recurrent* unprovoked epileptic seizures (Table 30.1).

Epileptic seizures must be clearly distinguished from nonneurologic paroxysmal disorders caused by psychiatric, cardiovascular, pulmonary, or gastrointestinal causes. There are also paroxysmal disorders that are neurologic but nonepileptic in nature, such as tics, dystonias, stereotypies, or other movement disorders. The correct diagnosis is critical to avoid unnecessary testing, interventions, and medication

trials. However, multiple types of events, both epileptic and nonepileptic, may occur in the same patient, necessitating that each spell be properly characterized.

EPIDEMIOLOGY AND CAUSES OF SEIZURES AND EPILEPSY

If febrile seizures are included, approximately 3.5% of children experience some kind of seizure by the age of 15 years; most seizures occur before the age of 3 years. The majority of children who present with a seizure do not have or will not develop epilepsy. Many children presenting with a seizure have febrile convulsions, which are a provoked, age-dependent paroxysmal neurologic condition; 13% of children with seizures have acute symptomatic seizures other than febrile convulsions; and 8% have single, unprovoked seizures of unknown cause. The incidence of acute symptomatic seizures is highest in the 1st year of life; the most common causes of these predominantly neonatal seizures are infection and metabolic disorders. After age 4 years, head injury is the most common cause of acute symptomatic seizures, and infection is the next most common.

The incidence of epilepsy among children younger than 15 years is 45-85/100,000 in developed countries. It is highest in younger children; in those younger than 1 year, it is ~100/100,000. The prevalence of active epilepsy in patients taking antiepileptic drugs (AEDs) is between 4.3 and 9.3/1000, or about 0.5-1% of the population. Traditionally, between 60% and 80% of children with epilepsy have no identifiable etiologic factors for the disease; however next-generation gene sequencing technology has moved the estimated underlying genetic etiology to approximately 40%. Of those children in whom a cause is identified, population-based studies report the following presumed causes: infection in 5%; head trauma in 3%; and miscellaneous causes (tumors, malformations of cortical development, vascular malformations, and cerebral infarction) in 2%. Epilepsy is found in association with other long-standing neurodevelopmental abnormalities in 13% of children.

GENETICS

It is estimated that a genetic etiology underlies epilepsy in approximately 40% of individuals. In some circumstances, unique clinical phenotypes can be a guide to the underlying etiology. Apnea or **systemic shock** requiring intubation and ventilation is seen in severe metabolic epileptic encephalopathic syndromes such as nonketotic hyperglycinemia, pyridoxine-5'-phosphate oxidase deficiency, molybdenum cofactor deficiency, pyridoxine-dependent epilepsy, Leigh syndrome, congenital neuronal ceroid lipofuscinosis, and atypical *MECP2*. The characteristic syndactyly of the 2nd and 3rd toes is seen in steroid metabolism disorders, Smith–Lemli–Opitz syndrome in particular, which additionally has associated genitourinary tract abnormalities. Skin **exanthems** are highly suggestive of biotinidase deficiency. Atypical coarse or thin hair and wormian bones are seen in copper disorders such as Menkes syndrome. **Cardiomyopathy** is characteristic of mitochondrial disorders including Barth syndrome and fatty acid oxidation disorders and is also seen in RASopathies and cobalamin C deficiency. **Atypical fat distribution** and a prominent suprapubic fat pad are seen in congenital disorders of glycosylation. The value of genetic testing and the circumstances in which genetic testing should be offered varies widely between centers. Gene panels are available that provide sequencing information from 20 genes to greater than 400 genes dependent on the commercial testing facility being utilized. Heterogeneity is mostly responsible for this variability in clinical testing; 1 gene can cause various types of seizure disorders (clinical heterogeneity), or a specific

TABLE 30.1   Types of Epileptic Seizures

Self-Limited Seizure Types	Unknown
Focal Seizures	**Epileptic Spasms**
Focal sensory seizures	**Continuous Seizure Types**
• With elementary sensory symptoms (e.g., occipital and parietal lobe seizures)	Generalized status epilepticus
• With experiential sensory symptoms (e.g., temporoparietooccipital junction seizures)	Generalized tonic-clonic status epilepticus
Focal motor seizures	Clonic status epilepticus
• With elementary clonic motor signs	Absence status epilepticus
• With asymmetric tonic motor seizures (e.g., supplementary motor seizures)	Tonic status epilepticus
• With typical (temporal lobe) automatisms (e.g., mesial temporal lobe seizures)	Myoclonic status epilepticus
• With hyperkinetic automatisms	
• With focal negative myoclonus	**Focal Status Epilepticus**
• With inhibitory motor seizures	Epilepsia partialis continua of Kojevnikov
Gelastic seizures	Aura continua
Hemiclonic seizures	Limbic status epilepticus (psychomotor status)
Secondarily generalized seizures	Hemiconvulsive status with hemiparesis
Reflex seizures in focal epilepsy syndromes	
	Precipitating Stimuli for Reflex Seizures
Generalized Seizures	Visual stimuli
Tonic-clonic seizures (includes variations beginning with a clonic or myoclonic phase)	• Flickering light—color to be specified when possible
Clonic seizures	• Patterns
• Without tonic features	• Other visual stimuli
• With tonic features	Thinking
Typical absence seizures	Music
Atypical absence seizures	Eating
Absence with special features:	Praxis
• Eyelid myoclonia	Somatosensory
• Myoclonic absence	Proprioceptive
Tonic seizures	Reading
Myoclonic seizures	Hot water
Myoclonic atonic seizures	Startle
Negative myoclonus	
Atonic seizures	
Reflex seizures in generalized epilepsy syndromes	

Modified from Berg AT, Berkovic SF, Brodie MJ, et al. Revised terminology and concepts for organization of seizures and epilepsies: report of the ILAE commission on classification and terminology, 2005–2009. *Epilepsia*. 2010;51:676-685.

subtype of seizure may have several genes with causal associations (genetic heterogeneity). Gene panels are designed to group disorders with common ages of onset and phenotypic characterizations together, thereby offering broad coverage in a cost-effective manner. There are circumstances in which targeted sequencing is still warranted (Tables 30.2 and 30.3).

Whole-exome sequencing should not be considered "end of the line" or "last resort," as the window of opportunity for targeted intervention may pass while more conventional options are investigated in the interim. This is particularly relevant in new-onset intractable or refractory seizures. There are several cases reported with digenic seizure disorders or rare metabolic disorders that will not be easily detected through more routine metabolite analysis, but benefit from early targeted intervention to reduce morbidity and improve overall quality of life. The general consensus for evaluating patients with suspected congenital disorders of glycosylation, mitochondrial disorders, or otherwise complex atypical disorders is to utilize exome sequencing as a first-line diagnostic test, with yields of up to 30% in these circumstances.

SEIZURE CLASSIFICATION AND TERMINOLOGY

Seizures are characterized according to their clinical semiology and presumptive etiology (see Table 30.1). Seizures can be difficult to classify and identify without a careful description of their onset, unfolding, and aftermath. Multiple seizure types may have the same brief general description, such as "twitching" or "staring." Without further details as to duration, additional symptoms, and postictal behavior, they may be incorrectly classified as to type, even if they are accurately determined to be seizures. This is clinically relevant because improper classification can lead to inappropriate treatment; for example, some antiepileptic medications for focal seizures will exacerbate generalized seizures.

Clonic movements are rhythmic, nonsuppressible, position-independent jerking movements (low frequency, high amplitude) caused by involvement of the motor cortex. They can be unilateral or bilateral, and can start with 1 body part and spread. If bilateral, they are synchronous, and do not alternate from 1 side to the other in a bicycling fashion. This should be distinguished from **clonus**, which is rhythmic twitching of a limb, generally the foot, caused by

TABLE 30.2   Clinical Conditions for Targeted Gene Sequencing

Targeted Gene Sequencing	Clinical Condition	Advantage of Testing
SCN1A	Dravet syndrome. Consider testing for recurrent episodes of febrile status epilepticus, intractable tonic–clonic seizures during the 1st year of life, epileptic encephalopathy attributed to vaccination, and adults with a history consistent with Dravet syndrome	Avoidance of sodium channel blockers, aggressive seizure management, justification of stiripentol, bromides, etc.
PCDH19	Females presenting with multiple clusters of brief febrile seizures and developmental delay or regression, particularly if there is a family history consistent with paternal transmission	Prognosis and potential forthcoming treatment options
SLC2A1	Onset of absence seizures <4 yr old, particularly if there is a family history of paroxysmal exercise-induced dyskinesia	Initiation of a ketogenic diet
POLG	Prior to starting valproic acid in patients with drug-resistant seizures and developmental delay or regression	Avoidance of potentially fatal liver failure starting as early as 2 mo after initiation of valproic acid therapy
HLA-B*1502	Prior to starting carbamazepine, oxcarbazepine, phenytoin, and lamotrigine in patients of Asian descent	Avoidance of a potentially fatal reaction (Stevens-Johnson syndrome/toxic epidermal necrolysis)

Modified from Ream MA, Patel AD. Obtaining genetic testing in pediatric epilepsy. *Epilepsia* 2015:56:1505-1514.

hyperreflexia and lack of descending cortical inhibition due to CNS injury such as is seen in cerebral palsy or stroke. This is generally provoked by movement, excitement, and positioning, and can be suppressed or halted by gently repositioning the affected limb. There is no alteration of alertness with clonus. In newborns, **jitteriness** (high frequency, low amplitude) may also be mistaken for clonic seizure activity; this tends to be stimulus-provoked and suppressible.

The term **tonic** refers to a change in tone as a manifestation of seizure activity, which clinically presents as stiffening or arching. This can occur as the only manifestation of a seizure (tonic seizure), or may be followed by clonic jerking, which is the so-called tonic-clonic seizure (GTC or grand mal). **Atonic** seizures refer to seizures where a sudden, brief loss of tone in the neck or entire body causes a head nod or fall to the ground. This type of seizure must be distinguished from falls due to complete loss of consciousness or those due to tonic stiffen-

ing of the entire body. With atonic seizures, the loss of tone is sudden but brief, and the patient is quickly responsive afterward.

Automatisms are semipurposeful movements that usually occur with impairment of consciousness either during or after a seizure, and can be very useful for identifying a spell as a seizure. They may be a perseveration of an activity in progress at ictal onset, such as turning pages of a book, or novel semipurposeful movements arising during the seizure. These novel movements are most often a mixture of masticatory, oral, and lingual movements (lip smacking or grimacing) and simple fragmentary limb movements, such as fidgeting with a held object or pulling at clothing. In infants, orofacial automatisms are more likely than complex gestures and must be distinguished from the normal behavior of infants. Automatisms can both be seen in focal seizures, specifically those of temporal lobe onset, as well as in some generalized seizures, specifically absence epilepsy, so they are not specific to a broad category of seizure.

Impairment of consciousness, defined as an alteration in awareness of external stimuli, may be combined with a complete loss or impairment of responsiveness to external stimuli. Assessment of consciousness during seizures is often difficult, particularly in young children. It is possible to be unresponsive because of an inability to speak or articulate clearly (aphasia, apraxia, or paralysis). It is also possible to be responsive to external stimuli, but to have altered awareness, often demonstrated by complete amnesia for events immediately before, during, or after the seizure, which implies that memory was not acquired during the seizure because of ongoing neuronal dysfunction. It is possible to have complex motor behaviors without loss of complete awareness or amnesia; frontal lobe seizures commonly have this presentation, and must be carefully distinguished from nonepileptic events. Both focal and generalized seizures can be associated with impairment of consciousness; the term **dyscognitive** is used to describe this symptom.

Seizure etiology was previously divided into *idiopathic, cryptogenic,* and *symptomatic*. There were also separate categories for infantile spasms and neonatal seizures. The terms *genetic, structural, metabolic,* and *unknown* are currently used to characterize presumptive etiologies (Table 30.4).

FOCAL SEIZURES

Localization-Related Seizures, Partial Seizures

Focal seizures are seizures in which the first clinical and electroencephalogram (EEG) changes indicate initial activation of a system of neurons limited to part of 1 cerebral hemisphere. The clinical symptoms and signs of focal seizures reflect the functional anatomy of the region of the brain undergoing the abnormal neuronal discharge.

When consciousness is impaired, this was historically known as a **complex** partial seizure; if there is no apparent loss of consciousness, this was known as a **simple** partial seizure. These terms have been replaced by the more descriptive terms **focal seizure with impairment of consciousness** or **focal dyscognitive seizure** in the case of complex partial seizures, and **focal seizure without impairment of consciousness** for simple partial seizures.

An **aura** is the portion of a seizure that is experienced before any loss of consciousness. Some auras can be difficult for a patient to describe; asking them if they know a seizure will happen before it happens, even if they cannot articulate precisely what they are experiencing, is one way to approach the topic. Examples of auras include an epigastric rising sensation; nausea; visual, auditory, or olfactory hallucinations; or limbic symptoms such as fear or a sensation of déjà vu. An aura may be suspected in very young children if there is a change in behavior before seizures, such as interrupting an activity to seek out parents, or complaining of abdominal pain. The presence of

TABLE 30.3   Identified Genes for Epilepsy Syndromes*[1]

Epilepsy Type	Gene	Protein
Infantile Onset		
Benign familial neonatal seizures	KCNQ2	Potassium voltage-gated channel
	KCNQ3	Potassium voltage-gated channel
Benign familial neonatal infantile seizures	SCN2A	Sodium channel protein type 2α
Early familial neonatal infantile seizures	SCN2A	Sodium channel protein type 2α
Early infantile epileptic encephalopathy (EIEE)	CDKL5 (EIEE2)	Cyclin-dependent kinase-like 5
	ARX (EIEE1)	Aristaless-related homeobox
	TSC1	Hamartin
	TSC2	Tuberin
	SCN1A (EIEE6)	Sodium channel protein type 1α
	PCDH19 (EIEE9)	Protocadherin-19
	KCNQ2 (EIEE7)	Potassium voltage-gated channel
	STXBP1 (EIEE4)	Syntaxin binding protein 1
	SLC2A1	Solute carrier family 2, facilitated glucose transporter member 1
	ALDH7A1	α-Aminoadipic semialdehyde dehydrogenase (antiquitin)
	POLG	DNA polymerase subunit γ1
	SCN2A (EIEE11)	Sodium channel protein type 2α
	PLCβ1 (EIEE12)	Phospholipase C β1
	ATP6AP2	Renin receptor
	SPTAN1 (EIEE5)	α2-Spectrin
	SLC25A22 (EIEE3)	Mitochondrial glutamate carrier 1
	PNPO	Pyridoxine-5′-phosphate oxidase
Generalized epilepsy with febrile seizures plus (early onset)	SCN1A	Sodium channel protein type 1α
	SCN1B	Sodium channel protein type 1β
	GABRG2	γ-Aminobutyric acid receptor subunit γ2
	SCN2A	Sodium channel protein type 2α
Childhood Onset		
Childhood-onset epileptic encephalopathies	SCN1A	Sodium channel protein type 1α
	PCDH19	Protocadherin-19
	SLC2A1	Solute carrier family 2, facilitated GTM1
	POLG	DNA polymerase subunit γ1
	SCN2A	Sodium channel protein type 2α
Early-onset absence seizures, refractory epilepsy of multiple types, at times with movement disorder	GLUT-1 deficiency syndrome, SLC2A1 gene	Solute carrier family 2, facilitated GTM1
Generalized epilepsy with febrile seizure plus	SCN1A	Sodium channel protein type 1α
	SCN1B	Sodium channel protein type 1β
	GABRG2	γ-Aminobutyric acid receptor subunit γ2
	SCN2A	Sodium channel protein type 1α
Juvenile myoclonic epilepsy (more commonly presents in adolescence)	EFHC1	EF-hand domain-containing protein 1
	CACNB4	Voltage-dependent L-type calcium channel
	GABRA1	γ-Aminobutyric acid receptor subunit α1
Progressive myoclonic epilepsy (different forms present from infancy through adulthood)	EPM2A	Laforin
	NHLRC1	NHL repeat-containing protein 1 (malin)
	CSTB	Cystatin-B
	PRICKLE1	Prickle-like protein 1
	PPT1, TPP1, CLN3, CLN5, CLN6, CLN8, CTSD, DNAJC5, MFSD8	Multiple proteins causing neuronal ceroid lipofuscinosis
Autosomal dominant nocturnal frontal lobe epilepsies (presents in childhood through adulthood)	CHRNA4	Neuronal acetylcholine receptor α4
	CHRNB2	Neuronal acetylcholine receptor β2
	CHRNA2	Neuronal acetylcholine receptor α2

Continued

TABLE 30.3	Identified Genes for Epilepsy Syndromes—cont'd	
Epilepsy Type	**Gene**	**Protein**
Adolescent Onset		
Juvenile myoclonic epilepsy (JME)	See Childhood-Onset JME	
Progressive myoclonic epilepsy (PME)	See Childhood-Onset PME	
Autosomal dominant nocturnal frontal lobe epilepsies (AD-NFLE)	See Childhood-Onset AD-NFLE	
Autosomal dominant lateral temporal lobe epilepsy (usually presents in adulthood)	*LGI1*	Leucine-rich glioma-inactivated protein 1

*Note that the same gene (different mutations) often appears as causing different epilepsy syndromes.
†Most of these genes can be tested for through commercially available targeted single-gene sequencing or through commercially available gene panels or though exome sequencing (http://www.ncbi.nlm.nih.gov/sites/GeneTests/review?db=genetests).

TABLE 30.4	Suggested Scheme for an Etiologic Classification of Epilepsy	
Main Category	**Subcategory**	**Examples***
Idiopathic epilepsy	Pure epilepsies due to single-gene disorders	Benign familial neonatal convulsions; autosomal dominant nocturnal frontal lobe epilepsy; generalized epilepsy with febrile seizures plus; severe myoclonic epilepsy of childhood; benign adult familial myoclonic epilepsy
	Pure epilepsies with complex inheritance	Idiopathic generalized epilepsy (and its subtypes); benign partial epilepsies of childhood
Symptomatic epilepsy Predominantly genetic or developmental causation	Childhood epilepsy syndromes	West syndrome; Lennox-Gastaut syndrome
	Progressive myoclonic epilepsies	Unverricht-Lundborg disease; dentato-rubro-pallido-luysian atrophy; Lafora body disease; mitochondrial cytopathy; sialidosis; neuronal ceroid lipofuscinosis; myoclonus renal failure syndrome
	Neurocutaneous syndromes	Tuberous sclerosis; neurofibromatosis; Sturge-Weber syndrome
	Other neurologic single-gene disorders	Angelman syndrome; lysosomal disorders; neuroacanthocytosis; organic acidurias and peroxisomal disorders; porphyria; pyridoxine-dependent epilepsy; Rett syndrome; urea cycle disorders; Wilson disease; disorders of cobalamin and folate metabolism
	Disorders of chromosome function	Down syndrome; fragile X syndrome; 4p– syndrome; isodicentric chromosome 15; ring chromosome 20
	Developmental anomalies of the cerebral structure	Hemimegalencephaly; focal cortical dysplasia; agyria-pachygyria-band spectrum; agenesis of the corpus callosum; polymicrogyria; schizencephaly; periventricular nodular heterotopia; microcephaly; arachnoid cyst
Predominantly acquired causation	Hippocampal sclerosis	Hippocampal sclerosis
	Perinatal and infantile causes	Neonatal seizures; postneonatal seizures; cerebral palsy
	Cerebral trauma	Open head injury; closed head injury; neurosurgery; epilepsy after epilepsy surgery; nonaccidental head injury in infants
	Cerebral tumor	Glioma; ganglioglioma and hamartoma; DNET; hypothalamic hamartoma; meningioma; secondary tumors
	Cerebral infection	Viral meningitis and encephalitis; bacterial meningitis and abscess; malaria; neurocysticercosis; tuberculosis; HIV
	Cerebrovascular disorders	Cerebral hemorrhage; cerebral infarction; degenerative vascular disease; arteriovenous malformation; cavernous hemangioma
	Cerebral immunologic disorders	Rasmussen encephalitis; SLE and collagen vascular disorders; inflammatory and immunologic disorders
	Degenerative and other neurologic conditions	Alzheimer disease and other dementing disorders; multiple sclerosis and demyelinating disorders; hydrocephalus and porencephaly
Provoked epilepsy	Provoking factors	Fever; menstrual cycle and catamenial epilepsy; sleep-wake cycle; metabolic and endocrine-induced seizures; drug-induced seizures; alcohol- and toxin-induced seizures
	Reflex epilepsies	Photosensitive epilepsies; startle-induced epilepsies; reading epilepsy; auditory-induced epilepsy; eating epilepsy; hot water epilepsy
Cryptogenic epilepsies†		

*These examples are not comprehensive, and in every category there are other causes.
†By definition, the causes of the cryptogenic epilepsies are "unknown." However, these are an important category, accounting for at least 40% of epilepsies encountered in adult practice and a lesser proportion in pediatric practice.
DNET, dysembryoplastic neuroepithelial tumor; HIV, human immunodeficiency virus; SLE, systemic lupus erythematosus.
From Shorvon SD. The etiologic classification of epilepsy. Epilepsia. 2011;52:1052-1057.

an aura is traditionally thought to be indicative of a focal seizure without impairment of consciousness, as it implies focal cortical dysfunction, but some studies have reported that up to 64% of patients with documented idiopathic generalized epilepsy experience some form of aura, possibly due to asymmetric propagation of the discharges through the thalamocortical networks.

Nonepileptic events such as **migraines** or **syncope** may also have a prodrome, further highlighting the value of a comprehensive history in distinguishing types of events.

The progressive symptoms of some seizures after the initial aura reflect the spread of the abnormal electrical discharge beyond the region of onset, which is why a detailed history is critical for evaluating paroxysmal spells and determining the likelihood that they represent seizure activity.

Focal seizures can have motor and/or sensory components, depending on which areas of what is termed *eloquent cortex* become involved in the seizure. However, the seizure may originate in a portion of the cortex that does not produce obvious physical symptoms (termed the *silent* or *noneloquent cortex*), and physical signs of the seizure only develop if the seizure discharge spreads to involve eloquent cortex. Seizures with clear electrical abnormalities but minimal or absent physical symptoms are commonly referred to as *electrographic seizures* or *subclinical seizures*. Subclinical electrographic seizures, particularly during sleep, can be associated with deterioration in development, behavior, attention, and learning.

Focal motor seizures produce rhythmic jerking (clonic) movements of the limb or limbs *contralateral* to the primary motor cortex involved. Other focal motor seizures include involuntary turning of the head and eyes in 1 direction (version), vocalization, and speech arrest. There may be tonic stiffening and extension of the arm ipsilateral to the seizure onset.

Involvement of the sensory cortex produces simple *somatosensory* experiences such as paresthesia or numbness, often with a dysesthetic quality, and visual, auditory, olfactory, or gustatory phenomena. Some of these sensory phenomena can be quite complex, including structured visual hallucinations, sensations of depersonalization, and affective symptoms such as anxiety or fear. Epileptic phenomena are a rare cause for such phenomena, and a broad differential diagnosis should be considered for paroxysmal spells where the primary symptoms are sensory or affective.

As the seizure continues to spread, both cerebral hemispheres may become engaged, and there is generalized clonic jerking of the body that closely resembles a GTC seizure. These secondarily generalized seizures may be mistaken for a generalized seizure if the onset is not witnessed. Occasionally after a seizure, there is persistent focal weakness or hemiparesis known as **Todd palsy**, which is strongly suggestive of a contralateral focal onset to the seizure.

Generalized Seizures

Generalized seizures are defined as seizures in which the first clinical changes indicate initial involvement of both hemispheres. Motor involvement, if present, is bilateral, as are the initial EEG changes. Consciousness is impaired in most generalized seizures, but not in all; for instance, brief myoclonic seizures and some atonic seizures may not be associated with any impairment of consciousness.

Absence (petit mal) seizures begin with sudden interruption of activity and staring; they are usually brief and end abruptly without postictal confusion. Simple absence seizures consist of only motionlessness and a blank stare lasting for several seconds, with immediate postictal reanimation. Lip-smacking, fumbling, or searching hand movements, or convulsive swallowing can appear during longer seizures, or preictal activities may be continued in a slow, automatic manner. Paroxysmal alterations in autonomic function may also accompany absence seizures, including pupillary dilation, pallor, flushing, sweating, salivation, piloerection, or a combination of these. Absence seizures that are more typically accompanied by eyelid fluttering, facial twitching, or myoclonic jerks of the trunk or extremities are referred to as *complicated* absence seizures. Atypical absence seizures are described as absence seizures with a less abrupt beginning and end, with more pronounced changes in muscle tone, and of longer duration. Distinctions should be made between the clinical features of absence seizures, focal dyscognitive seizures, and episodic daydreaming (Table 30.5). Staring spells that are prolonged beyond 15-20 seconds are less likely to represent absence seizures due to incorrect duration. Staring spells in infants and toddlers are also unlikely to represent absence seizures due to incorrect age of onset. Early-onset generalized epilepsy is associated with rare genetic syndromes. Children with prolonged staring spells, particularly starting at a young age, are at higher risk of partial-onset seizures or behavioral spells.

Tonic-clonic seizures are perhaps the most dramatic of the epileptic seizures. The **tonic phase** begins with sudden sustained contraction of facial, axial, and limb muscle groups, and there may be an initial involuntary stridorous cry or a moan secondary to contraction of the diaphragm and chest muscles against a partially closed glottis (the *ictal cry*). The tonic contraction is maintained for seconds to 10s of seconds, during which time the child falls if standing, is apneic and may become cyanotic, may bite the sides of their tongue, and may pass urine. The **clonic phase** of the seizure begins when the tonic contraction is repeatedly interrupted by momentary relaxation of the muscular contraction. This gives the appearance of generalized jerking as the contraction resumes after each relaxation. At the end of the clonic phase, the body relaxes and the patient is unconscious with deep respiration. If roused, the patient is confused, may complain of muscle soreness, and usually wishes to sleep.

Myoclonic seizures are sudden, brief, shocklike contractions of muscles. They may involve the whole body or a portion of the axial musculature such as the face and trunk, or they may be limited to the limbs. They can be isolated or repetitive, irregular or rhythmic. Myoclonic seizures arise from the cortex and are associated with a distinct EEG pattern. Some forms of myoclonus are of brainstem or spinal origin; those occurring without other seizure types are not regarded as epileptic myoclonus but thought of as *movement disorders*.

Generalized tonic seizures begin in the same way as tonic-clonic seizures; a massive generalized contraction produces any combination of facial grimacing, neck and trunk flexion or extension, abduction or elevation of the arms, and flexion of the hips. Subtle tonic seizures may produce only facial grimacing and slight neck and trunk flexion. Tonic seizures may be accompanied by pronounced autonomic activity with diaphoresis, flushing, pallor, and tachycardia, even when the muscular contraction is slight.

Atonic seizures are characterized by a sudden decrease or loss of postural muscle tone. The extent of muscle involvement may vary; an atonic seizure may be limited to a sudden head drop with slack jaw or may result in a fall because of loss of axial and limb muscle tone. The falls are referred to as *drop attacks*, and because they are unexpected and sudden in onset, they often result in injury.

DIAGNOSTIC EVALUATION OF A SEIZURE DISORDER

Electroencephalographic Studies

The incidence of EEG epileptiform activity in normal children without a history of seizures is very low (<2%); such findings are associated

TABLE 30.5	Differential Diagnosis of Episodic Unresponsiveness Without Convulsions		
Clinical	**Absence Seizures**	**Focal Dyscognitive Seizures**	**Staring, Inattention**
Frequency	Multiple daily	Rarely more than 1-2/day	Daily, situation dependent: e.g., may occur only at school
Duration	Often <10 sec, rarely >30 sec	Average duration >60 sec, rarely <10 sec	Seconds to minutes
Aura	Not present	May be present	Not present
Abrupt interruption of child's activity	Yes: e.g., speech arrest midsentence; pause while eating, playing, or fighting	Yes	Activities such as play or eating are not abruptly interrupted, no sudden onset
Eyelid flutter	Common, often with upward eye movement	Uncommon, but may be present	No
Myoclonic jerks	Common	Uncommon	Not present
Automatisms	Occur in longer absences, usually mild	Frequent and often prominent	No
Responsiveness	Unresponsive	Unresponsive	Responds to touch
Postictal impairment	None	Postictal confusion and malaise is typical; drowsiness may also occur	No
EEG	Generalized 3-Hz spike-and-wave complexes	Regional epileptic discharges (most often frontal or temporal)	Normal
MRI	Normal	Focal structural lesions not uncommon (e.g., tumor)	Normal
First-line medication	Valproate, ethosuximide	Carbamazepine, phenytoin, valproate	None

EEG, electroencephalogram; MRI, magnetic resonance imaging.

with a strong family history of genetic epilepsy. The incidence of recurrent epileptic seizures in patients with focal EEG spikes is 83%. In a child with suspected seizures, the finding of focal or generalized epileptiform activity on the EEG supports a diagnosis of epilepsy, whereas multiple negative EEG studies capturing both wakefulness *and* sleep argue against such a diagnosis, and should prompt the physician to consider alternative diagnoses and to attempt to record the episodes.

There are 2 basic types of EEGs: *conventional* and *amplitude-integrated*. A conventional EEG utilizes 19 or more electrodes distributed symmetrically over both hemispheres and along the midline. A routine outpatient EEG is run for at least 20 minutes, and more often 40-60 minutes. A prolonged EEG, or long-term monitoring, is run for over 24 hours, and can even be performed for over a week at a time. This type of prolonged study can be performed on an ambulatory basis at home, or as an inpatient in an epilepsy monitoring unit. Amplitude-integrated EEG, by contrast, utilizes only 2 or 4 EEG electrodes, and is primarily used in neonatal intensive care units.

An EEG should always attempt to capture sleep, and most will include hyperventilation and photic stimulation, all of which potentially activate epileptiform discharges, increasing the diagnostic yield. Hyperventilation produces absence seizures in about 80% of children with childhood absence epilepsy. Intermittent photic stimulation produces generalized epileptic discharges in several of the generalized epileptic syndromes, but photosensitivity is overall rare in epilepsy. Recording during wakefulness and sleep performed after sleep deprivation may have the highest yield. Overnight recording in the hospital provides for prolonged sampling of the interictal EEG in wakefulness and spontaneous sleep. For any patient with refractory seizures or an uncertain diagnosis, the use of video and EEG monitoring is usually helpful in clarifying the diagnosis. Defining the exact seizure type may lead to modification of drug treatment or consideration of epilepsy surgery, or a nonepileptic paroxysmal disorder may be discovered.

A single normal EEG does not definitively exclude a seizure disorder, particularly in people with infrequent seizures or seizures in specific contexts, such as illness or sleep.

Neuroimaging Studies

Magnetic resonance imaging (MRI) is superior to computed tomography for the evaluation of epilepsy. Any patient with a history or examination suspicious for focal-onset epilepsy should have MRI of the brain, unless the syndrome is clearly that of benign focal epilepsy of childhood with centrotemporal spikes. MRI may also reveal an abnormality in patients with symptomatic generalized epilepsy. Functional neuroimaging is important in the assessment of candidates for surgical resection in patients with intractable seizures. When available, a 3.0 Tesla MRI of the brain with specific protocols dedicated to epilepsy evaluation (e.g., proper alignment of the imaging axis with the hippocampi) is preferred.

Evaluation of the First Seizure

There is no clinical sign or diagnostic investigation that determines with certainty whether a child presenting with a first seizure has epilepsy or has had an isolated seizure. The assessment of patients with a first seizure must include a search for etiologic agents and features that may indicate the risk of recurrence. Factors to be considered include the circumstances of the seizure, the health of the child in the time before the seizure, the recent sleep patterns, the possibility of abuse or trauma, and the chance of ingestion of prescription or street drugs or syndromes such as the neurocutaneous disorders (Table 30.6).

The recurrence risk after a first unprovoked seizure, usually defined as a seizure or flurry of seizures within 24 hours in patients older than 1 month, is ~40-50%.

The most important predictor of recurrence appears to be the existence of an underlying neurologic disorder. The existence of intellectual disabilty or cerebral palsy is a common antecedent to epilepsy,

TABLE 30.6   Neurocutaneous Syndromes

Clinical Syndromes and Findings	Investigations
Sturge-Weber Syndrome	
Facial hemangioma, "port-wine stain" upper face, division of cranial nerve V; bilateral in 30%, absent in 5%, associated truncal and limb hemangiomas in 45%	CT scan: calcification, MRI scan with gadolinium
Intracranial leptomeningeal angiomatosis	EEG: attenuation of background rhythms, epileptiform discharges
Epilepsy in 70-90%, usually before 2 yr and before hemiparesis, intractable in 35%	
Intellectual disability in 50-60%	
Hemiparesis in 30%, often with hemisensory deficit and hemianopia	
Tuberous Sclerosis	
Diagnostic criteria*	
Any 1 of the following:	
Facial angiofibroma (adenoma sebaceum, nasolabial folds, and nose becomes more prominent with age) or periungual fibromas	Physical examination
Cortical tubers, subependymal nodule, giant cell astrocytoma	MRI examination: T1 and T2 sequences with gadolinium
Multiple retinal hamartomas (usually asymptomatic) or multiple renal angiomyolipomas (usually asymptomatic, may manifest as hematuria, hypertension, or renal failure)	Funduscopic examination and renal ultrasonography, abdominal CT scan
Or any 2 of the following:	
Infantile spasms (seizures in 90%, most commonly generalized; infantile spasms and myoclonus)	History and physical, EEG; focal or generalized abnormalities
Hypomelanotic papules (ash leaf spots; in 80-90%, 1-2 cm oval or leaf-shaped)	Wood lamp examination in darkened room
Single retinal hamartoma	Funduscopic examination
Subependymal or cortical calcification on CT scan	CT scan of the brain
Single renal angiomyolipomas or cysts	Renal ultrasonography or abdominal CT scan
Cardiac rhabdomyomas (single or multiple; may obstruct outflow, cause arrhythmias, or cause conduction defects)	Echocardiography, ECG
First-degree relative with tuberous sclerosis (autosomal dominant disorder, 80% of cases represent new mutations)	Examination of parents; echocardiography, MRI scans
Also associated:	
Mental retardation in 50-66%	
Shagreen patches; hamartomatous skin lesion in lumbosacral region in 50%	
Pulmonary involvement, fibrosis	Chest radiograph
Skeletal abnormalities	Hand, feet (cystic), long bone (sclerotic) radiographic changes
Epidermal Nevus Syndrome	
Hamartomatous lesions; subclassified according to most predominant histologic and clinical features (e.g., linear nevus sebaceus, see below)	Careful examination of the scalp, skin folds, and conjunctiva; funduscopic examination
Sporadic, affects both sexes equally; CNS abnormalities are common with epidermal nevus syndrome, including seizures (25% of patients), intellectual disability, and neoplasia; also, skeletal abnormalities, including kyphoscoliosis and hemiatrophy	Spine and limb radiographs, as appropriate
Linear nevus sebaceus; hairless verrucous yellow-orange or hyperpigmented plaques on the face and scalp	
Epilepsy in 76%	
Intellectual disabiity in 60%	
Associated neuronal migration disorders	MRI scan of the brain
Malignant transformation of a skin lesion	
Other Neurocutaneous Syndromes Associated with Seizures	
Neurofibromatosis; cutaneous lesions include café-au-lait spots, axillary freckling, neural tumors; seizure types include generalized tonic-clonic, partial complex, and partial simple-motor	MRI scan of the brain
Incontinentia pigmenti; involvement includes linear papular-vesicular cutaneous lesions at birth, later pigmentation, ocular and dental anomalies; female-to-male ratio > 20 : 1 (boys may die in utero); seizure types include neonatal onset and later generalized tonic-clonic	Skin biopsy; ophthalmology examination
Hypomelanosis of Ito (incontinentia pigmenti achromians)

as is a history of significant head injury. An EEG with generalized or focal epileptiform discharges or with focal or generalized slowing is also predictive of recurrence. Focal seizures are more likely to be associated with recurrence, although patients with such seizures are also more likely to have an existing neurologic deficit or an abnormal EEG. The duration of the first seizure or a presentation in status epilepticus is not associated with a higher incidence of recurrence. A family history of epilepsy is not a predictor of recurrence. Earlier age at onset, particularly before the age of 12 months, has been associated with a higher risk of recurrent seizures.

Most authorities believe that the majority of patients with a first seizure should not be treated unless the risk of recurrence is judged to be significantly higher than average. An abnormal neurologic examination, an abnormal MRI of the brain, and abnormal EEG all increase the risk of recurrence; the greater the number of risk factors, the more likely an AED may be initiated after a first known seizure, although some neurologists will still elect to wait for a second confirmed seizure. In adults or adolescents, the issues of driving and employment may influence the decision to treat a first seizure, but in otherwise healthy and developmentally normal children, there is almost no indication for chronic AED treatment in response to a single seizure. *Activities such as bathing, driving, and swimming must be carefully supervised.*

The decision to begin AED therapy is usually made after a patient has had 2 or more seizures in a short interval of time (6-12 months). Treatment with AEDs lowers the recurrence rate by about 50%.

STATUS EPILEPTICUS

Status epilepticus *is a medical emergency* where epileptic seizures are prolonged or occur in rapid succession without recovery between the seizures. There are 2 general categories of status epilepticus: convulsive and nonconvulsive ("subclinical") status epilepticus. **Convulsive status epilepticus** may involve repetitive or prolonged GTC, myoclonic, or tonic seizures. **Nonconvulsive status epilepticus** may involve repeated or continuous absence seizures or focal dyscognitive seizures with an altered state of consciousness lasting hours or even days.

The most common duration of a seizure defined as status epilepticus is 30 minutes or longer, but seizures continuing for more than 5-10 minutes warrant immediate attention, as they are statistically likely to progress to status epilepticus. One third of children presenting with status epilepticus have no history of epilepsy, another third have a history of chronic epilepsy, and an acute illness or injury has caused status epilepticus in another third. One of the most common precipitants of status epilepticus in people with a known history of epilepsy is abrupt *discontinuation* of a daily AED.

Status epilepticus has a significant acute mortality rate, partly because of the underlying cause of the seizures; intracranial infections (meningitis, encephalitis), poisoning, acute metabolic disorders, and head injuries are some of the most common causes.

The goals of the emergency management of status epilepticus are as follows:
1. Maintain normal cardiorespiratory function and cerebral oxygenation.
2. Stop clinical and electrical seizure activity, and prevent its recurrence.
3. Identify precipitating factors.
4. Correct any metabolic disturbances (hypoglycemia, hyponatremia) and prevent systemic complications such as cardiovascular collapse, cardiac arrhythmia, pneumonia, and renal failure.

Table 30.7 sets out a plan of initial assessment and management of convulsive status epilepticus. Lorazepam and diazepam are rapidly acting anticonvulsants when given intravenously, but must be combined with a primary AED, as their duration of action is short. Side effects include sedation, depressed respiration, decreased ability to protect the airway, and hypotension.

Phenytoin, fosphenytoin, phenobarbital, or valproic acid could be used in conjunction with the benzodiazepines in providing longer-lasting anticonvulsive action.

Phenytoin is less commonly used. It has a rare but serious complication called *purple glove syndrome,* which occurs in 1.7-5.9% of intravenous administrations; within 2 hours of administration, there is pain, bluish discoloration, and swelling of the affected limb. Treatment involves discontinuation of the phenytoin, elevation, and icing of the affected limb; compartment syndrome is a potential complication.

Fosphenytoin, a prodrug of phenytoin, can be administered either intravascularly or intramuscularly. Fosphenytoin has a maximum infusion rate of 150 mg PE/min; when it is infused faster, hypotension and arrhythmias may occur.

Valproate can be given intravenously and may be the appropriate therapy for patients with known idiopathic and symptomatic generalized epilepsies. It is also generally appropriate for children with a known static cerebral injury presenting with status epilepticus as their first seizure, such as a child with a history of neonatal hypoxic-ischemic encephalopathy who presents at age 4 in status epilepticus. It is contraindicated in children with known or suspected mitochondrial disease, multisystemic disease of unknown etiology, known hepatic disease, or in children under the age of 2 years.

Nonconvulsive status epilepticus may arise when frequent focal dyscognitive seizures or absence seizures occur. In both of these settings, discrete seizures may not be identifiable; instead, the child may present with confusion, clouded consciousness, and partial responsiveness or a stuporous state, all of which can last hours or even days. It should be treated urgently as soon as it is identified, especially if focal dyscognitive status is suspected, in which case treatment should follow that outlined for convulsive status epilepticus. In absence status epilepticus, intravenous benzodiazepines are usually effective but should be used in conjunction with intravenous valproate or oral ethosuximide.

CLASSIFICATION OF EPILEPSIES AND EPILEPTIC SYNDROMES

The clinician should attempt to determine whether the seizure disorder is focal or generalized, and then whether there is evidence of underlying brain dysfunction. Both the focal and generalized epilepsies in otherwise developmentally normal children respond favorably to treatment, and there is a good chance of long-term remission. Structural epilepsies may benefit from surgical intervention. Genetic and metabolic epilepsies respond less predictably to treatment, and the chance of remission is less certain.

Identification of 1 of the epileptic encephalopathies of infancy and childhood has grave prognostic significance (Table 30.8). These epilepsies vary in the seizure types and EEG features, but have certain features in common: specific age at onset and expression, intractable seizures, cognitive dysfunction, arrest in development, conspicuous interictal epileptic discharges on the EEG, and a poor response to treatment.

Neonatal Period

The paroxysmal disorders seen in the neonatal period (birth to 8 weeks) are presented in Table 30.9.

Paroxysmal Nonepileptic Disorders

Jitteriness. Jitteriness or tremulousness is a common movement disorder of neonates. It can be confused with seizures, especially if superimposed on normal tonic postural reflexes. Jitteriness,

TABLE 30.7 Management of Convulsive Status Epilepticus

Priority	Examination and Laboratory Investigations	Management
On arrival	Airway patency and respiratory rate, inspect pharynx, chest auscultation, BP, pulse, temperature; level of consciousness; response to command, pain; serum Na, K, glucose, creatinine, Ca, Mg; CBC, liver function studies, AED levels; serum and urine toxins screen; arterial blood gases, chest radiograph	Airway protection; suction pharynx and give supplemental oxygen Rectal antipyretic to lower temperature if elevated, IV access and administer: 25% glucose IV, 2-4 mL/kg, and lorazepam* IV, 0.1 mg/kg (to a maximum of 8 mg) as a bolus and fosphenytoin IV, 20 mg/kg at 150 mg/min with ECG monitoring and collection of serum level after loading dose *If immediate IV access is not possible, give diazepam 0.3-0.5 mg/kg rectally and fosphenytoin IM and arrange for central line or intraosseous access
After initial treatment	Neck stiffness, funduscopy, signs of trauma, rashes, symmetry of motor function and reflexes	If patient is febrile: appropriate cultures, other studies depending on age and other symptoms If any suspicion of head injury: obtain urgent CT scan
If seizures continue	Patient's level of consciousness becomes depressed with lorazepam and PB, and an EEG is necessary to assess adequacy of therapy	Arrange ICU bed and consider intubation; give further bolus of lorazepam 0.05-0.1 mg/kg, and push PHT serum level above 30 mg/L with further loading dose (~10 mg/kg) In an ICU setting, if seizures continue with PHT levels of 30-40 mg/L, then add PB 20 mg/kg IV loading over 15-30 min Continued clinical or electrical seizures may necessitate induction of pentobarbital therapy: loading dose of 5-15 mg/kg, followed by IV infusion of 1-3 mg/kg/hr titrated by EEG monitoring to achieve burst suppression pattern; maintain for 24-48 hr and review Elective intubation and ventilation, arterial line, BP monitoring
After stabilization or in tandem with escalating therapy	LP; if acute febrile illness with papilledema or focal neurologic signs, then CT/MRI first	If LP is delayed and intracranial infection is suspected, then cover with antibiotic and antiviral therapy

*Give lorazepam if actively convulsing; this may not be required in patients with serial seizures who can be quickly loaded with fosphenytoin.
AED, antiepileptic drug; BP, blood pressure; Ca, calcium; CBC, complete blood count; CT, computed tomography; ECG, electrocardiogram; ICU, intensive care unit; IM, intramuscularly; IV, intravenously; K, potassium; LP, lumbar puncture; MRI, magnetic resonance imaging; Na, sodium; Mg, magnesium; PB, phenobarbital; PHT, phenytoin.

TABLE 30.8 Cryptogenic and Symptomatic Epileptic Encephalopathies

Neonates and Infants
Early epileptic encephalopathy
Early infantile myoclonic epilepsy
Migratory partial seizures of infancy
West syndrome (infantile spasms)
Severe myoclonic epilepsy of infants
Epilepsy in association with inherited disorders of metabolism

characterized by rhythmic alternating movements of all extremities with equal velocity in flexion and extension, only occasionally has a true synchronized clonic appearance. Jitteriness is not accompanied by eye deviation or staring, is stimulus sensitive, and can usually be stopped by gentle passive flexion of the moving limb.

Jitteriness in the newborn can be associated with hypoxic-ischemic encephalopathy, hypoglycemia, hypocalcemia, and drug withdrawal; if any of these causative factors are identified, there may also be a higher risk of epileptic seizures. In otherwise healthy infants, jitteriness seems to be a benign movement disorder, resolving by 10-14 months of age.

Benign neonatal sleep myoclonus. Myoclonic jerks may appear during sleep in some healthy neonates. It has been reported within hours of birth and may disappear over the next few months or persist into childhood. The jerks can be bilateral and synchronous or asymmetric; they may migrate between muscle groups during an episode. They are repetitive but do not disturb sleep. These jerks have been described in all stages of sleep but are most prominent in quiet sleep; they are not confined to sleep onset. Features distinguishing this phenomenon from epilepsy are its presence exclusively during sleep with disappearance on awakening, normal EEGs, and normal psychomotor development.

Acute Symptomatic Seizures and Occasional Seizures

Most neonatal seizures are acute symptomatic seizures, and the number of children who continue to have seizures after the neonatal period is relatively small. Neonatal seizures have been classified according to the clinical features as subtle, tonic, clonic, and myoclonic. However, not all of these clinical seizure types have consistent ictal EEG patterns. The classification of neonatal seizures reflects the variable, poorly organized, and often subtle clinical expression of epileptic seizures at this age. Typical GTC or absence seizures are not seen at this age, perhaps because of the limited capacity of the neonatal brain for interhemispheric synchrony. Patterns include the following:

- Clinical seizures *consistently* associated with an EEG seizure pattern:
  - *Clonic seizures* with focal or multifocal jerking of the face or extremities fit this category, as do focal tonic seizures with focal tonic posturing of a limb or asymmetric posturing of the axial musculature. Clinical seizures with consistent focal jerking or posturing of 1 limb are most consistently correctly identified at the bedside, and are most commonly associated with a focal structural defect, such as a focal perinatal stroke.
- Clinical seizures *sometimes* associated with an EEG seizure pattern:
  - *Myoclonic seizures* consist of single or multiple flexor jerks of the upper or lower limbs. An ictal EEG pattern is not always seen in this group. Fragmentary (multifocal) myoclonus is not always associated with an ictal EEG.
- Clinical seizures *not consistently* associated with an EEG seizure pattern:
  - These include *motor automatisms* characterized by a diversity of signs, including any of the following: wide-eyed staring, rapid blinking, eyelid fluttering, drooling, sucking, repetitive limb movements such as rowing or swimming with the arms or pedaling with the legs, apnea, hyperpnea, tonic eye deviation, and vasomotor skin color changes. This group of **subtle seizures** is generally associated with EEG background abnormalities such as suppression; the seizure itself may not have a consistent EEG correlate. This is reflective of diffuse cerebral dysfunction, such as seen in hypoxic-ischemic encephalopathy or metabolic disorders.
  - Generalized tonic seizures and focal and multifocal myoclonus are also often not associated with neonatal ictal EEG patterns,

and when seen in stuporous or comatose children, the jerks may not be epileptic. However, if the EEG is completely normal, it is unlikely that the behaviors of concern represent subtle seizures.

Some simple clinical observations should guide the assessment of neonates with episodic abnormal behaviors. Epileptic behaviors are typically repetitive and stereotyped, but are not provoked by stimulation of the child or increased with increasing intensity of a stimulus. Nonepileptic movements may disappear with repositioning of a limb or the child. Gentle restraint of a limb should be able to suppress or abort nonepileptic motor activity, whereas epileptic movements are still palpable. The association of abnormal eye movements with unusual behavior or limb movements suggests a seizure rather than nonepileptic behavior.

Diagnostic investigations. EEG monitoring is useful in the evaluation of suspicious fluctuations in vital signs in neonates who are paralyzed and intubated or comatose, or in neonates with subtle but repetitive episodes of unusual behavior.

Many neonatal intensive care units have the capability to perform amplitude-integrated EEG (aEEG), which is a reduced electrode monitoring method that uses time-compressed baseline trends of 2 or 4 channels of EEG to allow the bedside practitioner to look for changes suspicious for seizure. However, both the sensitivity and specificity of aEEG are lower than that of full-montage conventional EEG; less than 50% if only a single channel of aEEG is available, but up to 76% and 78%, respectively, when 2 channels of raw EEG are available for comparison and direct review by expert aEEG interpreters. Conventional EEG is recommended over aEEG when both are available; however, the use of aEEG is associated with lower total seizure duration in neonates compared to no monitoring.

Proper treatment must include a thorough search for the cause of the seizures, because many conditions necessitate specific treatment. The possible etiologic factors are numerous and diverse (Tables 30.10 and 30.11). The most common cause is hypoxic-ischemic encephalopathy (60-65%); it is important to make a positive diagnosis of this historically and to exclude conditions such as local anesthetic toxicity, pyridoxine-dependent seizures, prenatal injury, and metabolic encephalopathies that may masquerade as perinatal asphyxia.

Prognosis. The prognosis for normal development after neonatal seizures depends on the cause of the seizures. Approximately 50% of neonates with seizures develop normally, 30% have neurologic sequelae, and 15-20% die. Neonates with seizures caused by CNS infection, hypoglycemia, structural brain malformations, intraventricular hemorrhage, and hypoxic-ischemic encephalopathy have a higher risk of poor outcome due to the prevalence of global brain injury in these conditions. Fifty percent of neonates with hypoxic-ischemic encephalopathy–related seizures develop normally, but fewer than 10% of neonates with seizures and intraventricular hemorrhage develop normally. In contrast, those infants with seizures caused by hypocalcemia (in the absence of asphyxia), drug withdrawal (from maternal drug use), and focal arterial ischemic stroke usually do well, as these are either caused by reversible, transient, or focal etiologies. The likelihood of recurrent seizures is 15-30% overall.

The EEG may add prognostic information; neonates with a normal background pattern are unlikely to have any neurologic deficits and are less likely to have seizures as a cause for their paroxysmal events, but persistent severe abnormalities of the background rhythms, such as burst-suppression patterns, suppression of background rhythms, and electrocerebral silence, have over 90% chance of a poor outcome, including death. Moderate abnormalities of the EEG in the form of amplitude asymmetries and patterns immature for the patient's conceptional age are associated with intermediate outcomes and are of less

TABLE 30.10 Causes of Neonatal Seizures

Ages 1-4 Days
Hypoxic-ischemic encephalopathy
Drug withdrawal, maternal drug use of narcotics or barbiturates
Drug toxicity: lidocaine, penicillin
Intraventricular hemorrhage
Acute metabolic disorders
    Hypocalcemia
        Perinatal asphyxia, small for gestational age
        Sepsis
        Maternal diabetes, hyperthyroidism, or hypoparathyroidism
    Hypoglycemia
        Perinatal insults, prematurity, small for gestational age
        Maternal diabetes
        Hyperinsulinemic hypoglycemia
        Sepsis
    Hypomagnesemia
    Hyponatremia or hypernatremia
        Iatrogenic or inappropriate antidiuretic hormone secretion
Inborn errors of metabolism
    Galactosemia
    Hyperglycinemia
    Urea cycle disorders
    Pyridoxine deficiency (must be considered at any age)

Ages 4-14 Days
Infection
    Meningitis (bacterial), encephalitis (enteroviral, herpes simplex)
Metabolic disorders
    Hypocalcemia
        Diet, milk formula
    Hypoglycemia, persistent
        Inherited disorders of metabolism: galactosemia, fructosemia,
          leucine sensitivity
        Hyperinsulinemic hypoglycemia
        Anterior pituitary hypoplasia, pancreatic islet cell tumor
        Beckwith syndrome
Drug withdrawal, maternal drug use of narcotics or barbiturates
Benign neonatal convulsions, familial and nonfamilial
Kernicterus, hyperbilirubinemia

Ages 2-8 Weeks
Infection
    Herpes simplex or enteroviral encephalitis, bacterial meningitis
Head injury
    Subdural hematoma, child abuse
Inherited disorders of metabolism
    Aminoacidurias, urea cycle defects, organic acidurias
    Neonatal adrenoleukodystrophy
Malformations of cortical development
    Lissencephaly
    Focal cortical dysplasia
Tuberous sclerosis
Sturge-Weber syndrome

value in isolation from other clinical data; these will require long-term neurologic follow-up.

Treatment. The primary treatment for neonatal seizures is the treatment of the underlying cause. All neonates with seizures should have a trial of pyridoxine and folinic acid treatment if the cause is not identified and seizures persist. Some neonates also require treatment with an AED, traditionally phenobarbital, but levetiracetam and fosphenytoin are also used. Protein binding is lower in neonates than in older children, and the speed of hepatic metabolism changes significantly in the first few days of life, so frequent serum levels of protein-bound, hepatically metabolized AEDs such as phenobarbital or fosphenytoin are necessary for the first several days of treatment, or when making major adjustments.

At an intravenous loading dose of 18-20 mg/kg, phenobarbital should produce a serum level of approximately 18-20 mg/L (Table 30.12). A daily maintenance dose of 3-5 mg/kg, either administered once daily or in 2 divided doses daily, keeps serum levels in this range. The serum level can be increased to 40-60 mg/L with further loading doses before consideration of a second drug for persistent seizures.

If a self-limited or correctable short-term insult is the cause, the clinician may administer a loading dose with phenobarbital and give no maintenance therapy, simply observing for recurrent seizures. Alternative management would be to administer a loading dose of phenobarbital and give maintenance doses throughout an illness or to treat for a maximum of 3-6 months if the time during which the child is at risk for seizures is uncertain.

Epileptic Syndromes

Benign idiopathic neonatal convulsions, familial and nonfamilial. Some neonatal seizures occur in otherwise healthy neonates without perinatal risk factors or identifiable causes that remit spontaneously and are not followed by developmental delay; these include benign idiopathic neonatal convulsions and benign familial neonatal convulsions. These are diagnoses of exclusion and a complete work-up for other causes of neonatal seizures must be performed before deciding upon these etiologies.

Benign idiopathic neonatal convulsions are common and may account for 2-7% of neonatal seizures. The disorder is sometimes referred to as **5th-day fits**, although the seizures may begin between 1 and 7 days of age. The seizures are typically focal and multifocal clonic seizures that may, in rare cases, develop into status epilepticus. The seizures remit within hours or days. Although normal at the onset of seizures, affected neonates may become drowsy and hypotonic during the seizures and for a few days after the seizures remit. Long-term follow-up data are not yet complete, but the majority of affected children appear to have normal psychomotor development and no increased risk for the development of epilepsy.

Benign familial neonatal convulsions are less common. There is a distinctive family history of transient neonatal seizures that shows autosomal dominant inheritance. The onset of seizures is usually between 2 and 4 days after birth, but in some cases, onset may occur at 1-3 months of age. The neonates are otherwise healthy without risk factors for seizures. The seizures are usually brief clonic seizures, but some neonates have tonic seizures. This group differs from the nonfamilial cases in that the seizures may persist longer, the interictal EEG is generally nonspecific, and later seizures occur more frequently in approximately 10-15% of children. Abnormalities in 2 potassium channel genes, *KCNQ2* on chromosome 20 and *KCNQ3* on chromosome 8, have been found in some kindreds (see Table 30.3).

Vitamin-dependent seizures. There are rare metabolic disorders that present in the first few days of life with encephalopathy and refractory seizures; a smaller percentage of these disorders can be treated with early diagnosis and administration of the correct vitamin. Pyridoxine-dependent and folinic acid-dependent seizures are 2 such disorders; pyridoxine is essential for amino acid metabolism, and folinic acid is necessary for DNA synthesis and repair. Multidisciplinary care with a geneticist and a neurologist is ideal for children with these rare disorders.

TABLE 30.11 Inherited Disorders of Metabolism and Neurodegenerative Diseases Associated with Seizures in Infants

Disorder	Clinical Features and Laboratory Findings	Investigations
Neonates		

These disorders are rare. The clinical features are nonspecific and usually do not distinguish between the inherited disorders of metabolism; however, they may suggest that a search for these conditions is warranted:
  Metabolic or degenerative disorder in another sibling
  Normal immediately after birth with symptoms and signs developing in the first days to weeks of life
  Food intolerance; vomiting, diarrhea, not settling after feedings
  Lethargy, may become stuporous after feeding
  Hypotonia
  Seizures; tonic, clonic, subtle neonatal seizures; myoclonus in some disorders
  Late signs: weight loss, failure to thrive, psychomotor retardation
	Initial investigations in neonatal seizures:
	  Glucose, urinalysis, ketones
	  Serum glucose, Na$^+$, K$^+$, Ca^{2+}, Mg^{2+}, blood urea nitrogen, creatinine
	  Serum ammonia, lactate, and pyruvate
	  Liver function tests, complete blood cell count, arterial blood gas measurements
	  Lumbar puncture and CSF analysis
	  EEG
	  CT or MRI scan may be indicated

Aminoacidurias Maple syrup urine disease	An unusual maple syrup odor of the urine may be detected; severe metabolic acidosis and increased anion gap; urine positive for ketones; boiled urine reacts with 2,4-DNPH to give yellow precipitate	Serum amino acid analysis; elevated serum leucine, isoleucine, and valine

Organic acidurias
  Propionic acid
  Methylmalonic acid
  Isovaleric acid
  Glutaric acid
	Hyperammonemia, metabolic acidosis and increased anion gap, ketosis, low blood urea nitrogen; secondary elevation of lactate and hypoglycemia may be present and secondary carnitine deficiency may occur; glycine level may be elevated in these disorders
	Thrombocytopenia, neutropenia, and anemia
	Characteristic body odor in some of these disorders
		Urine organic acid analysis
		Serum carnitine measurement
		Serum acylcarnitine profile

Urea cycle disorders	Hyperammonemia without hypoglycemia, ketoacidosis or hematologic abnormalities	Serum ammonia. Plasma amino acids and urine orotic acid can help define the specific urea cycle defect
Nonketotic hyperglycinemia D-glyceric acidemia	Intractable seizures and severe encephalopathy, often with coma, within the first weeks of life; may have the clinical syndrome of early myoclonic encephalopathy; myoclonic seizures, burst suppression on EEG, severe psychomotor retardation	Elevated urine and plasma glycine levels, normal organic acid pattern and ammonia level. Ratio of CSF : serum glycine necessary to make the diagnosis
Pyridoxine dependency	No specific clinical features; must be suspected in all neonatal seizures without alternative cause and especially in those not responding to simple measures	Therapeutic trial of pyridoxine; high dosage must be given for a period of weeks

Peroxisomal diseases
  Zellweger syndrome
  Adrenoleukodystrophy
  Refsum disease
	Characteristic facies
	Neonatal form
	Infantile form
		Screen with serum very-long-chain fatty acid analysis, specific measurement of phytanic acid, prystanic acid, pipecolic acid, red cell plasmalogens, and bile acids for biochemical diagnosis. Molecular diagnostics using comprehensive gene panels

Infants		
Pyruvate dehydrogenase deficiency Pyruvate carboxylase deficiency	Metabolic acidosis and increased anion gap, lactic acidosis, with normal lactate-to-pyruvate ratio (10 : 20); hyperammonemia may be seen; normoglycemic; serum and CSF alanine levels may be elevated Lactate-to-pyruvate ratio is normal or elevated The clinical features are nonspecific: encephalopathy, hypotonia, and seizures; intermittent hyperventilation may be present. Both these disorders can manifest later in childhood with developmental delay and episodic symptoms such as ataxia and vomiting	Serum lactate and pyruvate measurement Serum and CSF amino acids measurement
Biotinidase deficiency	Refractory seizures, rash, alopecia; lactic and organic acidosis	
Aminoacidurias		
Phenylketonuria	Onset in infancy with developmental delay and seizures; seizures occur in about 25%, and the infant may have severe epilepsy with West syndrome; deficiency of phenylalanine hydroxylase causes the accumulation of phenylalanine and phenylacetic acid	Nearly 100% identified through New Born Screening. Plasma amino acids will identify elevated phenylalanine in affected individuals

TABLE 30.11 Inherited Disorders of Metabolism and Neurodegenerative Diseases Associated with Seizures in Infants—cont'd

Disorder	Clinical Features and Laboratory Findings	Investigations
Phenylketonuria variant with biopterin deficiency	Hypotonia and seizures develop at or after 6 mo of age; generalized motor seizures, erratic myoclonus, and oculogyric seizures	Nearly 100% identified through New Born Screening. Plasma amino acids will identify elevated phenylalanine in affected individuals
Tay-Sachs disease GM$_2$ gangliosidosis	Abnormalities appear in the first weeks to months of life with irritability and acoustic startle or myoclonus, not seizures, in the first months; developmental delay and cherry-red macular spots are present; seizures develop in the second year of life; erratic myoclonus, focal seizures, and slowing of background rhythms on EEG	Blood sample and skin biopsy; hexosaminidase A deficiency detectable in blood lymphocytes and cultured fibroblasts
Sandhoff disease GM$_2$ gangliosidosis type II	Similar in phenotype to Tay-Sachs disease	Hexosaminidase B deficiency detectable in blood lymphocytes and cultured fibroblasts
GM$_1$ gangliosidosis	Dysmorphic features; three clinical subtypes, *infantile* with rapid progression in first 6 mo of life, seizures are frequent without specific characteristics; cherry-red spots on the maculae; juvenile or late onset form (6 mo to 3 yr), chronic form (4 to 30 yr). Dysmorphic features and skeletal changes similar to Morquio mucopolysaccharide storage disorder	Skin biopsy, blood β-galactosidase deficiency found in blood lymphocytes and cultured fibroblasts
Leigh disease (subacute necrotizing encephalopathy)	A clinical syndrome resulting from various abnormalities of mitochondrial oxidative phosphorylation Usually manifesting in infancy with regression of motor skills, hypotonia, lethargy, respiratory disorders (typically hyperventilation and apnea), and seizures; other features are nuclear and supranuclear oculomotor paralysis, brainstem dysfunction, choreoathetosis, cerebellar ataxia, and pyramidal signs	CSF lactate measurement; MRI of the brain (may show midbrain periaqueductal signal abnormalities) Muscle biopsy for oxidative metabolism analysis and DNA studies
Menkes disease	Sex-linked inheritance on long arm of X chromosome; hypotonia, failure to thrive, abnormal temperature regulation, hypothermia or hyperthermia, fragile wiry hair, poor pigmentation, generalized seizures, often infantile spasms	Deficiency of serum copper and ceruloplasmin
Krabbe disease	Appears before 3-6 mo of age; rigidity develops in an irritable, crying infant; opisthotonic posturing of the neck and trunk; generalized motor seizures may occur, but must be distinguished from tonic spasms; affected children become blind with optic atrophy	Skin biopsy and blood galactocerebrosidase deficiency
Angelman syndrome	Developmental delay from birth, characteristic facies, ataxia with jerky limb movements, inappropriate laughter ("happy puppet"), seizures in 86% of patients	Abnormal methylation of maternally inherited imprinted region of chromosome 15q11.2. Four known genetic mechanisms can cause Angelman syndrome; approximately 70% of cases result from de novo maternal deletions involving chromosome 15q11.2-q13; approximately 2% result from paternal uniparental disomy of 15q11.2-q13; a subset of the remainder result from other imprinting defects and pathogenic variants in the gene encoding the ubiquitin-protein ligase E3A gene *(UBE3A)*
Early infantile type of ceroid-lipofuscinosis Batten disease	Severe myoclonus at 3-18 mo; hypotonia, ataxia, impaired vision, dementia; diffuse cerebellar and cerebral atrophy EEG; no enzymatic defect identified; diagnosis must be based on clinical features and skin biopsy showing ceroid	Skin biopsy, inclusion bodies on electron microscopy of peripheral lymphocytes (buffy coat EM), rectal biopsy; genetic testing available
Other Rare Metabolic Disorders with Encephalopathy Seizures in Infancy Glutaric aciduria type II, multiple acyl-CoA dehydrogenase deficiency Medium-chain acyl–CoA dehydrogenase deficiency Canavan–van Bogaert disease Molybdenum cofactor deficiency		Specific testing based on suspected diagnosis

CoA, coenzyme A; CSF, cerebrospinal fluid; CT, computed tomography; DNPH, dinitrophenylhydrazine; EEG, electroencephalogram; MRI, magnetic resonance imaging.

TABLE 30.12 Neonatal Antiepileptic Medication: Pharmacokinetic Parameters

	Routes of Administration	% Protein Bound	Half-Life Loading Dose	Maintenance (hr)	Therapeutic Antiepileptic Dosage (mg/kg/day)	Range (mg/L)
Phenobarbital	IV, PR, PO	24	20 mg/kg	40-200	3-5	10-30
PHT	IV, PO	85-90	15-20 mg/kg	6.9-140*	IV: 8-10; PO: 18-20	5-20
Fosphenytoin	IV, IM	70, displaces PHT	15-20 mg/kg†	Fosphenytoin > PHT, 8-15 min	18-20	5-20
Diazepam	IV, PR	84	0.1-0.3 mg/kg/dose‡	31-75	3	0.3-0.7
Lorazepam	IV	85	0.05 mg/kg/dose§	18-73	NA	NA

*Great variation, shorter if exposed to enzyme-inducing drugs (e.g., phenobarbital) and within 1st 2-3 wk of life.
†Dosage is in PHT equivalents per kg.
‡Can be given every 15 min to a maximum of 2 mg.
§Up to 2 doses only.
IM, intramuscularly; IV, intravenously; NA, not applicable; PHT, phenytoin; PO, per os (orally); PR, per rectum.

Pyridoxine-dependent seizure is a rare autosomal recessive disorder in which seizures usually appear within the first 3 months of life, often within hours of birth, but in rare cases, as late as 2-5 years of age. The EEG may show focal, multifocal, and generalized epileptiform activity, and the child is encephalopathic. The seizures (myoclonic, GTC, and partial), and EEG discharges disappear over hours in response to 100 mg of intravenous pyridoxine (vitamin B$_6$), which can be repeated 3-5 times as necessary. The children require long-term pyridoxine, 50-100 mg/day.

Folinic acid-responsive seizures present very similarly to pyridoxine-dependent seizures, with medically intractable, relentless seizures of multiple types, often within the first days of life. The seizures respond to 2.5-5 mg of folinic acid twice daily.

These are rare disorders, but as they are neurologically devastating or fatal if untreated, it is reasonable to administer a trial dose of pyridoxine and/or folinic acid to seizing, encephalopathic infants where no other cause has been found for their seizures and encephalopathy. If there is a clinical, and ideally electrographic, response to the vitamin trial, then it is also reasonable to continue the supplement. Nonetheless, even with early diagnosis and treatment, these children may have developmental delays.

Structural focal epilepsy. **Malformations of cortical development**. Disorders of cell migration within the CNS may result in profound anatomic abnormalities and dysfunction or a spectrum of lesser abnormalities, ranging from focal areas of cortical dysgenesis and clinical deficits to subcortical collections of neurons (heterotopia) seen only under the microscope. Migrational abnormalities are rare but are commonly associated with seizures. Although these abnormalities are present from birth, seizures may develop at any age.

Lissencephaly, or agyria, is a profound abnormality characterized by a smooth brain without development of the normal gyral pattern and sulci; there are often large heterotopia in the white matter, and neuroimaging studies may reveal the appearance of a double cortex.

Hemimegalencephaly is characterized by gross enlargement of 1 hemisphere with no normal cortical development within that hemisphere. More restricted abnormalities may occur in the form of a limited area of gyral enlargement and distortion called pachygyria.

Schizencephaly refers to unilateral or bilateral clefts in the cerebral hemispheres, usually with abnormal arrangement (polymicrogyria) of the cortical gray matter lining the clefts.

Porencephaly refers to fluid-filled cavities within the brain. Porencephalic cysts communicate with both the subarachnoid space and the ventricular system and are lined not by cortical gray matter but rather by white matter because they result from loss of tissue as a consequence of insults, typically infarction or hemorrhage, during development.

Early-onset generalized epileptic syndromes with encephalopathy. **Early myoclonic encephalopathy** appears in neonates before 2-3 months of age, usually within the first 2 weeks of life. Myoclonus appears at the onset but may be fragmentary. Partial motor seizures, massive myoclonus, or infantile spasms may also occur. The EEG shows a suppression-burst pattern that may later evolve into a hypsarrhythmic pattern. There is a failure or arrest of psychomotor development and a high rate of mortality before 12 months of age. A number of patients have an inborn error of metabolism, including nonketotic hyperglycinemia, D-glyceric acidemia, propionic acidemia, and methylmalonic acidemia.

Early epileptic encephalopathy with suppression-burst EEG pattern (Ohtahara syndrome) has an onset during the same period. The affected child experiences intractable tonic seizures or epileptic spasms, and the EEG shows a suppression-burst pattern. Affected children have a severe encephalopathy, and the prognosis for remission from seizures or for normal development is very poor. Many of these patients have malformations of cortical development.

There appear to be neonates in whom the EEG features and clinical course of these 2 syndromes overlap; these syndromes may evolve into West syndrome and Lennox-Gastaut syndrome.

Infancy

The paroxysmal disorders of infancy (8 weeks to 2 years) are shown in Tables 30.3 and 30.13.

Paroxysmal Nonepileptic Disorders

Infantile syncope

Cyanotic infant syncope (breath-holding spells). Cyanotic infant syncope consists of episodes of loss of consciousness followed by tonic stiffening in crying infants. The peak incidence is between 6 and 18 months of age, but it may occur in neonates or in children as old as 6 years of age. The typical clinical picture is an infant who is frightened, frustrated, or surprised; begins to cry vigorously; and then becomes apneic and cyanotic before becoming unconscious, stiff, or limp. In rare cases, typical infant syncope may evolve into a brief GTC seizure. The child regains consciousness rapidly after being positioned horizontally or stimulated without a prolonged postictal state, although there may be a tendency to sleep.

TABLE 30.13   Paroxysmal Disorders in Infants

Nonepileptiform Disorders
Infantile syncope*
Cyanotic breath-holding spells
Pallid syncope
Shivering attacks
Paroxysmal torticollis
Extrapyramidal drug reactions, dystonia
Gastroesophageal reflux with dystonia[†]
Rumination[†]
Stereotypical; movements, autism, Rett syndrome, coexisting deafness and blindness[†]
Withholding, constipation[†]
Masturbation
Spasmus nutans
Opsoclonus
Benign paroxysmal vertigo
Myoclonus
Nonepileptic; anxiety, excitement, acute metabolic encephalopathy
Benign myoclonus of early infancy
Hyperexplexia[†]
Alternating hemiplegia of childhood
Sleep disorders*
Jactatio capitis, head banging

Acute Symptomatic Seizures, Occasional Seizures
Febrile convulsions*
Meningitis, encephalitis*
Head injury, child abuse
Poisoning
Intercurrent medical illness, renal, and liver disease, cardiac left-to-right shunt, and embolism
Metabolic disease, rickets

Epileptic Syndromes
Symptomatic focal epilepsy[†]
West syndrome
Early myoclonic encephalopathy[‡]
Early infantile encephalopathic epilepsy[‡]
Malformations of cortical development[‡]
Neurocutaneous disorders (see Table 30.6)
    Tuberous sclerosis
    Sturge-Weber syndrome
    Incontinentia pigmenti
    Epidermal nevus syndrome
Severe myoclonic epilepsy in infancy (Dravet syndrome)

*Common.
[†]See childhood section for discussion.
[‡]See neonatal section for discussion.

These episodes have also been called breath-holding spells, anoxic seizures, and convulsive syncope, but *cyanotic infant syncope* may be a better term because the loss of consciousness appears to be the result of transient impairment of cerebral perfusion. The subsequent tonic posturing in the typical attack is not epileptic, but is thought to have the same brainstem origin as decerebrate or decorticate posturing.

Cyanotic infant syncope is common and is seen in 4.6% of a large cohort of children monitored from birth. A thorough history is usually sufficient for diagnosing this condition. The crucial diagnostic point

is the history of an external event precipitating the episode. The differential diagnosis is noted in Table 30.14.

Although the spells appear to be unpleasant for the child and can be frightening to the parents, they do not result in neurologic sequelae and do not necessitate intensive investigation. The child should be evaluated for anemia; treatment of iron deficiency anemia reduces the frequency of syncopal events. Treatment with carbamazepine, phenytoin, or valproate may decrease the frequency or severity of postsyncopal convulsions in the rare child with epileptic seizures triggered by the anoxic event. Children with known brainstem or posterior fossa malformations may also be at higher risk of prolonged syncope and clinically significant anoxia due to their abnormal respiratory drive, and these children may benefit from treatment.

Pallid infant syncope. Pallid infant syncope occurs in response to transient cardiac asystole in children with a hypersensitive cardioinhibitory reflex. This form is less common but more alarming. There is minimal crying, perhaps only a gasp, and no obvious apnea before the loss of consciousness. Again, there is a precipitating event; the child appears to lose consciousness after minimal injury or fright, collapses limply, and then may have posturing and clonic movements before regaining consciousness (see Table 30.14).

Pallid infant syncope, if frequent and troublesome or if followed by prolonged GTC convulsions, can be treated with atropine, which blocks the vagus nerve–mediated asystole. Most affected children require no medical treatment.

Hyperekplexia. A startle response is normally seen in children and adults in response to sudden, unexpected stimuli. There are 2 phases to a startle response: the initial startle followed by an orienting response to locate the stimulus. Hyperekplexia is characterized by an excessive startle response interfering with daily living, usually causing patients to fall stiffly with preserved consciousness. This disorder may present as early as infancy with hypertonia and dramatic startle responses that do not habituate or extinguish with repeated stimuli (meaning they continue to startle, no matter how many times a stimulus is given in a short period of time). The excessive startle and hypertonia can lead to genuinely life-threatening apneas and breath-holding spells when startled or upset. Generalized seizures have been reported in some cases; intellectual disability and delayed motor development appear to be common. The background EEG is usually normal. There may be some improvement with benzodiazepines or valproic acid.

Mutations in the *GLRA1* gene, encoding the α-1 subunit of the glycine receptor, have been found in families with an autosomal dominant or recessive inheritance pattern. Glycine is a co-agonist for the *N*-methyl-D-aspartate (NMDA) receptor, which is an excitatory receptor critical for learning and neuronal plasticity.

Sleep disorders. Also referred to as head banging or rocking, jactatio capitis nocturna consists of rhythmic to-and-fro movements of the head or rocking of the body. It occurs typically at the transition from wakefulness to sleep, early in the evening, or after arousal during the night. This behavior is quite common, occurring in up to 15% of children; it begins in infancy or early childhood, but may persist up to 10 years of age. The child is not awake during the episode and does not remember the events, which usually last less than 15 minutes. In most cases, it is sufficient to ensure that the bed area is padded to prevent injury.

Shivering attacks. Shivering or shuddering attacks are brief episodes characterized by sudden flexion of the head and trunk associated with a rapid tremulous contraction of the musculature. The appearance is exactly that of a sudden brief shudder experienced normally when exposed to cold. In this condition, the shuddering occurs repeatedly. Some infants experience more than 100 brief shudders per day. There may be clustering, with intervals of several weeks free of the

TABLE 30.14 Differential Diagnosis of Infantile Syncope

Clinical	Infantile Syncope	Pallid Syncope	Tonic-Clonic Seizures	Infantile Spasms
Age range	1-6 yr; peak, 6-18 mo	1-6 yr	All ages	4-12 mo
Precipitating factors	Present (e.g., minor trauma, frustration, fright)	Present (e.g., minor trauma, frustration, fright)	Usually none	None
Occurrence in sleep	Never	Never	Common	At transition from awake to sleep and sleep to awake
Sequence of events	Crying → exhale; apnea → cyanosis, loss of consciousness; opisthotonos → relaxation, resumption of breathing	Upset, usually not crying → sudden pallor → limp fall with fainting → tonic posture, or clonic jerks may occur	Sudden loss of consciousness → increased tone, followed by synchronous jerking of body and limbs → unconsciousness; duration, 1-2 min	Sudden sustained flexion or extension of proximal limbs and trunk; duration, 2-20 sec; seizures usually occur multiple times daily
Postictal symptoms	Usually minimal; infant may be lethargic and irritable	Usually minimal; quick return to normal	Usually marked; unconsciousness initially, then confusion and lethargy	Rapid return to preictal state
Interictal EEG	Normal	Normal	Frequently abnormal with epileptiform discharges	Abnormal background and epileptiform discharges
Ictal EEG	Reflects global cerebral hypoxia, diffuse rhythmic slowing → suppression → slowing with return of consciousness	Reflects global cerebral hypoxia; diffuse, rhythmic slowing → suppression → slowing with return of consciousness	EEG seizure patterns; postictal diffuse suppression, then slowing	High-amplitude slow transient waves → diffuse suppression
Pathophysiology	Respiratory arrest without asystole	Vagal bradycardia or temporary asystole	Primary CNS event	Primary CNS event, age-related epileptic seizure

CNS, central nervous system; EEG, electroencephalogram.

episodes. The child may assume a characteristic posture with flexion of head, trunk, and elbows and adduction of elbows and knees.

The attacks have been described in children between the ages of 4 months and 10 years, although most often the onset seems to occur in infancy and early childhood. The phenomenon is nonepileptic and benign, eventually disappearing. Some children and their relatives have been reported to have an essential tremor. The shuddering is faster and of lower amplitude than myoclonus and is paroxysmal, not sustained, as occurs with a tremor. An important epileptic disorder that must be ruled out is infantile spasms.

Paroxysmal torticollis. Torticollis is an abnormal posturing of the head and neck, with the head flexed toward the shoulder and the neck rotated with the chin turned toward the opposite shoulder. The posturing is paroxysmal, although variable in duration, lasting minutes or days, and there is no loss of consciousness. Some children have associated pallor, agitation, and vomiting, and the disorder has been suspected to result from labyrinthine dysfunction, like benign paroxysmal vertigo of childhood. The disorder is self-limited and remits in early childhood. There is an association with migraine in patients later in life and among their relatives.

In older children, torticollis may occur as a **focal dystonia** persisting to adulthood. Familial cases have been described, and in some, the torticollis may be the earliest manifestation of a more generalized dystonia.

Sustained abnormal posturing should prompt appropriate radiologic investigations to exclude inflammatory or neoplastic disorders of the upper cervical spinal cord, posterior fossa, cervical spine, or soft tissues of the neck (particularly a retropharyngeal abscess). In very rare cases, gastroesophageal reflux manifests with dystonic posturing of the neck and upper trunk. Adverse extrapyramidal reactions to phenothiazines and related drugs may produce dystonic posturing of the neck and trunk.

The pharmacologic treatments for torticollis cover a number of different medication classes, including anticholinergics (trihexyphenidyl), dopamine agonists (pramipexole), nonsteroidal antiinflammatory drugs (NSAIDs), baclofen, benzodiazepines (clonazepam), and β blockers (propranolol). Botox injections may be used for more refractory cases. Physical therapy can also be very helpful. The most severe cases can be evaluated for surgical intervention, such as selective denervation or sternocleidomastoid release.

Infantile masturbation. Episodes of genital self-stimulation may occur in young children. Toddlers may assume stereotyped posturing with tightening of the thighs or applied pressure to the suprapubic or pubic area not associated with manual stimulation of the vulva or rhythmic movements. The episodes vary in duration from minutes to hours and are often accompanied by irregular breathing, facial flushing, and diaphoresis, and the child may be irritated and cry if interrupted. A thorough history or a video of the episodes may be sufficient to make this diagnosis.

Spasmus nutans. Spasmus nutans is a rare disorder of unknown origin characterized by nystagmoid eye movements, head nodding, and torticollis. Head nodding may develop before the nystagmus and can be horizontal, vertical, or mixed. Both the head movements and the nystagmus may be paroxysmal, allowing confusion with seizures. There is no loss of consciousness during an episode. Small-amplitude rapid eye movements are typical; they tend to be asymmetric between the eyes and may even be monocular. The eye movements vary in prominence with different directions of gaze.

This is usually a self-limited disorder with onset between 4 and 18 months of age and not persisting after age 3 years, although nystagmus alone may persist in some children. Investigations should include imaging of the brain with special focus on the optic nerves, optic chiasma, and brainstem, because some cases have been associated with CNS tumors.

Benign paroxysmal vertigo. Benign paroxysmal vertigo may be confused with seizures because attacks develop suddenly, are accompanied by ataxia, and may cause the infant or young child to fall. There is pallor, distress, and assumption of a motionless, often supine, position, but no loss of consciousness; older children can recall the event. There may be vomiting with associated nystagmus. Attacks last seconds to minutes and vary in frequency, sometimes occurring daily. Older children can identify symptoms of nausea and vertigo and are less likely to be thought to be experiencing seizures. The children are normal between attacks. The condition is closely related to **migraine**, with many shared symptoms and the later development of more typical migrainous headache.

Benign myoclonus of early infancy. This uncommon syndrome may resemble the cryptogenic form of infantile spasms at onset, with bilateral myoclonic jerks developing in a previously normal infant. However, this is a benign, probably nonepileptic condition occurring in infants 3-8 months of age and disappearing after a period of weeks or months. The pattern of myoclonus may differentiate it from infantile spasms, including predominant involvement of the head, neck, and upper limbs with adversive head movements or tremors without involving the lower limbs. The EEG is normal. Myoclonic movements are not accompanied by an EEG seizure pattern. These abnormal movements may necessitate monitoring to establish a nonepileptic diagnosis. There is no arrest of normal development or regression as is seen in West syndrome. Most important, the myoclonus remits, not persisting after 2 years of age, and there is increased risk for other seizure patterns after its cessation.

Alternating hemiplegia of childhood. Alternating hemiplegia of childhood is a rare syndrome of episodic hemiplegia that usually manifests in infancy with the following diagnostic criteria:

1. Onset before age 18 months, often before age 6 months
2. Recurrent episodes of fluctuating hemiparesis or hemiplegia affecting both sides of the body and disappearing during sleep
3. Other paroxysmal phenomena: tonic seizures, dystonic posturing, choreoathetosis, nystagmus, and other paroxysmal oculomotor disturbances; and autonomic dysfunction, occurring during or between hemiplegic episodes
4. Progressive cognitive and neurologic deficits

The pathophysiologic mechanism remains unknown, although there are reports of mitochondrial dysfunction in some cases and an autosomal dominant pattern of inheritance in others. The differential diagnosis includes paroxysmal choreoathetosis and dystonia syndromes, familial hemiplegic migraine, transient ischemic attacks associated with cerebral vascular abnormalities such as moyamoya disease or cardiac emboli, mitochondrial disorders, hyperviscosity, sickle cell anemia crises, inherited disorders of metabolism (pyruvate dehydrogenase deficiency and Leigh disease), and epileptic seizures with postictal paralysis. Symptomatic treatment is available with calcium channel blockers; flunarizine is the one most commonly cited in the literature, but is not available in the United States or Japan. An alternative calcium channel blocker would be nimodipine.

There have been case reports of a similar-appearing disorder with nocturnal paroxysmal events of flaccid hemiplegia lasting up to several hours at a time. The key differentiating factors are that these children are essentially normal prior to diagnosis, the events occur during sleep, and the children appear to outgrow these spells by midchildhood without significant long-term neurologic sequelae. This is known as **benign nocturnal alternating hemiplegia of childhood.** No consistent genetic mutations have been associated with this disorder, and there is no consistent response to antiepileptics or calcium channel blockers.

Acute Symptomatic Seizures and Occasional Seizures

Febrile convulsions. Febrile convulsions are common and are defined as seizures occurring between the ages of 6 months and 5 years in association with a fever in the absence of intracranial infection. Patients with a history of previous afebrile seizures are not included in the affected population. The temperature elevation is variable. The highest incidence of febrile convulsions occurs between 1 and 2 years of age, and 85% of febrile convulsions occur before the age of 4 years. The incidence is between 2% and 5%; it is slightly more common in boys.

The seizures are usually brief with generalized clonic or tonic-clonic motor involvement without any postictal paralysis or a prolonged postictal state of confusion or drowsiness. The seizures generally occur well within the first 24 hours of a febrile illness, not necessarily when the fever is highest; they may be the first indication of illness. **Complicated febrile convulsions** are defined as those lasting longer than 15 minutes, recurring during a single febrile illness, having unilateral or focal features, or followed by postictal paralysis. Seizures occurring late in a febrile illness should raise suspicions of encephalitis, brain abscess, or meningitis. Febrile delirium and even rigors may be mistaken for seizure activity.

The initial investigation must include a search for the cause of the febrile illness. For this diagnosis, it is essential that primary CNS infection be ruled out as the cause of both the fever and the seizures. A lumbar puncture is recommended in children younger than 12 months of age if there is any suspicion of intracranial infection, and when features of the seizure or postictal state suggest a focal or lateralized seizure. Herpes simplex encephalitis in particular should be considered in children presenting with evidence of encephalitis and focal seizures. Computed tomography, MRI, and EEG may be part of the work-up if an underlying CNS infection is suspected or a neurologic deficit has been revealed by the history or examination.

However, if the history is consistent with a febrile seizure, the child is in the appropriate age range and is developmentally normal, a fever has been documented, and an obvious source of infection has been found, extensive investigations are unnecessary. Many clinicians would not perform a lumbar puncture or obtain an EEG in an otherwise healthy child with an uncomplicated febrile seizure over the age of 2 years who has an obvious source of infection such as otitis media or a urinary tract infection.

Treatment of a child still in convulsion on arrival at the hospital should include prompt attention to protection of the airway and circulation. Giving acetaminophen rectally should lower the fever. Nasal or rectal diazepam or intravenous lorazepam should be administered if the child has been seizing for more than 10 minutes. Some children may require hospital admission. The family should be advised that future fevers with temperatures above 38°C (100.4°F) may be treated with regular acetaminophen or ibuprofen to make the child more comfortable; however, this does not guarantee that future febrile convulsions will be prevented, even if the parents respond to the first elevated temperature.

There is no increased rate of mortality from true febrile convulsions, and the mental and neurologic development can be expected to be normal after a simple febrile convulsion. However, approximately 30% of febrile convulsions recur in future febrile illness, and the parents should be warned of this. Recurrence is most likely in the first 6-12 months after the initial febrile convulsion. Other factors that increase the chance of recurrence are onset at a young age, preexisting neurologic abnormalities, and family history of epilepsy or febrile convulsions.

Most authorities would advise no treatment for almost all children with febrile convulsions. Rare exceptions include children presenting

with prolonged (>15 minutes) seizures and children younger than 12 months old with multiple recurrences. For children with recurrent prolonged febrile seizures, rectal diazepam could be considered as an abortive therapy. Children with recurrent episodes of **febrile status epilepticus**, particularly starting under 1 year of age, with focal features, or associated with any insidious neurologic or cognitive decline, should be referred to a neurologist for further evaluation, particularly for sodium channelopathies such as **Dravet syndrome** or **generalized epilepsy with febrile seizures plus (GEFS+)**, as detailed in Tables 30.3 and 30.15. Informing and reassuring parents of the benign nature and usual course of febrile convulsions are very important and may be of greater value than any medication.

There appears to be an increased risk of epilepsy among children with febrile convulsions. Overall, the risk is approximately 3%. Risk factors increasing the likelihood of future epilepsy include existence of a prior neurologic abnormality, prolonged convulsions (>30 minutes), focal or lateralized features of the seizure, and repeated convulsions within 24 hours. The incidence of epilepsy increases from 3% of those without risk factors to 49% of those with 3 risk factors. Risk factors for epilepsy with generalized seizures are more than 3 febrile seizures and epilepsy in a first-degree relative, which suggests that febrile convulsions in these individuals may be a manifestation of an increased predisposition to epilepsy. For epilepsy with focal seizures, the risk factors are prolonged convulsions, focal features of the seizure, and repeated seizures within 24 hours, which suggest either a causative role of febrile convulsions in partial epilepsy or a preexisting brain lesion. The number of recurrences of febrile seizures has not been shown to be a risk factor for later epilepsy. There is no evidence that AED treatment of febrile seizures affects the risk for later development of afebrile seizures.

Epileptic Syndromes

West syndrome

- Peak presentation: ages 4-8 months
- Red flags: daily clusters of brief hiccupping or startle-type seizures, particularly upon waking up or falling asleep. Developmental regression.
- Acuity: emergent to urgent; ideally obtain an EEG within a week and call a neurologist if this diagnosis is suspected. Must be managed by a neurologist due to atypical treatment needs (adrenocorticotropic hormone [ACTH]), which may require hospital admission.
- Prognosis: generally poor, particularly if the diagnosis is missed

West syndrome, or severe encephalopathic epilepsy in infants, is characterized by infantile spasms, the hypsarrhythmic EEG pattern, and developmental delay. It is a severe and devastating form of epilepsy, usually with evidence of diffuse cerebral dysfunction and a poor prognosis in most cases. The incidence is about 1/4000-6000 infants with onset between 3 and 12 months of age; peak onset is 4-8 months.

A spasm is a brief bilateral tonic contraction of muscles of the trunk, neck, and limbs, usually but not always symmetric. These seizures are commonly overlooked by both families and physicians for weeks to months; they can be confused for hiccupping, startling, the Moro reflex, or be subtle enough to be missed entirely. They classically occur in multiple daily clusters lasting 10-15 minutes, with each cluster containing anywhere from a few spasms to dozens. The clusters occur during the transitions between wakefulness and sleep, so are most common in the early morning and evening, or occasionally around naptimes.

The extent of muscle involvement varies from a powerful contraction that *jackknifes* the body to minimal contraction of truncal muscles that causes only stiffening. Spasms may involve truncal flexion, extension, or both; the child may fling out their arms or elevate them for

---

TABLE 30.15 Paroxysmal Disorders of Childhood

Nonepileptiform Disorders

Breath-holding spells[*][†]
Syncope[‡]
Migraine and migraine equivalents, recurrent abdominal pain, cyclic vomiting[*]
Tic[*]
Spasmodic torticollis[†]
Drug reactions, dystonia
Paroxysmal choreoathetosis
Gastroesophageal reflux
Benign paroxysmal vertigo[†]
Myoclonus, nonepileptic; anxiety, excitement, acute metabolic encephalopathy[†]
Hyperexplexia
Masturbation[†]
Withholding, constipation[*]
Daydreaming, staring spells[*]
Stereotypical movements, autism, coexistent deafness and blindness
Factitious syndrome by proxy (Munchausen syndrome by proxy)
Hyperventilation[‡]
Psychogenic seizures[‡]
Transient global amnesia[‡]
Sleep[*]
Head banging, jactatio capitis[†]
Pavor nocturnus
Somnambulism, somniloquy

Acute Symptomatic Seizures, Occasional Seizures

Febrile convulsions[*]
Brain tumor
Meningitis, encephalitis
Head injury, child abuse
Poisoning
Intercurrent medical illness; renal, liver disease; cardiac right-to-left shunt; and embolism
Metabolic disease, rickets

Epileptic Syndromes

Benign partial epilepsies[*]
Symptomatic focal epilepsy[*]
Epilepsia partialis continua
Rasmussen encephalitis
Autosomal dominant nocturnal frontal lobe epilepsy
Epileptic encephalopathy with continuous spike-and-wave pattern during sleep
Benign epilepsy with centrotemporal spikes (benign rolandic epilepsy)
Hemiconvulsion hemiplegia syndrome
Childhood absence epilepsy[*]
Epilepsy with myoclonic absences
Lennox-Gastaut syndrome
Epilepsy with myoclonic atonia (previously astatic) seizures (Doose syndrome)
Landau-Kleffner syndrome
Febrile seizures plus
Panayiotopoulos syndrome

[*]Common.
[†]See infant section for discussion.
[‡]See adolescent section for discussion.

several seconds. Eye movements are commonly associated with the spasm, either as deviation or as repetitive nystagmoid upward jerks. Apnea is common, but tachypnea is uncommon. Children may cry out or seem to giggle at the end of the spasm.

As the spasms continue, there may be insidious loss of developmental motor milestones such as sitting, rolling, babbling, or head control. Another commonly described regression is a decline in visual attentiveness, meaning that the child no longer easily regards faces, tracks moving objects, or reaches for toys. This is due to the progressive cortical dysfunction caused by the underlying hypsarrhythmic EEG pattern.

The differential diagnosis can include colic, exaggerated Moro reflexes, or normal myoclonic jerks on falling asleep or waking. Multiple myoclonic seizure syndromes, both benign and otherwise, occur in this age group and must be distinguished from infantile spasms by a neurologist.

Evaluation: EEG, MRI. The term **hypsarrhythmia** in an EEG report is specific for a diagnosis of infantile spasms. The hypsarrhythmic EEG pattern is a high-amplitude, chaotic slowing of generalized distribution without interhemispheric synchronization and with multifocal epileptiform discharges throughout. Hypsarrhythmia is more frequent in younger infants and early in the course of the disorder, and it is more common to find some modified variant of it. In a child with a strong clinical suspicion of infantile spasms, sleep must be captured in the EEG, as early in the course, the hypsarrhythmic pattern is only evident during sleep.

Investigation of patients with infantile spasms is directed at determining the cause and then determining whether there is an underlying genetic, structural, or metabolic etiology. Infantile spasms can be caused by a wide variety of neurologic insults; the most common etiologic factor is perinatal hypoxic-ischemic encephalopathy. Other important associations include intrauterine infection, prematurity, intracranial hemorrhage, malformations of cortical development, tuberous sclerosis, head injury, CNS infection, and inborn errors of metabolism. If infantile spasms are seen in conjunction with agenesis of the corpus callosum and retinal abnormalities on eye examination, this suggests a diagnosis of **Aicardi syndrome**.

Approximately 95% of children with an identified cause (structural, genetic, or metabolic) have a prognosis of moderate-to-severe neurologic injury, including refractory epilepsy, cognitive impairment, or permanent developmental sequelae.

Approximately 10-15% of patients have no identifiable underlying cause and a history of normal development before the onset of their illness; this subset is referred to as cryptogenic, or idiopathic, West syndrome. This subset of patients is likely to have a much better long-term outcome: 38% of these patients are normal or mildly impaired, in comparison with only 5% of symptomatic patients.

A unique subset of patients who may develop infantile spasms is children with **trisomy 21 (Down syndrome)**. The incidence of infantile spasms in this group is 1-5%. Though they have a genetic disorder and baseline neurologic abnormalities, these children have a particularly high response rate to treatment with ACTH with rapid resolution of the abnormal hypsarrhythmia on EEG.

About 50% of infants go on to have other seizure types when spasms cease. Persistence of the epilepsy in most of the patients is associated with loss of the spasms and development of other seizure types, such as tonic seizures, focal seizures, and tonic-clonic seizures. Approximately half of children with Lennox-Gastaut syndrome, a combination of cognitive disability, generalized seizures, and a distinctive abnormal EEG pattern, have a history of infantile spasms. Seizures very similar in appearance to infantile spasms (brief myoclonic or tonic seizures occurring in clusters) may recur later in childhood, and these are referred to as epileptic spasms.

Treatment with corticosteroids aborts the spasms in a significant number of infants. There are 2 approaches: intramuscular injections of synthetic ACTH gel or high-dose oral steroids. Both treatment regimens generally last 8-12 weeks, and both require frequent monitoring for side effects. The spasms should cease and the EEG patterns improve if the child has responded. The pediatrician may be called upon to monitor electrolytes, blood pressures, or signs of illness while the child is under treatment. Live vaccinations are generally held for 6-12 months after a course of immunomodulatory therapy.

Vigabatrin is another effective AED for infantile spasms, and it has been shown to be particularly effective in the treatment of infantile spasms with tuberous sclerosis or other focal cortical dysplasias. However, this medication is currently strictly regulated in its prescription, and patients on vigabatrin require examinations by an ophthalmologist every 3 months due to the small risk of permanent peripheral vision loss with prolonged use of the medication. Most patients with infantile spasms take vigabatrin for 6 months or fewer.

Many other antiepileptic medications, including topiramate, lamotrigine, valproic acid, and benzodiazepines, have had some efficacy in isolated cases, but this response is unpredictable. ACTH, corticosteroids, and vigabatrin are the most commonly used medications with the highest efficacy across multiple etiologies.

Severe myoclonic epilepsy in infancy (Dravet syndrome)
- Peak presentation: ages 9-18 months
- Red flags: normal development until the onset of multiple episodes of prolonged febrile status epilepticus, often with focal features; seizures provoked by warm ambient temperatures, hot baths, fever, or vaccinations
- Acuity: urgent due to the development of medically refractory epilepsy and potential for multiple episodes of status epilepticus
- Prognosis: poor; identified cause of some cases of so-called vaccine encephalopathy

Severe myoclonic epilepsy in infancy is a rare generalized epilepsy appearing in the first year of life. The syndrome differs from the myoclonic syndromes already described (early myoclonic encephalopathy and early infantile encephalopathic epilepsy) by its later onset and the EEG findings. A mutation of a voltage-gated sodium channel gene *(SCN1A, SCN9A)* is seen in up to 79% of cases (see Table 30.3).

The child may present with febrile or afebrile seizures, usually with normal psychomotor development preceding the onset of seizures, and often with a family history of epilepsy. The seizures are generalized or unilateral clonic seizures; myoclonic seizures appear later (and may not be a major feature of the disorder, despite the name), between 8 months and 4 years of age; and focal seizures and atypical absences may occur. The interictal EEG may be normal initially and only later show fast, generalized, spike-and-wave epileptiform discharges and focal abnormalities.

The seizures are usually refractory to many commonly used AEDs due to the fact that these AEDs act on sodium channels and this disorder is generally caused by sodium channel mutations. Antiepileptic medications that may worsen seizures or be ineffective in Dravet syndrome include phenytoin, lamotrigine, carbamazepine, oxcarbazepine, and vigabatrin.

Childhood

The paroxysmal disorders of childhood (2-12 years) are given in Table 30.15.

Paroxysmal Nonepileptic Disorders

Migraine and migraine equivalents. Migraine is a common disorder, and some episodes may be confused with seizures because of their

paroxysmal nature and association with neurologic deficits or altered consciousness (see Chapter 28). The presentation of migraines in children may also be markedly different than that in adolescents and adults; "migraine equivalents" are paroxysmal disorders that are strongly associated with the later development of migraines and may share similar underlying pathophysiologic mechanisms.

When evaluating paroxysmal events suspected to be migraines or migraine equivalents, the following **red flags** should prompt expedited neuroimaging, specialist evaluation, or emergency room evaluation, depending upon the severity of the symptom and how ill the child appears:
- Sudden severe head pain that awakens the child from sleep
- Positional symptoms, meaning that the child's headache or vomiting dramatically worsens or improves with simple positional changes from lying to sitting
- Abnormal eye movements, such as prominent nystagmus (jerky eye movements) or a forced downward gaze
- Focal neurologic symptoms including focal limb weakness or facial droop
- Altered mental status

In **cyclic vomiting**, recurrent attacks of nausea, vomiting, and abdominal pain occur on a daily or weekly basis without any evidence of intercurrent illness or objective evidence of gastrointestinal pathology. There is no confusion or disorientation associated with these spells. Typically, there are symptom-free intervals lasting weeks to months, and recurrence is unpredictable. There may be a strong family history of migraine, and there appears to be some overlap of the cyclic vomiting with migraine.

Tic disorders
- Peak presentation: age 5-7 years
- Classical features: no alteration of awareness, stereotyped behaviors, a sensation of "compulsion" to perform the behavior and "relief" once it is completed.
- Acuity: low
- Prognosis: excellent, although disabling tics and psychiatric comorbidities should be addressed, if present

Tics are common and are sudden, brief, purposeless involuntary movements or vocalizations that occur during wakefulness only; children may describe a sense of compulsion and can briefly suppress the behavior, but have a sense of relief when performing the suppressed action (Table 30.16). Children may have phonic tics (such as tongue clicking or throat clearing), motor tics (such as blinking, sniffing, or shrugging), or any combination of both. Tics are treated when they become disruptive, socially unacceptable, or physically uncomfortable, but otherwise they are considered benign and normally do not require pharmacologic treatment. Common comorbidities that should be screened for include anxiety, attention-deficit/hyperactivity disorder (ADHD), and obsessive-compulsive disorder.

TABLE 30.16 Abnormal Involuntary Movements

Movement	Characteristics	Associations
Tics	Brief involuntary movements (motor tics) or sounds (phonic or vocal tics) occurring against a background of normal motor activity Tics may be simple, sudden brief movements such as shrugging a shoulder, blinking, or grimacing; or complex, more coordinated movement that might appear purposeful, such as hitting or touching Snorting, sniffing, or throat clearing are examples of simple phonic tics and short utterances, echolalia, or coprolalia are complex phonic tics	Idiopathic tic disorders Tourette syndrome
Tremor	Movements caused by rhythmically alternating contractions of a muscle group and its antagonists The movements may involve proximal and axial muscles Classified as resting, postural, or action tremors according to the response to these maneuvers	Physiologic tremor, essential tremor
Chorea	Random brief limb movements of variable duration; these can be incorporated into voluntary movements by the patient	SLE Wilson disease Rheumatic fever Autoimmune encephalitis Postinfectious
Athetosis	Slow writhing movements of the extremities, often distal extremities The movements are random Often involuntary movements of this type have some features of chorea and are termed *choreoathetoid*	Kernicterus
Dystonia	Sustained muscle co-contraction of agonist and antagonist muscle groups, frequently causing twisting and repetitive movements or abnormal postures The velocity of the movements varies, usually being sustained at the height of the involuntary contraction for 1 sec or longer The duration also varies in different syndromes; in spasmodic torticollis, there may be rhythmic jerks or spasms into the abnormal posture Subclassified by extent (focal, segmental, multifocal, and generalized) and relationship to movement (action and rest)	Idiopathic (inherited) syndromes Postlesional syndromes
Myoclonus	Rapid brief muscle jerks with an irregular or occasionally rhythmic quality Can be epileptic or nonepileptic in origin	Encephalopathies Idiopathic and symptomatic epilepsies
Ballismus	Wild, large-amplitude, irregular limb movements	Postlesional
Asterixis	Repetitive movements caused by sudden, brief, irregular lapses in posture of an extremity	Metabolic encephalopathies
Dyskinesia	Sometimes used as a general term to describe abnormal involuntary movements	

SLE, systemic lupus erythematosus.

They often become noticeable in early grade school years, around the time that some children start stimulant medications for attention deficit disorder. This temporal association has led to the misconception that the stimulant medications have caused the tics.

α_2-Agonists such as clonidine are common first-line treatments for disruptive or disabling tics; more severe tics can be treated with atypical antipsychotics such as risperidone.

Tourette syndrome is diagnosed when a child has had multiple motor tics and at least 1 phonic tic present for longer than 1 year. Other tic disorders can be purely motor or purely phonic, and are classified according to their symptoms and duration (transient vs. chronic).

Table 30.16 outlines some of the clinical features of episodic abnormal movements that may appear in children.

Sleep disorders
- Peak presentation: age 2-7 years
- Classical features: occurring a few hours after falling asleep ("around midnight"), nonstereotyped behaviors, screaming, agitation, and inconsolability despite being apparently awake, no memory of frightening imagery
- Acuity: low
- Prognosis: excellent, although children with frequent episodes may need to be monitored by their parents to prevent injury during a panicked state

Night terrors and confusional arousals. Night terrors are a common phenomenon in children and are most frequent in boys aged 5-7 years. Up to 15% of children younger than 7 years have experienced some form of these episodes. The attacks are characterized by sudden arousal from sleep, often screaming in terror, and then crying with agitation and tachycardia. There may be vigorous and potentially injurious motor activity in older children, such as running or hitting the bed or wall. The striking feature of these episodes is that the child is inconsolable but seemingly awake. The episodes arise out of slow-wave non–rapid eye movement sleep, usually occurring 1-2 hours after bedtime, and are not responses to dream imagery (i.e., not nightmares). Episodes last several minutes. Prior sleep deprivation, febrile illness, emotional stress, and some medications (sedatives/hypnotics, neuroleptics, stimulants, antihistamines) may be precipitants. In contrast to the experience of nightmares, children are amnestic for the events and their distress in night terrors.

Confusional arousals are less dramatic attacks with similar origin from slow-wave sleep and are more typical in younger children. The affected child stirs and begins crying and whimpering inconsolably. These arousals may be prolonged in infants, lasting up to 30-40 minutes.

There is no specific treatment for these events; parents should be educated about the nature of these arousals and reassured that they are self-limited.

The most important mimic of parasomnias is nocturnal seizures. **Nocturnal frontal lobe seizures** occur during sleep and can have bizarre hypermotor behaviors such as rolling, turning, picking, yelling, and fumbling. In school-aged children, **benign rolandic epilepsy** manifests itself as seizures when coming out of sleep with gurgling, salivation, hemifacial and hemibody twitching, and often partially preserved consciousness of the event. Important distinguishing historical factors between seizures and parasomnias are the time of onset (seizures: shortly after falling asleep or early in the morning), duration (most seizures last 1-2 minutes, and parasomnias can have a significantly longer duration), and any associated tongue bite, urinary incontinence, or insidious behavioral or developmental regression.

Somnambulism. Somnambulism, or sleepwalking, is common in childhood. Approximately 15% of children have walked in their sleep, especially in the 2-3 years old age group, and 2.5% are habitual

sleepwalkers, having episodes at least once a month. The age at onset peaks between 4 and 10 years. There is a family history of sleepwalking and other parasomnias in 60-80% of patients. These episodes of apparent unresponsiveness and "automatisms" could be mistaken for focal dyscognitive seizures or a postictal state.

Self-stimulatory behavior/stereotypies. Repetitive purposeless movements may be performed by children on the autism spectrum or with cognitive disabilities. Combined with unresponsiveness, these behaviors may be mistaken for automatisms in focal dyscognitive seizures. The important features that distinguish such behavior from epileptic activity are the setting in which it occurs, the variable content and duration of the "attacks," and the complete failure of the episodes to interrupt more stimulating activities. However, it may be very difficult to determine the nature of the episodes by interview; video and EEG monitoring may be required. These behaviors are not harmful and may provide soothing sensory input to the child performing them.

Acute Symptomatic Seizures and Occasional Seizures

Febrile convulsions remain one of the most common causes of occasional seizures in early childhood. Head injury is more common in childhood than in infancy, but the list of other potential causes of seizures, including brain tumor, intracranial infection, and poisoning, is very similar. In addition, some metabolic and neurodegenerative disorders manifest in childhood, not in infancy (Table 30.17).

Epileptic Syndromes

Benign partial epilepsies of childhood. Focal seizures and focal EEG discharges usually suggest the presence of a localized cerebral lesion. There is a group of idiopathic partial epilepsies beginning in children without abnormalities on neurologic examination or neuroimaging studies, and frequently with a family history of epilepsy. The benign partial epilepsies of childhood (BPECs) are characterized by focal seizures and focal epileptiform discharges, both with age-dependent spontaneous recovery, in the absence of anatomic lesions.

Clinically, the seizures begin between 18 months and 12 years of age, most often at 8-10 years; there is no neurologic deficit or developmental delay. The seizures are brief and stereotyped in an individual, although they vary among patients. The seizures do not have a prolonged postictal deficit, are usually infrequent, and respond well to AED treatment. The focal epileptiform discharges occur with normal background rhythms. The sharp waves or spikes have a characteristic structure and are often very frequent, increasing during sleep. Rare generalized epileptiform discharges may occur, but if they are prominent, the diagnosis of BPEC should be questioned.

The most well-defined form of BPEC is **benign epilepsy with centrotemporal spikes and seizures (BECTS)**, often referred to as **benign Rolandic epilepsy**. Brief hemifacial motor seizures with anarthria and drooling are typical, frequently when coming out of sleep. Consciousness is typically preserved, although this may not be true with longer seizures. A somatosensory aura involving the tongue, cheek, or gums may precede the motor seizure. Many seizures occur at night as tonic-clonic seizures, presumably secondary generalized with unwitnessed partial onset. Onset is between 3 and 13 years, with a peak onset at 9-10 years; there is a male-to-female predominance of approximately 3:2.

Management depends on seizure frequency; if the typical EEG discharges have been found in a child without seizures or after a first seizure, there is usually no indication to treat with AEDs. If seizures are infrequent and nocturnal, the option of no treatment should be discussed. AED treatment should be considered for patients experiencing more frequent seizures, troublesome seizures during the day, or seizures associated with any morbidity such as postictal headaches or

TABLE 30.17   Inherited Disorders of Metabolism and Neurodegenerative Diseases Associated with Seizures in Childhood and Adolescence

Name	Clinical Features and Laboratory Findings	Investigations
Syndrome of Progressive Myoclonus Epilepsy		
Multiple specific disorders cause the clinical syndrome of PME		
Prominent myoclonus: irregular repetitive, spontaneous or with action, stimulus sensitive		
Associated seizure types: usually tonic-clonic, but also tonic, absence, and partial seizures		
Progressive neurologic deterioration, with prominent ataxia and other motor signs developing later		
Progressive dementia, varying in degree between the specific disorders		
Most Cases Are Caused by the Following 5 Disorders:		
Unverricht-Lundborg	Onset, ages 8-15 yr; myoclonus and GTC seizures, cerebellar ataxia, slowly progressive but mild cognitive decline; patients have long survival in comparison to other disorders in this group	Chromosome 21q22; cystatin B mutations Clinical diagnosis must exclude other causes of PME syndrome
Myoclonus epilepsy and ragged red fibers (MERRF)	Onset, ages 5-12 yr (range, 3-62 yr); myoclonus, GTC seizures, progressive ataxia, dementia Other features include deafness, optic atrophy, neuropathy, myopathy, pyramidal signs, dysarthria, and nystagmus There may be clinical overlap with other mitochondrial encephalomyopathies: mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes (MELAS) and Kearns-Sayre syndrome	Serum and CSF lactate and pyruvate measurements Muscle biopsy; light microscopy, electron microscopy (EM), biochemical analysis of oxidative metabolism, and DNA studies
Lafora body disease	Onset, ages 10-19 yr; generalized clonic, GTC, and partial seizures with visual auras; myoclonus develops later and becomes very disabling; severe dementia; death within 5 yr of disease onset Lafora bodies (intracellular amyloid inclusions) are found in skin, muscle, neurons, and hepatocytes	Biopsy of skin must include eccrine sweat glands (i.e., axilla) to exclude lafora bodies Chromosome 6q24; gene *EPM2A* produces laforin
Neuronal Ceroid Lipofuscinosis		
Late infantile form (Jansky-Bielschowsky)	Onset, ages 2-4 yr; severe epilepsy, myoclonic, GTC, atonic, atypical absence seizures (not tonic, vs Lennox-Gastaut syndrome), progressive severe dementia, ataxia, pyramidal and extrapyramidal signs, visual loss later, usually death in adolescence Ophthalmologic examination necessary; on EEG, marked photic sensitivity to 1-Hz stimulation, electroretinogram (ERG) and visual evoked potential (VEP) abnormalities	Skin, conjunctival, or rectal mucosal biopsy; skin biopsy is the most practical and least morbid. EM of circulating lymphocytes can be used for screening Lipopigment accumulation in lysosomes best seen in eccrine secretory cells; the inclusions have a characteristic structure on EM that differs between the different subtypes of neuronal ceroid lipofuscinosis EEG, ERG, and VEP testing
Juvenile form (Batten-Spielmeyer-Vogt)	Onset, ages 4-10 yr; usually manifests with decreased visual acuity secondary to retinal degeneration, psychomotor delay, cerebellar and extrapyramidal signs, later onset of seizures, and GTC and myoclonus Progressive severe dementia accompanies the other neurologic signs Death in early adulthood ERG and VEP abnormalities	Same as for the late infantile form
Adult onset (Kufs)	Onset, ages 11-50 yr; dementia, psychiatric symptoms, cerebellar signs, and extrapyramidal signs are most prominent; seizures often tonic; visual disturbances are less common; fundi are normal; on EEG, marked photic sensitivity to 1-Hz stimulation	
Sialidosis		
Type 1	Onset, ages 8-20 yr; decreased visual acuity and macular cherry-red spot; action- and stimulus-induced myoclonus; cerebellar ataxia; no dementia or decreased length of survival A peripheral neuropathy may be present	Urine specimen, blood sample for cultured leukocytes, and skin biopsy to obtain cultured fibroblasts for enzyme analysis
Type 2	Onset, ages 10-30 yr; described in Japanese patients Coarse facial features and PME syndrome Elevated excretion of urinary sialylated oligosaccharides, enzyme analysis shows deficiency of α-N-acetylneuraminidase (both type 1 and type 2)	Same as for type 1

TABLE 30.17   Inherited Disorders of Metabolism and Neurodegenerative Diseases Associated with Seizures in Childhood and Adolescence—cont'd

Name	Clinical Features and Laboratory Findings	Investigations
Less Common Causes of PME Syndrome in This Age Group:		
Juvenile neuronopathic Gaucher disease; PME, supranuclear palsy, and splenomegaly; no dementia; pancytopenia on CBC, leukocytes show low β-glucocerebrosidase activity		CBC, leukocytes for enzyme analysis
Dentatorubral-pallidoluysian atrophy, seen in Japanese patients; PME is 1 manifestation		Clinical diagnosis in life
Neuroaxonal dystrophy; may appear as PME; also, chorea, lower motor neuron signs; axon steroids in neurons, may be seen in autonomic nerve endings around eccrine secretory coils		Peripheral nerve biopsy, skin biopsy
Late-onset GM$_2$ gangliosidosis; sensitivity to acoustic stimulus; myoclonus, severe dementia, dystonia, pyramidal signs; cherry-red spot may be seen on the macula		Hexosaminidase A activity
Hallervorden-Spatz disease		Clinical diagnosis in life
Action myoclonus–renal failure syndrome, described in French-Canadians; tremor, PME, and, later, proteinuria and renal failure; no dementia		Clinical diagnosis, renal function
Other Rare Disorders with Seizures in Childhood and Adolescence		
Juvenile Huntington disease	Onset, age >3 yr; developmental delay; dystonia; parkinsonian features may be present	GTC, atypical absence, myoclonic seizures
Alpers syndrome	Progressive neurologic degeneration of childhood A clinical syndrome; suspected to be a mitochondrial encephalopathy Normal at birth, then failure to thrive with developmental delay, myoclonic jerks, seizures, episodes of status epilepticus, hypotonia, and visual loss followed by spastic quadriparesis Epilepsy partialis continua may be present The spectrum of clinical features includes deafness, ataxia, chorea, and liver disease	Muscle biopsy
Rett syndrome	Onset, ages 1-2 yr; in girls only; delay or regression in motor development, loss of language, ataxia, "hand-ringing" mannerism Seizures occur later; myoclonic, partial, and GTC Episodes of apnea, ataxic breathing, and hyperventilation; pyramidal signs	Muscle biopsy for mitochondrial enzyme analysis and histologic study, although cause is unknown, genetic testing
Maple syrup urine disease	Less severe forms may manifest late, even in adulthood, with episodic symptoms of encephalopathy and ataxia	Serum amino acids and possibly seizures
Porphyria	Onset, late adolescence, after puberty; 15% of affected patients have seizures during an acute attack of porphyria	Urinary and/or stool porphyrins

CBC, complete blood cell count; CSF, cerebrospinal fluid; EEG, electroencephalogram; GTC, generalized tonic-clonic; PME, progressive myoclonus epilepsy.

lethargy. The seizures are usually controlled easily with a variety of AEDs, including carbamazepine or levetiracetam.

The seizures of BPEC resolve spontaneously before 16 years of age, and the EEG may be helpful in deciding when to withdraw treatment. Patients older than 14 years who are seizure-free for 1-2 years with normal EEGs should withdraw from treatment; the clinician should strongly consider a trial of withdrawal in patients 10-14 years old who are seizure-free and have a normal EEG. Younger patients with active EEGs are likely to have recurrence of seizures with AED withdrawal; if seizures and/or abnormal EEGs persist well into the teenage years, syndromic diagnosis should be reconsidered. Subtle neuropsychologic deficits may be present in children with BECTS, suggesting that this disorder may not be entirely as "benign" as thought.

Benign childhood epilepsy with occipital paroxysms forms a subset of idiopathic partial epilepsies of childhood. There are 2 types of this subset: 1 with early onset (peak onset at 3-5 years), nocturnal seizures with tonic eye deviation, and vomiting; and another with later onset (peak onset at 7-9 years) characterized by seizures beginning with visual symptoms, which is consistent with an occipital origin.

These are also referred to as **Panayiotopoulos syndrome** and the **benign occipital epilepsy of Gastaut**, respectively. Hemiclonic seizures or the automatisms of temporal lobe complex seizures often follow according to whether the seizure spreads to suprasylvian or infrasylvian regions. A severe headache may follow the visual auras and a diagnosis of childhood migraine is often considered. The EEG typically shows high-amplitude sharp waves or spike-and-wave complexes recurring at 0.5-1 Hz posteriorly, usually maximal in the occipital regions. The discharges are present when the eyes are closed and should disappear with eye opening. There is some controversy about the specificity of the electroclinical features and whether these cases are true variants of benign childhood epilepsy. The conditions are relatively uncommon, and the same EEG pattern may be seen with symptomatic occipital epilepsy.

Acquired epileptic aphasia and continuous spike-and-wave patterns in slow-wave sleep. These 2 conditions are age-related epileptic encephalopathies with disturbances in language and cognition occurring in association with persistent focal or bilaterally synchronous epileptiform activity and seizures without an underlying structural

lesion. In each, the epileptiform activity is thought to disturb synaptogenesis and connectivity in the maturing brain. Although they are rare, some authorities consider them part of the spectrum of benign childhood epilepsy.

Epileptic aphasia, *or* **Landau-Kleffner syndrome,** begins in a previously normal child (peak age at onset, 5-7 years) with the regression of language. There is severe auditory agnosia, speech may disappear, and the child often appears to be deaf due to impairment of cortical processing of sound and language. There is usually a marked deterioration in behavior as well, and social interactions become altered. Childhood psychosis and the autistic spectrum disorders are often considered in the differential diagnosis, although the age of behavioral regression is atypical for those disorders and should be a red flag when this clinical history presents. Seizures occur, but are not frequent and cannot explain the language deficits. The EEG in sleep shows almost continuous bilateral epileptiform discharges maximal over the temporal regions. The seizures are partial and easily controlled with medication, but the language regression and the EEG discharges do not remit with conventional AEDs. Treatment with corticosteroids does improve the condition in many children, but more than half have persistent language and learning deficits, despite the eventual disappearance of the EEG abnormalities.

In **continuous spike-and-wave patterns in slow-wave sleep** or **electrical status epilepticus of slow-wave sleep** (CSWS and ESES, respectively), there is a more diffuse cognitive dysfunction, and more than 85% of the sleep EEG record is occupied by epileptiform discharges. The disorder typically manifests at 5-7 years of age, and there is a broader spectrum of seizure types, including absences, atonic seizures, and focal dyscognitive seizures, which may be frequent in some patients. In Landau-Kleffner, the speech and auditory disturbances are the most striking feature, and in CSWS, executive and behavioral dysfunction predominate. Both are caused by heterozygous mutations in the ionotropic NMDA glutamate receptor subunit 2A gene *(GRIN2A)* and inherited as an autosomal dominant.

Symptomatic focal (localization-related) epilepsy. The most common seizure type in children with focal epilepsy with an identified cause is the **focal dyscognitive seizure**. Focal dyscognitive seizures may arise from temporal, frontal, parietal, or occipital lobes, but most often from the temporal lobe. The causes of focal epilepsy in childhood are diverse and include birth asphyxia, later anoxic episodes, head injury, neoplasms, infection, malformations of cortical development, the cerebral lesions of neurocutaneous syndromes, vascular malformations, and cerebral infarction. MRI is a crucial diagnostic procedure and can reveal a variety of structural abnormalities.

Focal epilepsy commonly evolves as a medically refractory disorder; in some patients, it can be amenable to surgical resection. The investigation of children for epilepsy surgery is a highly specialized process that follows documentation of medical intractability, which is defined as failure of at least 2 appropriately chosen and optimized antiepileptic medications. Concordant evidence of a single epileptogenic region within the brain must be found with ictal video and EEG monitoring, both structural neuroimaging (MRI) and functional neuroimaging (single-photon emission computed tomography and positron emission tomography), and neuropsychologic evaluation. If a focus can be demonstrated, it must be shown that resection of that area will not cause unacceptable loss of sensorimotor or cognitive function.

Childhood absence epilepsy. Childhood absence epilepsy is an idiopathic generalized epilepsy beginning in previously normal children between 4 and 12 years of age, with peak incidence at 6-7 years of age; girls are more frequently affected. It accounts for only about 8-10% of school-aged children with epilepsy. There is a family history of epilepsy in approximately 15-25% of patients. The absence seizures are simple, or more often, complicated with mild automatisms or other motor features. Absence seizures are very frequent, occurring daily, but they generally respond well to antiepileptic therapy. The EEG is normal apart from runs of 3-Hz spike-and-wave complexes; clinical seizures are associated with discharges lasting more than 2-3 seconds. The discharges and clinical seizures can be produced by hyperventilation. Prognosis is generally favorable, with remission in approximately 80% of cases by late adolescence. GTC seizures occur in 40-50% of patients with childhood absence epilepsy. They typically develop years after the onset of absences and may appear after remission from the absence seizures. Usually, the tonic-clonic seizures are infrequent and medically controllable.

Treatment with ethosuximide or valproate controls absence seizures in most patients. However, ethosuximide offers no protection against tonic-clonic seizures, whereas valproate is also effective against tonic-clonic seizures. Therefore, valproate is the drug of choice if both seizure types are present. If either ethosuximide or valproate proves ineffective after an adequate trial at maximum tolerated doses, a trial of the other should be commenced. Combination ethosuximide and valproate therapy has been effective in some patients with absence seizures not controlled by either drug alone. Clonazepam may also be effective, but it is associated with sedative and behavioral side effects. Alternatives may include lamotrigine, topiramate, or zonisamide; medications such as carbamazepine or phenytoin that are specific for focal-onset seizures will in fact exacerbate absence seizures.

Epilepsia partialis continua and Rasmussen encephalitis. Epilepsia partialis continua describes continuous focal motor seizures usually manifesting as repetitive clonic jerks of the face, upper limb, lower limb, or larger portion of one-half of the body that continue in this localized manner for hours to days or months. These seizures are caused by cortical processes that directly overlie the motor cortex that include vascular lesions, focal cortical dysplasia, neoplasms, and unidentified focal areas of atrophy. More generalized metabolic disorders such as mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes (MELAS) and an inherited disorder of metabolism (nonketotic hyperglycinemia) have also been reported to cause epilepsia partialis continua.

The focal seizures in this condition are generally impossible to control with AEDs, and surgical management with a limited cortical resection may be necessary. The risk of motor and sensory deficits limits possible resections, and careful mapping of the site of seizure onset and its relationship to functional cortex is required.

Rasmussen encephalitis is a clinically defined syndrome of predominantly hemispheric cerebral dysfunction, with onset of seizures between 2 and 10 years of age. A variety of seizure types can occur, including focal motor seizures and focal dyscognitive seizures with secondary generalization, myoclonus, and epilepsia partialis continua; they are refractory to management with AEDs. The disorder is characterized by a progressive hemiparesis, language disturbances if the dominant hemisphere is affected, and intellectual decline. Progressive hemispheric atrophy, maximal in the central, temporal, and frontal regions, can be documented with neuroimaging studies. Pathologic specimens show nonspecific changes suggestive of encephalitis, although no etiologic agent has been identified. Worsening of the neurologic deficits can be expected over time, although the seizures may lessen and even "burn out."

Functional hemispherectomy performed early in the course of the disease before complete hemiparesis should control seizures, arrest the motor deterioration, and in most cases, lead to stabilization or even improvement in language and intellectual function. However, significant morbidity and mortality rates are associated with the surgery, and

the child is left with a paretic upper limb, although he or she can walk unaided.

Lennox-Gastaut syndrome. Lennox-Gastaut syndrome is characterized by generalized seizures and epileptiform discharges with delayed mental development and behavioral problems beginning between the ages of 1 and 8 years. The patients have a mixed seizure disorder with multiple seizure types; the typical seizures are tonic seizures, atypical absences, and atonic seizures, although patients may also have tonic-clonic, myoclonic, and focal dyscognitive seizures. The seizures are not easily controlled and are usually frequent, often with several occurring per day. Episodes of status epilepticus are common, and nonconvulsive stupor with continuous spike-and-wave discharges or a stuporous state with repeated tonic seizures is typical. The waking EEG has abnormally slow background activity, and the EEG correlates of sleep may also be poorly organized. The epileptiform abnormalities consist of slow (<3 Hz) spike-and-wave discharges, multifocal spikes, or sharp waves and paroxysmal fast activity (>10 Hz) in sleep.

Treatment is always indicated, but AEDs are rarely able to control seizures completely. More often, some reduction in frequency and severity of seizures may be obtained. Patients commonly need combinations of AEDs to address their multiple seizure types. Valproate should be used as a first-line agent for patients with atonic, tonic, and myoclonic seizures and may be helpful with tonic-clonic seizures. Patients with refractory tonic-clonic seizures or focal seizures as well as generalized seizures may benefit from the addition of lamotrigine. Combinations of AEDs must be monitored carefully for drug toxicity and unwanted interactions. Carbamazepine has been reported to exacerbate atypical absence seizures in some patients. Phenytoin can be an effective drug in controlling GTC and tonic seizures. Barbiturates may be effective, although they are often poorly tolerated in children with abnormalities of tone, and drug-related drowsiness may exacerbate tonic seizures in some patients. Other alternatives include clonazepam, topiramate, and levetiracetam. Felbamate has been reported to improve control of the debilitating tonic or atonic "drop attacks" in patients with this syndrome.

A major source of morbidity and an important management issue are repeated falls associated with tonic and atonic seizures. Appropriate restriction in daily activities and the wearing of helmets with face protection are often required. Division of the anterior portion of the corpus callosum (anterior corpus callosotomy) has been successful in controlling the falls associated with tonic or atonic seizures, but it is considered a palliative and not a curative surgical procedure, and the goal is not complete seizure freedom.

Adolescence

The paroxysmal disorders of adolescence (12-18 years) are shown in Table 30.18.

Paroxysmal Nonepileptiform Disorders

Syncope. Loss of consciousness with falling is the salient feature of syncope (see Chapter 6 and Table 30.19). Children may be able to describe a distinct trigger, such as needles or the sight of blood, and often describe palpitations, tunnel vision, and nausea. There may be a family history in vasovagal syncope. Cardiac arrhythmias should be ruled out; autonomic testing may be beneficial in patients with very frequent syncope.

Paroxysmal psychiatric events. **Nonepileptic behavioral events** (psychogenic seizures) are events where the patient may have dramatic convulsions, stiffening, unresponsiveness, or dissociative symptoms including amnesia of the events. They are common, but are frequently misdiagnosed as epileptic seizures, leading to unnecessary interventions including intubation, hospitalization, invasive testing, or simply

TABLE 30.18   Paroxysmal Disorders of Adolescence
Nonepileptiform Disorders
More Common
Syncope
Migraine
Psychogenic nonepileptic behavioral events
Dissociative states, conversion disorders
Panic attacks, hyperventilation
Daydreaming
Sleep
Nocturnal myoclonus, hypnic jerks
Narcolepsy
Somnambulism
Somniloquy
Less Common
Episodic rage
Malingering
Paroxysmal choreoathetosis
Tremor
Tic
Drug reactions, dystonia
Transient global amnesia
Acute Symptomatic Seizures, Occasional Seizures
More Common
Drug abuse
Reflex seizures (see Table 30.1)
Head injury
Meningitis and encephalitis
Less Common
Brain tumor
Intercurrent medical illness, endocrine disorder, systemic neoplasia
Epileptic Syndromes
More Common
Reflex seizures (see Table 30.1)
Symptomatic localization-related epilepsy
Juvenile myoclonic epilepsy
Less Common

Epilepsy with generalized tonic-clonic seizures on awakening
Epilepsia partialis continua (Kojewnikow syndrome)
Rasmussen encephalitis
Progressive myoclonic epilepsy
Autosomal dominant epilepsy with auditory features (ADEAF)

years of antiepileptic medications that do not help the patient (see Table 30.19). Most cases are best thought of as a manifestation of psychiatric illness, such as post-traumatic stress disorder, anxiety, or depression. Nonepileptic behavioral events should be treated compassionately by the physician as a sign of significant psychiatric distress, and not as malingering or a factitious disorder.

Among adults, 20% of patients referred with refractory seizures are found to have psychogenic nonepileptic behavioral events; in children, the number is smaller. *Both epileptic seizures and nonepileptic behavioral events can coexist in the same person*, likely due to the high incidence of anxiety and depression in people living with epilepsy, as well

TABLE 30.19	Differential Diagnosis of Syncope	
Clinical	**Syncope**	**Tonic-Clonic Seizures**
Precipitating factors	Almost always patient is standing; environment is warm; fright; pain	Usually none, although sleep deprivation or awakening may be contributory
Prodrome	Lightheaded, dizzy, queasy; vision dims; loss of color, "grey out"; sweating May be averted by head down or recumbency	Aura or sense of déjà vu or jamais vu may be present
Occurrence in sleep	Never	Common
Evolution	Limp faint → fall → motionless unconsciousness, often with pallor, clammy skin; there may be a tonic phase with generalized stiffening	Sudden loss of consciousness → increased tone and massive truncal flexion or extension, followed by synchronous jerking of body and limbs with rubor or cyanosis and sweating → unconsciousness
Skin	Pale and cool	Flushed, cyanosed, warm
Incontinence	Rare	Occasional
Self-injury	Rare	Common (biting tongue)
Degree of postictal confusion	Minimal	Marked
Family history	Often positive for syncope	May be positive for seizures
Interictal EEG	Usually normal	Frequently abnormal, epileptiform discharges

EEG, electroencephalogram.

as the stress associated with an unpredictable chronic illness. Typically, they are characterized by marked motor activity such as pelvic thrusting, arching of the back, thrashing of the limbs, and even self-injury. The episodes may have a gradual onset with buildup of motor activity, and they usually last longer than epileptic seizures (Table 30.20). Other forms that the psychogenic nonepileptic behavioral events may take include a gradual slump to a motionless supine position with unresponsiveness and eyes closed, often with some flickering of the eyelids.

Other types of paroxysmal psychiatric events include panic attacks *and* rage attacks. **Panic attacks** may begin without the patient being able to identify an external precipitant, and then the sense of dread or fear may be mistaken for a psychic aura. Many of the symptoms experienced, including palpitations, paresthesia, formication, lightheadedness, and carpopedal spasm, result from hyperventilation and tachycardia. There may be some apparent disturbance of consciousness. Historically, the sequence of events is important, especially the hyperventilation and associated symptoms. The patient may be asked to hyperventilate in the office to see whether symptoms are reproduced; hyperventilation must continue for 3-5 minutes with good effort for a negative result to be useful.

Rage attacks may also be confused with epileptic seizures. Often seen in intellectually impaired patients, they represent intense frustration in the presence of an inability to vent the frustration in other ways or to communicate it. Rage attacks may also occur in children with normal intelligence or in those taking anabolic steroids.

The interictal EEG is repeatedly normal in patients with psychogenic nonepileptic behavioral events, but may be abnormal in children with both epileptic and nonepileptic events. For definitive diagnosis, it may be necessary to record a clinical episode with continuous video and EEG monitoring.

Treatment of psychogenic nonepileptic behavioral events must include an identification of underlying psychosocial and psychiatric problems. Major mood disorders and severe environmental stress, especially sexual abuse, are common among children and adolescents with psychogenic seizures and should be considered in every case. This history, though uncomfortable for both parties to discuss, must be specifically asked about and may require multiple visits to develop the necessary rapport to receive a truthful answer.

Presentation of a nonepileptic diagnosis to the patient after monitoring of a typical spell must be positive ("These attacks are not epileptic and will not necessitate chronic medication or further neurologic investigation") and truthful ("We don't know exactly what is causing them, but emotional factors are clearly playing a major role"). This diagnosis can be received with disbelief or hostility by families for multiple reasons. First, the societal stigma against psychiatric illness may make it difficult for parents to accept that a child has a psychiatric disorder; a genuine neurologic disorder is almost preferable to some families and they may visit multiple medical centers searching for a positive organic diagnosis. Second, even if the family accepts the diagnosis, there may be the perception that these events are "all in the child's head" or "attention-seeking," leading to a nontherapeutic familial and medical response to the diagnosis. If the child has been having events for a prolonged period of time, there is immense social pressure to continue having events, as they may feel that their peers, family, and school would react negatively to the psychiatric diagnosis after having been supportive of the presumptive epileptic diagnosis.

Terminology and phrasing is critical when discussing this diagnosis with families. Referring to them as "psychiatric" or "hysteric" or "conversion disorders" may come across as dismissive, particularly given the stigma around mental illness. The terms "psychogenic seizures" or "pseudoseizures" frequently confuse sufferers and families, as they then believe they are similar to epileptic seizures in pathology.

The prognosis of nonepileptic behavioral events in the pediatric population is much better than in adults, with 80% of patients seizure-free at the 3-year follow-up. Involvement of psychiatry and counseling is critical; in particular, cognitive-behavioral therapy appears to be specifically helpful in allowing people to achieve some conscious control over the physical symptoms of their psychiatric illness and to modulate their stress responses. However, the practitioner should be familiar with the concept of nonepileptic behavioral events. The degree and duration of pretreatment disability (school withdrawal, etc.) is a prognostic marker of response to treatment.

Acute Symptomatic Seizures and Occasional Seizures

The causes of acute symptomatic seizures in adolescence include those described in the preceding neonatal and childhood sections, except for

TABLE 30.20	Differential Diagnosis of Psychogenic Seizures	
Clinical Factors	**Psychogenic Seizures**	**Epileptic Seizures**
Age at onset	Usually older than 8-10 yr Predominates in girls; 15-30% of patients are boys	Either sex; no sex predominance
Duration of seizures	May be very prolonged	Usually seconds to minutes
Evolution	May have a very gradual onset and ending	Usually more abrupt onset
Quality of convulsive movements	Thrashing, asynchronous limb movements, often with partial responsiveness	Usually rhythmic and synchronous with loss of consciousness
Stereotypical attacks	Typically variable	Typically stereotyped
Examination during the seizure	May resist examination, combative	Usually unresponsive and amnestic for ictal events
Self-injury	Rare	Common in GTC seizures
Incontinence	Rare	Common in GTC seizures
During sleep	No; may occur nocturnally, but while the patient is awake	Common
Changes in seizure frequency with medication	Rare	Usual
Interictal EEG	Repeatedly normal	Often abnormal
Ictal EEG	No EEG seizure patterns; normal rhythms while patient is unresponsive	EEG seizure patterns
Pitfalls in diagnosis	1. Psychologic factors may not be immediately apparent 2. Misleading information may be given by parents (as in factitious [Munchausen] syndrome by proxy)	1. Asynchronous vigorous automatisms are found in frontal lobe seizures 2. Bilateral limb movements and posturing without loss of consciousness occurs in supplementary motor seizures 3. EEG seizure patterns may be absent during some seizures (e.g., auras, SMA)

EEG, electroencephalogram; GTC, generalized tonic-clonic; SMA, supplementary motor area.

febrile convulsions. Head injury may be more common among adolescents, because participation in contact sports and motor vehicle accidents occur in the middle-to-late teen years. Street drug abuse can be associated with seizures.

Epileptic Syndromes

Juvenile myoclonic epilepsy. Juvenile myoclonic epilepsy has an onset between 12 and 18 years of age. The hallmark of the disorder is early-morning myoclonus involving axial and upper limb muscles, usually with sparing of the facial muscles. Episodes typically occur on awakening. Tonic-clonic seizures occur in the majority of patients. A history of early-morning myoclonic jerks may not be volunteered, and should be asked of all patients presenting with GTC seizures. The patients may not have identified the myoclonus and instead describe nervousness, shakiness, or clumsiness for the first 1-2 hours of a morning, such as dropping their toothbrush or spilling their cereal. Fatigue, sleep deprivation, stress, and alcohol exacerbate the seizures; some patients have their first seizure shortly after starting college due to a combination of the above risk factors. The tonic-clonic seizures typically begin with a clustering of repeated myoclonic jerks. Absence seizures occur in 15-40% of patients. Neurologic examination findings, brain MRI, and cognition are normal. The interictal EEG shows spike-and-wave complexes at 3.5-6 Hz. Linkage analysis of patients and their family members has suggested that the disorder is linked to chromosome 21.

Valproate is the preferred AED, as it has efficacy on all seizure types in this disorder. Lamotrigine is another effective agent and is preferentially used in adolescent and adult women because of the potential side effect profile of valproate (weight gain, teratogenicity, and potential hormonal disturbances including polycystic ovarian syndrome). Alternatives may include topiramate, zonisamide, and

benzodiazepines, although extensive data concerning their efficacy in this setting are not available.

The seizures are well controlled in 80-90% of patients, but lifelong treatment is required. It is estimated that more than 90% of patients suffer relapse within the first 6-12 months after cessation of AEDs, and relapse is still common, even with prolonged periods of seizure freedom. Although many benign childhood-onset epilepsies remit with adolescence, most adolescent-onset epilepsies do not remit.

Juvenile absence epilepsy. In comparison with *childhood* absence epilepsy, juvenile absence epilepsy has a later onset, at about the time of puberty, and the seizures are less frequent (less than daily). Neurologic examination findings and IQ are normal. The EEG shows generalized spike-and-wave discharges, usually at rates faster than 3 Hz. Tonic-clonic seizures may occur, usually on awakening, more frequently than in childhood absence epilepsy.

The treatment is the same as that for childhood absence epilepsy, but the prognosis for complete remission therapy is less favorable.

Epilepsy with generalized tonic-clonic seizures on awakening. This idiopathic generalized epilepsy involves GTC seizures occurring more than 90% of the time within 2 hours of awakening or in an early-evening period of relaxation. Sleep deprivation and disruption are often potent precipitants of seizures. The age at onset of the seizures is usually between 10 and 20 years; a family history of epilepsy occurs in approximately 10-13% of cases. Myoclonic and absence seizures may also be present, and the distinction between juvenile myoclonic epilepsy and juvenile absence epilepsy is not clear. The EEG may show generalized spike-and-wave complexes or polyspikes.

Treatment starts with valproate, although barbiturates may be very effective. Lamotrigine is also used because of concern about the side effects of valproate. Topiramate and zonisamide may also be helpful. The prognosis for complete control of seizures with therapy is very

good: 65-79% of patients have experienced remission with therapy. Avoidance of precipitating factors that disrupt sleep patterns is important. The relapse rate if AEDs are stopped is high (83%).

PRINCIPLES OF ANTIEPILEPTIC DRUG USE

The goal of AED therapy is to use a single agent in adequate dosages to completely control seizures. If seizures recur, the dosage of an AED should be gradually increased to achieve the maximum tolerated dose for the patient without causing symptoms of drug toxicity. Therapeutic ranges are derived from population studies in which the serum levels of patients with seizures controlled by an AED were compared with those of patients experiencing side effects. The therapeutic levels should be used as a guide, and may also be used to assess compliance.

Around 67% of all seizure patients achieve seizure freedom on their first antiepileptic medication; the response rate is strongly tied to underlying etiology. If 1 agent does not control the seizures, another AED should be substituted and tried as monotherapy with a period of overlap during the transition period from 1 antiepileptic to another. An adequate trial of therapy entails the maximum tolerated dose of an AED for a period of time in which several of the patient's seizures (or clusters of seizures) would usually occur or for at least 2 months, whichever is longer. This interval may be shortened in infants and children with very frequent seizures. Changes in AED dosages and regimens should be made gradually, and due regard must be given to time taken to reach steady-state serum concentrations on the new regimen (Tables 30.21, 30.22, 30.23, and 30.24). Drug changes can be made gradually on an outpatient basis, but the physician must warn the parents and child that AED toxicity or an increase in the seizure frequency may occur during the changeover period. More rapid medication changes, especially if barbiturates are to be stopped, often require that the patient be admitted to the hospital during the changeover period.

Only about an additional 10% of patients achieve better control with the addition of a second drug to the first; 20-30% of patients with epilepsy have medically refractory epilepsy. Failure to respond to 2 AEDs at maximum tolerated doses should prompt a referral for assessment in a specialty epilepsy program. In some patients, resistance to AEDs may be genetically determined by mutations affecting drug transport or in metabolizing proteins such as the multidrug resistance–associated family of drug transporters.

It is important to design dosage schedules that are realistic. Dosing more often than 3 times a day may result in a high incidence of poor compliance. Parents must be advised to be careful with other prescribed and over-the-counter medications. Many medications may interfere with AED metabolism. Table 30.22 outlines indications for monitoring AED serum levels.

Special considerations for women with epilepsy who take antiepileptic medications and are of childbearing age include the teratogenicity of several antiepileptic medications, including valproic acid. Additionally, valproic acid is known to increase the risk of polycystic ovarian syndrome, with its attendant hormonal and metabolic disturbances. Finally, several antiepileptic medications have significant interactions with hormonal contraception, and the provider should familiarize themselves with these interactions to avoid failure of either medication.

Choice of Antiepileptic Drugs
Focal Epilepsies
Focal seizures and secondary generalized tonic-clonic seizures. Among the traditional AEDs, phenytoin, carbamazepine, phenobarbital, and primidone are equally effective in controlling partial and secondary GTC seizures in adults. In the symptomatic focal epilepsies, only approximately 35-50% of patients become seizure-free with AED monotherapy; another 20-30% experience more than a 75% reduction in seizure frequency. First-line treatment in this group of seizures is usually with carbamazepine, oxcarbazepine, or levetiracetam (see Table 30.23). Although the barbiturates and the benzodiazepines have been shown to be effective, the sedative and cognitive side effects prevent them from being drugs of first choice; they are generally reserved for patients in whom first-line drugs are not effective or tolerated. Valproate is also effective against focal seizures in children, although large comparative studies are not available.

Other drugs, including lamotrigine, vigabatrin, gabapentin, topiramate, and zonisamide, can be efficacious in treating refractory focal seizures.

Idiopathic Generalized Epilepsy
Primary generalized tonic-clonic seizures. It is widely thought that valproate should be the first-choice drug for primary GTC seizures, especially if they occur in association with absence seizures or myoclonic seizures. However, its side effect profile (teratogenicity, increased risk of polycystic ovarian syndrome) makes this medication less appropriate for use in adolescent women, but may be used in prepubescent girls. However, if valproate is the most efficacious antiepileptic medication for an adolescent woman after alternatives have been tried, it is reasonable to continue it after a risk-benefit discussion with the family.

Lamotrigine, topiramate, and zonisamide have also been shown to be effective for this seizure type (see Table 30.23). Phenytoin, carbamazepine, and valproate are equally effective in controlling primary GTC seizures in adults, and between 60% and 70% of patients can become seizure-free. Phenytoin does not control any associated absence seizures, and carbamazepine may exacerbate absence seizures. Phenobarbital and primidone are not the drugs of first choice because of potential adverse sedative and cognitive effects.

Absence seizures. Ethosuximide and valproate are the 2 drugs of first choice for absence seizures (see Table 30.23). Monotherapy with valproate controls absence seizures in more than 90% of children with childhood absence epilepsy. Ethosuximide and valproate have been successfully combined in patients with refractory absence seizures. Clonazepam is also effective but has the disadvantages of sedation and development of tolerance with chronic treatment. Lamotrigine, topiramate, and zonisamide have been effective for absence seizures, but experience is limited.

Myoclonic seizures. Specific myoclonic syndromes associated with absence seizures and tonic-clonic seizures, such as juvenile myoclonic epilepsy, are usually treated with valproate (see Table 30.23). Approximately 80% of patients with this epilepsy can become seizure-free, although lifelong treatment is required with juvenile myoclonic epilepsy. Clonazepam is also useful in myoclonic syndromes, although sedation occurs, and it does not tend to be useful in the long term because of tolerance; there are even some reports of exacerbation of seizures with long-term high-dose clonazepam. Exacerbation of seizures is particularly frequent with this drug when abrupt withdrawal is attempted. Clonazepam must be withdrawn very gradually, and the daily dose is reduced by only 0.25 mg every 3 weeks. Lamotrigine, topiramate, and zonisamide have a role in the treatment of myoclonus. Lamotrigine is an effective agent for juvenile myoclonic epilepsy and may become an alternative monotherapy option for this syndrome in young women. Valproate is associated with the development of ovarian cysts and teratogenicity.

TABLE 30.21 Dosages of Selected Antiepileptic Drugs

Medication	FDA Approval (Age Approved)	Maintenance Oral Dosage (mg/kg/day) Unless Otherwise Specified	Usual Dosing	Therapeutic Levels	Preparations
Acetazolamide	Absence seizures (adults)	1-12 mo: 10; <1 yr: 20-30	bid or tid	10-15 mg/L	125, 250, 500 mg tabs
Bromide		50-100	bid or qd	10-15 mEq/L	Supplied as triple bromide soln (240 mg/mL of bromide salt)
Carbamazepine*	Partial and GTC (all ages)	10-20	tid or qid SR usually bid	3-12 mg/L	150, 300 mg ER caps 100, 200, 400 mg ER tabs 100 mg chewable tabs 200 mg tabs 100 mg/5 mL susp
Clobazam[†]	LGS (all ages above 2 yr)	Up to 1	bid or tid	60-200 µg/L	5 mg, 10 mg, 20 mg tabs 2.5 mg/mL soln
Clonazepam[†]	Absence sz, LGS, myoclonic sz (all ages)	0.05-0.2	bid or tid	25-85 µg/L	0.5, 1, 2 mg tabs 0.125, 0.25, 0.5 mg orally disintegrating tabs
Diazepam	Partial sz (all ages >6 mo)	0.25-1.5 0.01-0.25 IV 0.2-0.5 mg/kg rectal (according to age)	bid or tid	100-700 µg/L	2, 5, 10 mg tabs 5 mg/mL, 5 mg/5 mL soln Rectal gel that can be dialed to dispense 2.5, 5, 7.5, 10, 12.5, 15, 17.5, 20 mg
Ethosuximide	Absence sz (>3 yr)	20-30	bid or tid	40-100 mg/L	250 mg caps 250 mg/5 mL syrup, soln
Ezogabine	Partial sz (adults)	No pediatric dose approved	tid	—	50, 200, 300, 400 mg tabs
Felbamate	LGS (>2 yr), p sz (>14 yr)	15-45	bid or tid	50-110 mg/L	400, 600 mg tabs 600 mg/5 mL susp
Gabapentin[‡]	Partial sz (>3 yr)	30-60	tid	2-20 mg/L	100, 300, 400 mg caps 600, 800 mg tabs
Lacosamide	Partial sz (>17 yr)	No FDA-approved dose 4-12	bid	≤15 µg/L	50, 100, 150, 200 mg tabs 10 mg/mL oral soln
Lamotrigine	LGS, partial and tonic-clonic sz (age >2 yr)	5-15[§] 1-5[¶]	tid bid	1-15 mg/L	25, 100, 150, 200 mg tabs 5, 25 mg chewable dispersible tabs 25, 50, 100, 200 mg ODTs 25, 50, 100, 200, 250, 300 mg ER tabs
Levetiracetam[†]	Myoclonic, partial, and tonic-clonic sz (age >4-6 yr)	20-40	bid or tid	6-20 mg/L	250, 500, 750 mg tabs 100 mg/mL soln 500, 750 mg SR (ER) tabs
Lorazepam	Status epilepticus (all ages)	0.05-0.1	bid or tid	20-30 µg/L	0.5, 1, 2 mg tabs 2 mg/mL soln
Methsuximide (or methsuximide)	Absence sz (children and older)	10-30	bid or tid	10-50 mg/L	150, 300 mg caps
Nitrazepam	—	0.25-1	bid or tid	<200 µg/L	5 mg tabs
Oxcarbazepine*	Partial sz (>2 yr)	20-40	bid	13-28 mg/L	150, 300, 600 mg tabs 300 mg/5 mL susp
Perampanel	Partial sz (>12 yr)	2-12 mg/day (older than 12 yr)	qhs	—	2 mg, 4 mg, 6 mg, 8 mg, 10 mg, 12 mg tabs
Phenobarbital	Myoclonic, partial, and tonic-clonic sz and status epilepticus (all ages)	<5 yr, 3-5 >5 yr, 2-3	bid or qd	10-40 mg/L	15, 30, 60, 90, 100 mg tabs 4 mg/mL soln
Phenytoin	Partial, tonic–clonic sz and status epilepticus (all ages)	<3 yr, 8-10 >3 yr, 4-7	tabs, susp: tid caps: qd	5-20 mg/L	50 mg tabs 30, 100 mg caps 125 mg/5 mL susp

Continued

TABLE 30.21 Dosages of Selected Antiepileptic Drugs—cont'd

Medication	FDA Approval (Age Approved)	Maintenance Oral Dosage (mg/kg/day) Unless Otherwise Specified	Usual Dosing	Therapeutic Levels	Preparations
Pregabalin	Partial sz (adults)	2-14	bid	Up to 10 µg/mL	25, 50, 75, 100, 150, 200, 225, 300 mg caps 20 mg/mL soln
Primidone	Partial and tonic-clonic sz (all ages)	10-20	bid or tid	4-13 mg/L	50, 250 mg tabs, susp
Rufinamide[†]	LGS (age >4 yr)	30-45	bid	<60 µg/mL	200, 400 mg tabs
Sulthiame[‖]		5-15	bid or tid	1.5-20 µg/mL	50, 200 mg caps Not available in all countries
Tiagabine	Partial sz (age >2 yr)	0.5-2	bid, tid, qid	80-450 µg/L	2, 4, 12, 16 mg tabs
Topiramate[†]	LGS, partial and tonic-clonic sz (all ages)	3-9, slow titration	bid or tid	2-25 mg/L	25, 100, 200 mg tabs 15, 25 mg sprinkle caps
Valproate	Absence, myoclonic, partial and tonic-clonic sz (age >2 yr)	15-40. Higher doses are used if the patient is on enzyme inducers (up to 60 kg/day)	Sprinkle caps: bid Soln: tid	50-100 mg/L	250 mg caps 125 mg sprinkle caps 125, 250, 500 mg tabs 250 mg/5 mL soln
Vigabatrin	Infantile spasms and partial sz (age >1 mo)	50-150	bid	20-160 µg/mL	500 mg tabs 500 mg powder for soln
Zonisamide	Partial sz (age >16 yr)	4-8	bid or qd	10-40 mg/L	100 mg caps

Unless specified otherwise, as above, one would usually target the lower range of the therapeutic dose, then adjust as needed depending on response and/or levels. Dosing schedule (e.g., bid or tid) can depend on if a sustained-release preparation is available and if the patient is on enzyme inducers (e.g., carbamazepine) or inhibitors (e.g., valproic acid) that could affect that drug (as indicated in the dosing in the table and in the text).

*Usually start by one-fourth maintenance dose and increase by one-fourth every 2-3 days to full dose.

†Usually start with one-fourth maintenance dose and increase by one-fourth every 7 days to full dose.

‡Usually start with one-fourth maintenance dose and increase by one-fourth every day to full dose.

§Child on enzyme inducers.

‖Available in some European countries.

¶Child on valproate.

bid, twice daily; cap, capsule; ER, extended release; FDA, US Food and Drug Administration; GTC, generalized tonic–clonic; IV, intravenously; LGS, Lennox-Gastaut syndrome; ODT, orally disintegrating tablet; qd, once daily; qid, 4 times a day; qhs, at bedtime; soln, solution; SR, sustained release; susp, suspension; sz, seizure(s); tab, tablet; tid, 3 times a day.

TABLE 30.22 Indications for Anticonvulsant Serum Level Monitoring

Introduction and stabilization of a patient on phenytoin
Alteration in seizure pattern or frequency
A change in the dosage of an anticonvulsant
Commencement or withdrawal of other medications that interfere with anticonvulsants
Symptoms of toxicity
To check patient compliance

Symptomatic Generalized Epilepsies

Tonic, atonic, and atypical absence seizures. These seizures are most commonly seen in children with complex, medically refractory epilepsy syndromes such as Lennox-Gastaut syndrome. They require specialist care due to the high incidence of polypharmacy and complex antiepileptic monitoring needs.

Drugs useful in the treatment of these seizures include valproate and benzodiazepines such as clonazepam and clobazam. Valproate monotherapy should be introduced first, although complete control of seizures is likely to occur in only 10-30% of patients (see Table 30.23). Carbamazepine and phenytoin are often not effective, and carbamazepine may exacerbate absence seizures in Lennox-Gastaut syndrome. Primidone and phenobarbital often have unacceptable side effects of drowsiness or worsening intellectual handicap at the dosages needed to control seizures; sedation may increase the frequency of tonic seizures. Benzodiazepines such as clonazepam, or in particular, clobazam in combination with valproate, are often used. Felbamate has been shown to be a useful drug as an adjunctive treatment for tonic and atonic seizures in Lennox-Gastaut syndrome. Lamotrigine, topiramate, and zonisamide have efficacy against the spectrum of seizures in the symptomatic generalized epilepsies, and their use is being explored. The combination of valproate and lamotrigine has been shown to be very effective in the control of intractable generalized seizure disorders.

The **ketogenic diet** is a high-fat, low-carbohydrate, low-protein diet designed to promote the use of fatty acids rather than carbohydrates for adenosine triphosphate (ATP) production in the brain. It is an effective treatment option in some children with intractable generalized seizures. The diet is most often used as second-line treatment for intractable structural, genetic, or metabolic generalized epilepsies,

TABLE 30.23 Comparison of Recommendations for the Treatment of Pediatric Epilepsy

Seizure Type or Epilepsy Syndrome	FDA Approved	Sign (2005)	NICE (2012)	AAN (2004)	ILAE (2013)*	Pediatric Expert Consensus Survey (North America–2005)	Pediatric Expert Consensus Survey (Europe–2007)
Partial-onset	CBZ, ezogabine, lacosamide, LEV, LTG, OXC, PB, perampanel, PHT, TPM, VGB	CBZ, CLB, LTG, OXC, PHT, TPM, VGB, VPA	CBZ, LEV, LTG, OXC, VPA	CBZ, GBP, LTG, OXC, PB, PHT, TPM	A: OXC; B: None; C: CBZ, PB, PHT, TPM, VGB, VPA; D: CLB, CZP, LTG, ZNS	CBZ, OXC	CBZ, OXC
BCECT	None	Not specifically mentioned	CBZ, LEV, LTG, OXC, VPA	Not surveyed	A, B: None; C: CBZ, VPA; D: GBP, LEV, OXC, STM	CBZ, OXC	VPA
Childhood absence epilepsy	ESM, VPA	ESM, LTG, VPA	ESM, LTG, VPA	LTG	A: ESM, VPA; B: None; C: LTG; D: None	ESM	VPA
Juvenile myoclonic epilepsy	LEV, LTG, TPM	VPA	LEV, LTG, TPM, VPA	Not surveyed	A, B, C: None; D: TPM, VPA	LTG, VPA	VPA
Lennox-Gastaut syndrome	CLB, FLB, LTG, rufinamide (atonic), TPM	CLB, LTG, VPA	VPA	Not surveyed	Not reviewed	LTG, VPA	VPA
Infantile spasms	VGB	Nitrazepam, TPM, VGB, VPA	Corticosteroids, VGB	ACTH, VGB (updated IS guidelines 2012)	Not reviewed	ACTH, VGB	VGB
Primary generalized tonic-clonic seizures	LEV, LTG, TPM	TPM, VPA	LTG, TPM, VPA	No evidence given	A: None; B: None; C: CBZ, PB, PHT, TPM, VPA; D: OXC		

*ILAE recommendations are listed according to levels of evidence supporting the efficacy of the options. Level A: ≥1 class I randomized controlled trial (RCT) or ≥2 class II RCTs; Level B: 1 class II RCT or ≥2 class III RCTs; Level C: ≥2 class III RCTs; Level D: 1 class III double-blinded or open-label study *or* 1 class IV clinical study *or* data from expert committee reports, opinions from experienced clinicians.
AAN, American Academy of Neurology; ACTH, adrenocorticotropic hormone; BCECT, benign childhood epilepsy with centrotemporal spikes; CBZ, carbamazepine; CLB, clobazam; CZP, clonazepam; ESM, ethosuximide; FDA, Food and Drug Administration; FLB, felbamate; GBP, gabapentin; ILAE, International League Against Epilepsy; IS, infantile spasms; LEV, levetiracetam; LTG, lamotrigine; NICE, National Institute for Clinical Excellence; OXC, oxcarbazepine; PB, phenobarbital; PHT, phenytoin; SIGN, Scottish Intercollegiate Guidelines Network; STM, sulthiame; TPM, topiramate; VGB, vigabatrin; VPA, valproic acid; ZNS, zonisamide.
Modified and updated from Wheless JW, Clarke DF, Arzimanoglou A, et al. Treatment of pediatric epilepsy: European expert opinion. *Epileptic Disord.* 2007;9:353-412; Perucca E, Tomson T. ILAE Subcommission on AED Guidelines. Updated ILAE evidence review of antiepileptic drug efficacy and effectiveness as initial monotherapy for epileptic seizures and syndromes. *Epilepsia.* 2013;54:551-563.

especially those with myoclonus. One specific indication for implementing the diet is in the context of *GLUT1* gene mutations in which the glucose transporter is defective and, in the presence of low cerebrospinal fluid (CSF) glucose, an alternative energy source for neural tissue optimizes chances for seizure control. Efficacy varies among studies, but approximately 50% of children achieve a clinically significant reduction in seizures. The diet requires a tremendous effort on the part of the parents and is successful only with proper education and close support by experienced ketogenic dietitians and physicians. Children are at risk for osteopenia, hypoglycemia, growth retardation, metabolic acidosis, and renal calculi with use of the diet; aspiration of

the ketogenic diet formula by a hypotonic child can cause a life-threatening pneumonia due to the high lipid content. For these reasons, this diet must only be undertaken under close medical supervision; the ketogenic diet plans intended for weight loss would be completely inappropriate for a child with refractory epilepsy who needs to maintain sufficient caloric intake for normal growth. Some adolescents and adults opt for a **modified Atkins diet** instead, again under close supervision of a ketogenic dietitian.

Palliative epilepsy surgery is available for patients with intractable tonic or atonic seizures causing "drop attacks" and falls. Surgical division of the corpus callosum can modify the intensity of these seizures

TABLE 30.24 Management of Seizures Refractory to Medical Therapy

Incorrect Diagnosis

Review seizure type

Focal dyscognitive seizures may be mistaken for absence seizures

Reflex epilepsy with uncontrolled precipitating factors, photosensitivity, reading epilepsy

Repeat EEG with hyperventilation, photic stimulation, and sleep recording. If results are negative, consider nonepileptic paroxysmal disorders

Psychogenic nonepileptic behavioral events (see Table 30.20)

Migraine

Porphyria, hypoglycemia, hypocalcemia

Continuing seizures: admit for video/EEG monitoring to record the event

Inappropriate Medication

Review anticonvulsant levels

A second AED may have caused a drop in the serum level of a first-line drug

Review seizure type

Phenobarbital and carbamazepine may exacerbate atypical absence seizures

Drowsiness caused by phenobarbital and benzodiazepines may exacerbate tonic seizures

Phenytoin often worsens the function of patients with progressive myoclonus epilepsy syndromes

Noncompliance with Medication or Medical Advice

Check AED levels; ask patient to record medication doses taken

Check sleep habits, drug use; arrange review by social worker, psychiatrist

Inability to cope with epilepsy and avoidance of precipitating factors (adolescence, low intelligence, dysfunctional home situation)

Review all patient's prescribed and over-the-counter medication; urine drug screen for drug abuse

Exacerbation by other medication or toxins

Intercurrent Illness or Metabolic Complication from Another Medication

Serum Na^+, K^+, glucose, Ca^{2+}, Mg^{2+}, creatinine, liver function studies, complete blood cell count, pregnancy test

Intractable Epilepsies

Up to one-third of cases of symptomatic focal epilepsy are refractory to current medical therapy

After an adequate attempt with 2 first-line medications and available new AEDs, refer for epilepsy surgery assessment

Symptomatic generalized epilepsies such as West syndrome and Lennox-Gastaut syndrome are often refractory

Need to reassess goals of therapy

Refer for surgical assessment if there are recurrent falls caused by tonic or atonic seizures in an older child

Epilepsy with progressive neurologic deterioration: e.g., brain tumor, inherited disorders of metabolism, degenerative neurologic disease, progressive myoclonus epilepsy, phakomatosis, systemic or cerebral vasculitis

Review history, family history, and physical examination; repeat neuroimaging; repeat EEG studies

AED, antiepileptic drug; EEG, electroencephalogram.

so that the patient does not fall. Hemispherectomy may be indicated in Rasmussen syndrome. Local resection of areas of mesial temporal sclerosis in patients with refractory temporal lobe seizures is a highly successful therapy. **Vagal nerve stimulation**, through surgical placement of a stimulating electrode on the left vagus nerve in the neck, is a technique developed to treat intractable focal seizures resistant to medication. It has also been used effectively in the symptomatic generalized epilepsies.

Stopping Antiepileptic Drugs

Most children (60-75% of patients) remain seizure-free when AEDs are withdrawn after a seizure-free interval on medication for more than 2 years. If relapse occurs, it is generally in the first few months after cessation of medication, and 60-80% of the relapses occur before 12 months after cessation. Patients with underlying neurologic disorders and deficits and those with multiple seizure types are more likely to suffer relapse. A long duration of epilepsy before remission carries a slightly higher risk of relapse. The EEG is a strong predictor in idiopathic epilepsy; among patients with frequent epileptic discharges that are recorded in generalized epilepsy, the rate of relapse is higher. For most children with epilepsy, it is recommended that children who have been seizure-free for 2 years undergo a trial of AED withdrawal.

LIFESTYLE

Parents should be encouraged to let their children lead a normal lifestyle, although some activities are inherently more dangerous for people with epilepsy. In general, climbing to significant heights, bathing, and swimming alone are not safe for children with active epilepsy. However, the clinician must stress the importance of avoiding overprotection of the child. Participation in sports and other school activities should be encouraged within the limits of avoiding dangerous activities such as rock climbing and scuba diving, in which even a brief loss of awareness could result in serious injury or death. If seizures are well controlled, minimal restrictions apply. In children with active seizures characterized by loss of consciousness, the physician has to make judgments on the basis of an individual assessment considering the nature of the seizures, their frequency, and the degree of supervision during the activity in question. Driving restrictions vary from state to state; it is advisable that an adolescent be seizure-free for at least 2 years before applying for a driver's permit. In general, heavy-impact contact sports such as football are best avoided by children with active epilepsy, but are not contraindicated for children in remission. In adolescents, some advice regarding birth control may be necessary because many adolescents are unaware of the interaction of AEDs and oral contraceptives.

Altered Mental Status

Jacquelyn C. Kuzminski

Coma is the lack of any awareness of self and environment despite painful or other external stimulation (Table 31.1). **Delirium** is an alternation in consciousness that falls along the spectrum from normal awareness to coma and is characterized by irritability, agitation, lack of contact with the environment, and confusion. Periods of lucidity may alternate with the delirious state, and patients may proceed rapidly from delirium to lethargy or coma. Any alteration in the level of consciousness whether delirium, lethargy, obtundation, stupor, or coma must be managed as a life-threatening emergency until proven otherwise.

BACKGROUND

Arousal and awareness form the foundation for normal cognitive function. **Arousal** is determined in the brainstem's ascending reticular activating system, and **awareness** is generated in the cortex. The cortex is the central processing center that interprets neuronal input and generates awareness. Injury to these areas creates an alteration in consciousness. *Standardized language is necessary to properly diagnose and treat alterations in consciousness since terms, such as lethargy, obtundation, stupor, and coma, are qualitative descriptions.* Rating scales allow different observers to follow the progression of the patient's mental status over time and facilitate effective communication of clinical information. The most widely used grading system is the **Glasgow Coma Scale (GCS)** (Table 31.2), which has been modified for children less than 5 years of age based on their age-appropriate developmental abilities (Table 31.3). The GCS was initially intended for use in traumatic injury but has been successfully applied in patients with nontraumatic altered mental status. This 15-point scale evaluates 3 areas of central nervous system (CNS) function: eye opening, verbal response, and motor response. A score of 15 indicates full function, whereas a score of 3 indicates no function. The 1st area of assessment is eye opening, in which the arousability and alertness of the patient are evaluated. Spontaneous eye opening indicates intact arousal mechanisms but does not imply awareness. The 2nd area, verbal response, requires a high degree of integration within the CNS. Oriented responses indicate awareness of person, place, and time. The 3rd area, motor functioning, reflects mentation as well as the integrity of the major CNS pathways. For purposes of gauging global brain function, the best motor response from any limb is taken as the score. Variation in response from one side of the body to the other is indicative of an asymmetric brain lesion. Spinal cord lesions resulting in paralysis or significant orthopedic injuries to the extremities prevent evaluation of the motor portion of the GCS.

The GCS can provide a general assessment of consciousness but is not intended to take the place of a complete neurologic evaluation (Table 31.4). The scale is an objective measure of the improvement or

worsening of the patient's level of consciousness over time, and interventions are often based on the score. Most patients with traumatic brain injury should undergo endotracheal intubation if their score is 8 or less. Deterioration of a patient's score by 2 or more points indicates a need for quick re-evaluation of the patient and the possible need for interventions such as endotracheal intubation and diagnostic studies such as a brain computed tomography (CT) scan. The score has been used to assign a prognosis to patients with brain injury, particularly with traumatic brain injury. It may take days to weeks for patients with initial scores of 3-5 to become conscious as opposed to a few days in patients with scores of 6 or higher.

The GCS score has also been used as a prognostic indicator in nontraumatic coma. Children presenting after near-drowning with an initial score of 6 or higher have a good outcome. Patients presenting with a score of 5 or less have a high probability of mortality or profound neurologic sequelae, although a patient with a score of 4 or 5 may survive with minimal impairment. A score of 3 on transfer to an intensive care unit after near-drowning has been associated with a nearly 100% rate of poor outcome.

Although the GCS is a widely applied tool for assessment, it does not assess *brainstem function* and fails to discriminate between low scores and intubated patients. The **Full Outline of Unresponsiveness (FOUR)** scale is another tool to assess consciousness that has been validated in several different settings with high inter-rater consistency. The FOUR score evaluates eye response, motor response, brainstem reflexes, and respiratory effort on a 4-point scale. The FOUR score eye and motor responses are defined very similar to the GCS (see Table 31.2). The assessment of brainstem response focuses on the pupillary and corneal reflexes. The respiratory assessment includes the intubated patient along with respiratory effort. Because the FOUR score includes brainstem responses and not only recognizes but differentiates intubated patients, this scale is better able to discriminate an unresponsive patient with a GCS of 3. In children with nontraumatic impairment of consciousness, using endpoints of mortality and functional outcome, both scales have similar predictive value. Regardless of the scoring system used, reporting the score for each element can increase the precise description of alteration in consciousness in order to make management decisions.

Other scales have been developed to measure the level of consciousness in specific disease states, such as poisonings, and hepatic failure. The **Reed classification** of coma has been used in the setting of poisoning or intoxication (Table 31.5) and is used to evaluate increasing depths of coma encountered with CNS-depressant drugs. The cardiovascular system is included in this classification because toxic ingestions may depress myocardial contractility or cause vasodilation. Neurologic function in a patient with **hepatic encephalopathy** is graded according to the scoring system in Table 31.6.

TABLE 31.1 States of Altered Consciousness or Unresponsiveness

Coma: A state of unarousable unresponsiveness; even strong exteroceptive stimuli fail to elicit recognizable psychologic responses; unresponsive to pain

Stupor: Spontaneous unarousability interruptible only by vigorous, direct external stimulation; responsive only to pain

Hypersomnia, pathologic drowsiness, obtundation: Terms applied to an increase above the patient's normal sleep/wake ratio, often accompanied during wakefulness by reduced attention and interest in the environment; responsive to pain and other stimuli

Delirium: An acute or subacute reduction in awareness, attention, orientation, and perception ("clouding of consciousness"), usually fluctuating and accompanied by abnormal sleep/wake patterns and often psychomotor disturbances

Syncope: Brief loss of consciousness caused by global failure of cerebrovascular perfusion

Dementia: A sustained or permanent multidimensional or global decline in cognitive functions

Vegetative state: A sustained, complete loss of cognition, with sleep/wake cycles and other autonomic functions remaining relatively intact; can either follow acute, severe bilateral cerebral damage or develop gradually as the end stage of a progressive dementia

Locked-in state: Preservation of intellectual activity accompanied by severe or total incapacity to express voluntary responses as a result of damage to or dysfunction of descending motor pathways in the brain or peripheral motor nerves; most, but not all, such patients can use vertical eye movements to signal by code

Modified from Plum F. Neurology/disturbances of consciousness and arousal. In: Wyngaarden JB, Smith LH, Bennett JC, eds. *Cecil Textbook of Medicine.* 19th ed. Philadelphia: WB Saunders; 1992:2049.

FIGURE 31.1 Management approach to coma. ABCs, airway, breathing, and circulation; CNS, central nervous system; CT, computed tomography.

◆ Differential Diagnosis

Coma is caused by 1 of 3 etiologies: structural brain disease, diffuse neuronal injury, or to a lesser degree, psychogenic causes. Within these 3 categories, the differential diagnosis of coma in the child is extensive. Excluding traumatic head injuries, broad category causes of altered mental status in children include intracranial infections, hypoxic-ischemic, epilepsy, metabolic encephalopathies, abusive head trauma, toxic ingestion, anatomic abnormalities, and cerebral vascular abnormalities such as emboli or vasculitis (Table 31.7). Some diagnoses (subdural hematoma, hydrocephalus, cerebral edema) may apply to more than 1 category. The age of the patient can help the clinician differentiate the likely causes of coma, although there is considerable overlap (Table 31.8). Patients with delirium must be differentiated from an acute psychotic event (Table 31.9). In addition, in patients who are awake but presenting with an altered mental status, performing an appropriate mental status exam may help evaluate the degree of impairment and potential etiology (Table 31.10). The mental status exam is most abnormal with organic (encephalopathy, encephalitis) causes of altered behavior and mental status.

◆ Management Approach

The approach to the child with an alteration of consciousness can be divided into 4 parts: (1) stabilization, (2) rapid clinical assessment, (3) reversal of immediately treatable toxic or metabolic causes, and (4) determination of level of CNS function and of the cause of the coma (Fig. 31.1).

Stabilization

Initial stabilization includes assessment of the patient's airway, breathing, and circulation (ABCs), as well as securing a patent airway, establishing access, and ensuring adequate circulatory volume. Evaluating a patient's airway and responding appropriately to ensure patency is the 1st step in management. This may involve positioning, suctioning, or intubating. This is closely tied to the assessment of respiratory drive via auscultation and observation. Obtunded, stuporous, or comatose patients usually require intubation unless their mental status is improving or can be readily reversed to secure an airway, treat hypoventilation, protect the airway if a gag reflex is not present, and to facilitate hyperventilation therapy in a child with suspected intracranial hypertension. Manipulation of the neck, particularly extension, should be avoided when an airway is being stabilized or secured, unless the cervical spine has been cleared via history or imaging.

Attention is next directed toward an assessment of the circulation; this mandates evaluation of vital signs, presence and volume of peripheral pulses, and adequacy of end-organ perfusion. Blood pressure must

TABLE 31.2 Glasgow Coma Scale Versus Full Outline of Unresponsiveness Score

Glasgow Coma Scale (GCS)		Full Outline of Unresponsiveness (FOUR)	
Eye Opening:		**Eye Response:**	
1	Does not open eyes	4	Eyelids open and comply with verbal stimuli
2	Opens eyes in response to noxious stimuli	3	Eyelids open but not tracking
3	Opens eyes in response to voice	2	Eyelids closed but open to loud noise
4	Opens eyes spontaneously	1	Eyelids closed but open to noxious stimuli
		0	Eyelids remain closed
Verbal Response:		**Motor Response:**	
1	No verbal response	4	Thumbs up, fist or peace sign
2	Incomprehensible sounds	3	Localize to pain
3	Inappropriate words	2	Flexion to pain
4	Confused and disoriented fluid speech	1	Extension to pain
5	Oriented with normal speech	0	No response to pain or myoclonus
Motor Response:		**Brainstem Reflexes:**	
1	No movements	4	Pupil and corneal reflexes present
2	Extension to noxious stimuli	3	One pupil wide and fixed
3	Flexion to noxious stimuli	2	Pupil or corneal reflex absent
4	Withdrawal to pain	1	Pupil and corneal reflexes absent
5	Localizes to pain	0	Absent pupil, corneal, and cough reflex
6	Obeys commands		
		Respirations:	
		4	Regular breathing pattern
		3	Cheyne–Stokes respirations
		2	Irregular breathing
		1	Intubated but breathing above the vent
		0	Breathing at vent rate or apnea

(See *Nelson Textbook of Pediatrics*, Table 67-3.)

TABLE 31.4   The Neurologic Examination in Coma

1. Guarantee vital functions.
2. Feel the scalp for hematomas (overlying fracture lines); be sure the neck is not fractured; test gently for stiff neck.
3. Test language. Test arousability by words, loud sounds, noxious stimuli. If vocalizations occur, check quickly for appropriate phrases, actual words, and presence or absence of aphasia.
4. Perform a neuro-ophthalmologic examination.
   Funduscopy (if difficult, can be deferred until patient is stabilized).
   Papilledema (increased intracranial or venous sinus pressure)
   Hemorrhages (subarachnoid hemorrhage; hypertensive encephalopathy; hypoxic-hypercarbic encephalopathy)

   Pupils
   Light reaction: Use bright flashlight and, if necessary, a magnifying glass to be certain of findings. Absence means potentially fatally deep sedative poisoning or acute or chronic structural brainstem damage.
   Equality: 15% of normal patients have mild anisocoria, but new or >2-mm dilation means parasympathetic (3rd nerve) palsy.
   Extraocular movements: Absence acutely means deep drug poisoning, severe brainstem damage, polyneuropathy, or botulism.
   Dysconjugate deviation: At rest, this means an acute 3rd, 4th, or 6th nerve palsy or internuclear ophthalmoplegia. Tonic conjugate deviation toward a paralytic arm and leg means forebrain seizures or a contralateral pontine destructive lesion; such deviation away from the paralytic arm and leg means forebrain gaze paralysis.
   Spontaneous eye movements: In comatose patients, nystagmus, bobbing, and independently moving eyes all mean brainstem damage.
   Oculocephalic (away from direction of head turning) or oculovestibular (toward cold caloric irrigation) responses: Absence of responses means drug overdose or severe brainstem disease; dysconjugate responses with equal pupils mean internuclear ophthalmoplegia; responses with unequal pupils mean 3rd nerve disease.
5. Examine the motor systems.

   Strength
   Unilateral weakness or motionlessness of arm and leg means contralateral supraspinal upper motor neuron lesion, most often cerebral; if of arm, leg, and face, contralateral cerebral lesion. Occasionally, arm and leg weakness reflects contralateral brainstem lesion.
   Weakness or motionlessness of all 4 extremities implies metabolic disease; less likely is brainstem disease (tone and reflexes increased) or peripheral disease (tone and reflexes decreased).

   Attempt to Elicit Reflex Posturing
   Arm flexed, leg extended: contralateral deep cerebral-thalamic lesion
   Arm and leg extended: thalamic or mesencephalic lesion
   Arms extended and legs flexed or flaccid: pontine lesion
   Legs flexed, arms flaccid: pontomedullary or spinal lesion
   Compare side-to-side reflexes and examine plantar responses.
6. Seek seizure activity or abnormal movements: (1) generalized, (2) focal, (3) multifocal, and (4) myoclonic.
   Control (1) immediately, (2) and (3) deliberately; if (4) is present, treat underlying disease.
   Acute tremor, asterixis, multifocal myoclonus: seek metabolic cause.
7. Inspect breathing.
   Regular hyperpnea: metabolic acidosis; pulmonary infarction; congestive failure or alveolar infiltration; sepsis; salicylism; hepatic coma
   Cyclically irregular (Cheyne–Stokes): low cardiac output plus bilateral cerebral or upper brainstem dysfunction
   Irregularly irregular gasping, slow or weak: lower, brainstem dysfunction (including hypoglycemia, drug effects); less often, peripheral ventilatory paralysis
8. Proceed with laboratory tests and emergency management as described in text.

Modified from Plum F. Neurology/sustained impairments of consciousness. In: Wyngaarden JB, Smith LH, Bennett JC, eds. *Cecil Textbook of Medicine.* 19th ed. Philadelphia: WB Saunders; 1992:2057.

---

be high enough to support perfusion of vital organs. Patients may be in shock with a normal blood pressure and may manifest tachycardia and often, tachypnea. In early shock, except for septic shock, peripheral pulses are diminished in comparison with central pulses. As shock progresses and stroke volume decreases, the pulse pressure narrows, and the peripheral pulses become weak or "thready" and finally non-palpable. Early septic shock or "warm" shock is often characterized by a widened pulse pressure and bounding pulses.

End-organ perfusion is best evaluated in the skin, kidneys, and brain. The skin should be checked for temperature, color, and capillary refill. Cool extremities, pallor, mottling, peripheral cyanosis, and capillary refill of more than 2 seconds indicate poor perfusion. As perfusion worsens, the coolness of the extremities extends proximally. Urine output may not be helpful in the initial evaluation of a patient, but it becomes an important marker to monitor during therapy. As renal perfusion improves, urine flow rate increases. The patient's alteration in consciousness may be a consequence of shock. In early stages of shock, the patient is typically lethargic or confused, and lethargy alternating with combativeness is often seen.

Rapid Clinical Assessment

After initial stabilization, attention should turn to rapid clinical assessment including focused history from available friends, family, witnesses, 1st responders and the medical record as applicable, and a physical exam with a targeted neurologic examination. Using this data, the etiology of coma (structural, diffuse neuronal dysfunction, and

TABLE 31.5 Reed Classification of Coma

Grade 0*	Asleep Can be aroused Will answer questions
Grade 1*	Comatose Withdraws from painful stimuli Intact reflexes
Grade 2*	Comatose Does not withdraw from painful stimuli No respiratory, circulatory depression Intact reflexes
Grade 3†	Comatose Reflexes absent No respiratory, circulatory depression
Grade 4†	Comatose Reflexes absent Respiratory or circulatory problems

*Good prognosis.
†Very serious, may need measures to enhance elimination.

TABLE 31.6 Classification of Hepatic Encephalopathy

Grade 0	Normal
Grade I	Altered spatial orientation, sleep patterns, and affect
Grade II	Drowsy but arousable, slurred speech, confusion, and asterixis
Grade III	Stuporous but responsive to painful stimuli
Grade IV	Unresponsive, with decorticate or decerebrate posturing possible

From Rogers EL, Perman JA. Gastrointestinal and hepatic failure. In: Rogers MC, ed. *Textbook of Pediatric Intensive Care.* 2nd ed. Baltimore: Williams & Wilkins; 1992:1151.

psychiatric) may be clarified for initial treatment decisions. Pertinent questions include recent history preceding the change in mental status, the patient's medical history, and family history, particularly of seizures or encephalopathy. Specific questions should be targeted at identifying any traumatic injuries in the previous few days, and any recent fevers or other signs or symptoms of infection or systemic disease. A dietary history in infants presenting with a depressed level of consciousness is paramount and may raise suspicion of hypoglycemia (fasting or emesis) or hyponatremia (ingestion of free water). Exposure to drugs or toxins should be suspected in any patient with a sudden onset of unexplained symptoms (coma, seizures) or a gradual onset of symptoms preceded by a period of confusion or delirium. The caregivers should be asked directly about possible access to medications, illicit drugs, and environmental toxins.

After collecting the available historical information, the next phase in management is completing a physical exam including a rapid neurologic assessment (see Table 31.4), which should take no more than a few minutes. The general physical exam should include assessment of vital signs with emphasis on the cardiovascular, respiratory, and head and neck exams as well as a general assessment. Special attention should be paid to identify any physical exam findings that may suggest a specific toxidrome. The absence of a history of trauma or physical findings suggestive of a rapidly progressive intracranial process does not preclude a traumatic or an anatomic cause of coma. Traumatic injuries can result in life-threatening illnesses at any age, including newborns. The head and neck should be carefully inspected and the skull palpated for evidence of trauma (Table 31.11). In infants, a bulging fontanel represents raised intracranial pressure, which may have various causes. In the absence of a febrile illness, trauma, including that caused by abusive head trauma, should be suspected in any infant with a bulging fontanel. Retinal hemorrhages are often present on funduscopic examination in children with abusive head trauma. In addition to abusive head trauma, a child may have a subarachnoid hemorrhage (ruptured aneurysm, arteriovenous malformation) or hydrocephalus without any of the aforementioned signs or symptoms of raised intracranial pressure.

After completing a brief general physical exam and noting impaired consciousness, a rapid neurologic assessment is required. The neurologic assessment should focus on identifying lateralizing or focal findings, recognizing brainstem dysfunction, and defining severity of illness. Intrinsic to this assessment is differentiating 1 hemisphere with mass effect versus both hemispheres involvement versus suspected brainstem dysfunction (Table 31.12). The presence of focal findings can be determined by examination of a child's pupils for asymmetry in size or reactivity and examination of the motor system for asymmetric movement of the extremities or face. The motor response is part of the GCS and FOUR scores as referenced previously. Motor response should be tested by 1st observing spontaneously purposeful movement, then movement in response to command and finally, movement in response to noxious stimuli. Because localization to pain relies on the contralateral arm to cross the midline to address pain, both sides should be tested.

Brainstem function is evaluated by observing the child's respiratory pattern, assessing corneal reflexes, and testing oculocephalic (doll's eye) or oculovestibular (cold caloric) reflexes. The oculocephalic reflex should not be checked unless a cervical spine injury has been ruled out. Significant brainstem dysfunction is rarely associated with a normal breathing pattern (Fig. 31.2). Cheyne–Stokes respiration is a pattern of breathing in which periods of hyperpnea alternate with shorter apneic phases, observed in the presence of bilateral hemispheric or diencephalic dysfunction. It may also precede transtentorial herniation. The hyperpneic periods have a characteristic smooth, crescendo-decrescendo pattern.

Central neurogenic hyperventilation is encountered with midbrain dysfunction; patients with this problem are tachypneic and hyperpneic. Apneustic breathing is associated with damage in the middle to lower pontine region. This pattern is characterized by a prolonged pause at full inspiration. Clusters of breaths separated by periods of apnea may be observed in patients with low pontine to upper medullary lesions, whereas medullary lesions result in ataxic or irregular breathing, slow regular breathing, or agonal respiration. Absent or asymmetric corneal reflexes or abnormal oculocephalic or oculovestibular reflexes suggest serious brainstem involvement. Normal brainstem response combined with withdrawal to pain suggests a supratentorial abnormality. Roving eye movements suggest an intact brainstem, whereas vertical malalignment suggests the brainstem is affected.

Increasing intracranial pressure is a worrisome sign. Indications of clinically significant intracranial hypertension are usually apparent during an assessment of pupillary responses, vital signs, and motor responses (Tables 31.13 and 31.14). A unilaterally fixed and dilated pupil in a patient who is not awake represents uncal herniation precipitated by an increase in intracranial pressure in the supratentorial space. Anisocoria or ptosis may be a sign of increased intracranial pressure.

TABLE 31.9	Special Problems in the Differential Diagnosis of Delirium*			
Clinical Feature	Delirium	Dementias	Schizophrenia	Depression
Course	Acute onset; hours, days, or more	Insidious onset[†]; months or years; progressive	Insidious onset, 6 mo or more; acute psychotic phases	Insidious onset, at least 2 wk, often months
Attention	Markedly impaired attention and arousal	Normal early; impairment later	Normal to mild impairment	Mild impairment
Fluctuation	Prominent in attention arousal; disturbed day/night cycle	Prominent fluctuations absent; lesser disturbances in day/night cycle	Absent	Absent
Perception	Misperceptions; hallucinations, usually visual, fleeting; paramnesia	Perceptual abnormalities much less prominent[‡]; paramnesia	Hallucinations, auditory with personal reference	May have mood-congruent hallucinations
Speech and language	Abnormal clarity, speed, and coherence; disjointed and dysarthric; misnaming; characteristic dysgraphia	Early anomia; empty speech; abnormal comprehension	Disorganized, with a bizarre theme	Decreased amount of speech
Other cognition	Disorientation to time, place; recent memory and visuospatial abnormalities	Disorientation to time, place; multiple other higher cognitive deficits	Disorientation to person; concrete interpretations	Mental slowing; indecisiveness; memory retrieval difficulty
Behavior	Lethargy or delirium; nonsystematized delusions; emotional lability	Disinterested; disengaged; disinhibited; delusions and other psychiatric symptoms	Systematized delusions; paranoia; bizarre behavior	Depressed mood; anhedonia; lack of energy; sleep and appetite disturbances
Electroencephalogram	Diffuse slowing; low-voltage fast activity; specific patterns	Normal early; mild slowing later	Normal	Normal

*The characteristics listed are the usual ones and not exclusive.
[†]Patients with vascular dementia may have an abrupt decline in cognition.
[‡]Patients with dementia with diffuse cortical Lewy bodies often have a fluctuating mental status and hallucinations.
From Mendez MF, Padilla CR. Delirium. In: Daroff RB, Jankovic J, Mazziotta JC, et al., eds. *Bradley's Neurology in Clinical Practice.* 7th ed. Philadelphia: Elsevier; 2016:32; Table 4.2.

Impending central herniation from increased pressure on the caudal brainstem may be preceded by the **Cushing triad** of hypertension, bradycardia, and irregularities of respiration. Decerebrate or opisthotonic posturing should also be considered a sign of raised intracranial pressure in an unresponsive patient. A lateral rectus palsy (cranial nerve VI) may also be an early sign of intracranial hypertension.

Reversal of Immediately Treatable Toxic or Metabolic Causes

If the etiology for altered consciousness is not yet known, emphasis should shift to a systemic review of the reversible causes. Hypoglycemia and narcotic intoxication are 2 rapidly reversible causes of coma. Hypoglycemia is a medical emergency that must be reversed because sustained hypoglycemia may result in permanent neurologic damage. A blood glucose level should be obtained as soon as possible in an altered child. Once an intravenous catheter has been placed, all unresponsive children should receive dextrose unless a diagnosis other than hypoglycemia is apparent. In the absence of a central line, the percent dextrose solution used may vary; however, the absolute dose of glucose remains the same. If the child's mental status improves or if there is laboratory confirmation of hypoglycemia, the dextrose bolus should be followed by a continuous infusion of glucose and electrolytes to prevent rebound hypoglycemia.

Naloxone is also administered to children who have marked depression of consciousness without an obvious cause, particularly if hypoventilation is observed and opioid ingestion is suspected. Miosis is not a necessary finding because ingestion of multiple agents, including narcotics, may not result in small, constricted pupils. Large ingestions of narcotics may necessitate larger single doses of naloxone because of the competitive nature of its antagonistic effect, or they may necessitate multiple doses because its half-life is shorter than that of the narcotic ingested.

Another reversible cause of coma is a benzodiazepine ingestion. Flumazenil, a specific competitive antagonist of benzodiazepines, should only be given if benzodiazepine ingestion is suspected as administration of flumazenil to a patient who has ingested multiple agents may precipitate seizures.

When there are clinical signs or symptoms of meningitis or encephalitis, the child should be assessed for the presence of a bulging fontanel, nuchal rigidity, and Kernig or Brudzinski signs. Prior administration of antibiotics does not affect meningeal irritation. Most (85%) children with meningitis have an alteration in mental status (53% lethargic, 22% stuporous, 10% comatose). If meningitis is suspected, a lumbar puncture, including measurement of the opening pressure, should be performed unless the procedure is contraindicated (Table 31.15). If a contraindication exists, the child should be stabilized, receive empirical antimicrobial therapy, and undergo head CT imaging. The patient should undergo lumbar puncture as soon as it is no longer contraindicated. If a patient presents with sudden nuchal rigidity not preceded by a prodromal illness, a subarachnoid hemorrhage should be suspected and a CT scan performed before the lumbar puncture.

Level of Central Nervous System Function and Cause

The coma can be initially considered stable if (1) focal neurologic findings are not present, (2) there is no evidence of significant brainstem dysfunction, (3) intracranial pressure is not raised, (4) there is no evidence of head trauma or CNS infection, and (5) the child does not have a rapidly reversible toxic or metabolic cause. At this point a

detailed physical examination and expanded laboratory evaluation can be undertaken to determine the level of CNS function and the cause of the coma.

Coma can be thought of as resulting from hemispheric or brainstem (including reticular activating formation) dysfunction. Dysfunction in either location may be produced by anatomic or nonstructural causes and a detailed physical examination may provide further clues to the cause of the coma (Table 31.16). The origin of coma (hemispheric vs brainstem) and its cause (metabolic vs structural) can be elucidated by evaluation of pupillary size and reactivity, eye movements, motor responses, and respiratory pattern.

Pupillary light reflexes are generally preserved in metabolic encephalopathy, whereas their absence strongly suggests a structural lesion. The only exception to the latter is drug effect, particularly with potent anticholinergic compounds, such as glutethimide, atropine, or scopolamine, which produce fixed and dilated pupils. The balance between sympathetic and parasympathetic stimulation, which result in pupillary dilation and constriction, normally determines pupillary size and reactivity. A **unilaterally dilated and fixed pupil** is a sign of uncal herniation with entrapment of the oculomotor nerve. Parasympathetic fibers innervating the eye accompany the oculomotor nerve. Sympathetic fibers originate from at least 4 hypothalamic nuclei so that diencephalic dysfunction results in small, reactive pupils. Hypothalamic damage often results in ipsilateral miosis associated with **Horner syndrome** (miosis, ptosis, and anhidrosis).

Injury to nuclei located in the midbrain disrupts both sympathetic and parasympathetic pathways, resulting in midsized, fixed pupils. Damage to the midbrain tectal regions also produces mid-position or slightly large, fixed pupils. In contrast to nuclear damage, however, accommodation may be intact, so that pupillary size fluctuates spontaneously. Pontine lesions, principally hemorrhage, interfere with descending sympathetic fibers, causing symmetrically small pupils for which a magnifying glass may be needed to detect a light reflex. Lateral medullary lesions may also produce Horner syndrome, whereas central herniation results in fixed, dilated pupils. Fig. 31.3 summarizes pupillary findings in comatose patients.

Evaluation of eye movements is helpful in differentiating hemispheric from brainstem causes of coma. Frontal regions of the cerebral hemispheres are responsible for voluntary eye movements, the quick phase of nystagmus, and control over brainstem reflexes that determine eye movements. Bilateral hemispheric depression may result in

TABLE 31.12 Neurologic Findings That Help to Localize Site of Structural Brain Disease by Location of Lesion

Neurologic Findings

Bilateral hemispheric	Spontaneous eye movements (roving, dipping,* ping-pong, nystagmoid jerks)
	Upward or downward eye deviation
	Intact oculovestibular reflexes
	Intact pupillary and corneal reflexes
	Variable motor responses
	Adventitious limb movements (subtle manifestations of seizures, myoclonus, asterixis)
Brainstem displacement from a hemispheric mass	Anisocoria or unilateral fixed and dilated pupil (predominant lateral displacement)
	Midposition fixed pupils (predominant downward displacement)
	Extensor or flexor posturing
	Central hyperventilation (diencephalic)
Brainstem displacement from a cerebellar mass	Direction-changing or vertical nystagmus from the cerebellar lesion
	Ocular bobbing†
	Absent corneal reflexes with intact pupillary reflexes
	Extensor or flexor posturing
	Facial or abducens nerve palsy
	Skew deviation (vertical misalignment of eyes)
	Internuclear ophthalmoplegia
Intrinsic brainstem lesion	Vertical nystagmus or bobbing
	Miosis (with pontine lesions)
	Internuclear ophthalmoplegia
	Variable pupillary and corneal reflexes (can both be absent)
	Absent oculocephalic and oculovestibular responses
	Extensor or flexor posturing
	Ataxic breathing (pontomedullary damage)

*Slow eye movement down followed by rapid return up to the mid plane.
†Rapid eye movement up followed by slow return down to the mid plane.

roving eye movements if brainstem function is intact. Because stimulation of a frontal gaze center causes conjugate deviation of the eyes to the opposite side, tonic lateral deviation of the eyes implies a seizure emanating from the contralateral hemisphere. Eye deviation may also result from an ipsilateral hemispheric injury with unopposed stimulation from the undamaged hemisphere or from a contralateral pontine lesion. The degree of eye deviation is usually more dramatic with hemispheric damage than with brainstem damage.

If the patient's eyes are not moving, then reflex eye movements are tested by the oculocephalic and oculovestibular responses (Fig. 31.4). These maneuvers involve the same major neuronal pathways. Afferent fibers from the labyrinth, cerebellum, and cervical muscles reach the vestibular nuclei (cranial nerve VIII) in the medulla. Fibers from the vestibular nuclei then course to the ipsilateral abducens nuclei (cranial nerve VI). Fibers from the abducens nuclei then decussate in the midpons and ascend in the medial longitudinal fasciculus to reach the contralateral oculomotor nuclei (cranial nerve III). Positive reflexes indicate the absence of cortical input on an intact brainstem.

The oculocephalic reflex is elicited by rotating the child's head from side to side and observing the eye movements. If brainstem function is intact, the eyes deviate in a direction opposite to the head movement. Both left and right lateral rotation should be tested. This reflex should then be tested in a vertical plane by rapidly flexing and extending the neck. A positive response is upward gaze when the neck is flexed and downward deviation when the head is extended. Such maneuvers are contraindicated if cervical spine injury is suspected.

The oculovestibular reflex is tested by instilling ice water into the ear canal. The ear canal must be visualized to ensure that there is no obstruction and that the tympanic membrane is intact. The head is then placed at a 30-degree angle from the horizontal so that the semicircular canal is vertical, and up to 120 mL of ice water is then injected slowly into the external ear canal over a few minutes through an angiocatheter. After a minimum of 5 minutes, the other ear may be tested; this interval allows time for the oculovestibular system to re-equilibrate. A positive response in an awake patient is nystagmus with the slow component toward the irrigated ear and the fast component away from the stimulus. With bilateral hemispheric depression, the fast phase of nystagmus dissipates, and the eyes are tonically deviated toward the irrigated ear.

Both the oculocephalic and oculovestibular reflexes are absent in patients with low brainstem lesions because neurotransmission between the vestibular and abducens nuclei is interrupted. In patients with damage to the medial longitudinal fasciculus, the ipsilateral eye fails to adduct on irrigation of the contralateral ear canal. However, the

TABLE 31.13 Signs of Incipient Downward Herniation

	Central	Uncal
Arousal	Impaired early, before other signs	Impaired late, usually with other signs
Breathing	Sighs, yawns, sometimes Cheyne–Stokes respiration	No early change
Pupils	First, small reactive (hypothalamus); then 1 or both approach mid-position	Ipsilateral pupil dilates, followed by somatic 3rd nerve paralysis
Oculocephalic responses	Initially sluggish, later tonic conjugate	Unilateral 3rd nerve paralysis
Motor signs	Early hemiparesis opposite to hemispheric lesion followed late by ipsilateral motor paresis and extensor plantar response	Motor signs late, sometimes ipsilateral to lesion

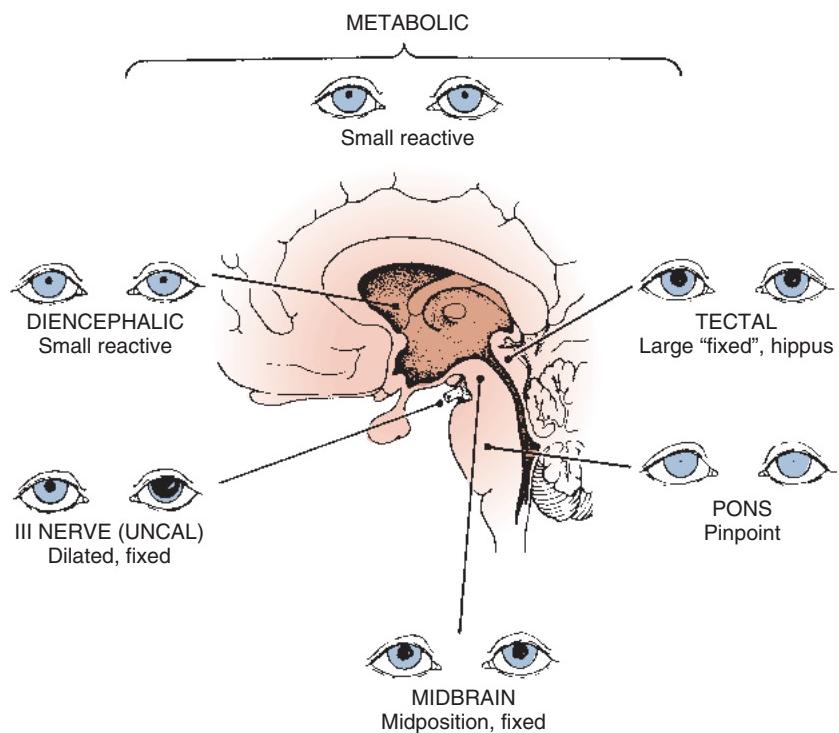

FIGURE 31.3 Pupils in comatose patients.

opposite eye abducts normally. For example, with a lesion in the left medial longitudinal fasciculus, the right eye abducts, but the left eye does not, in response to irrigating the right ear canal. This reaction is caused by disruption of fibers between the abducens and the contralateral oculomotor nuclei (see Fig. 31.4).

In addition to assessing ocular motility, the examiner should test the corneal reflex and determine the presence or absence of a blink. The absence of a blink in response to a loud noise or bright light implies dysfunction of the pontine reticular formation secondary to either metabolic or structural causes. Unilateral absence of a blink implies a facial nerve lesion. The afferent limb of the corneal reflex is carried by the trigeminal nerve (cranial nerve V). The normal effector response involves both upward deviation of the eye (oculomotor nerve) and closure of the eyelid (facial nerve). A normal reflex suggests that the integrity of pathways between the midbrain and the pons has not been violated.

Examination of the motor system includes observation of body position, spontaneous movements, and response to noxious stimuli (Fig. 31.5). A normal body position usually denotes an intact brainstem, as do spontaneous, nonposturing movements. Hemiparesis or hemiplegia implies a structural lesion in the contralateral hemisphere or subcortical region or an ipsilateral spinal cord injury. The presence of hypertonia or hyperreflexia suggests previous corticospinal tract disease or an acute brainstem injury at the midbrain-pontine level. It can also be observed in patients with severe metabolic derangements, such as hepatic coma, hypoglycemia, anoxia, and uremia. Hypotonia implies bilateral hemispheric dysfunction or a medullary or spinal cord lesion. In patients with severe depression of brain function, motor function can be assessed only after the application of a noxious stimulus, such as a sternal rub or increasing subungual pressure to the fingernails or toenails. Ascending sensory pathways to the cerebral hemispheres are intact, and descending motor pathways are

functioning to some degree if the response to a noxious stimulus includes verbalization or eye opening or a normal motor response, such as localization of the stimulus, withdrawal of the limb, or movement away from the stimulus.

Decorticate posturing implies hemispheric dysfunction with an intact brainstem; decerebrate posturing is more ominous (see Fig. 31.5). Opisthotonos with clenched teeth is a severe form of decerebration. This response usually suggests brainstem compression or a severe structural injury to the midbrain-pontine region. It can also occur in association with severe metabolic diseases, such as hepatic coma, anoxia, and hypoglycemia. Less commonly, decerebrate posture may represent delayed cortical demyelination after a hypoxic-ischemic

injury. Pontomedullary or spinal cord damage is associated with a flaccid response to noxious stimulation.

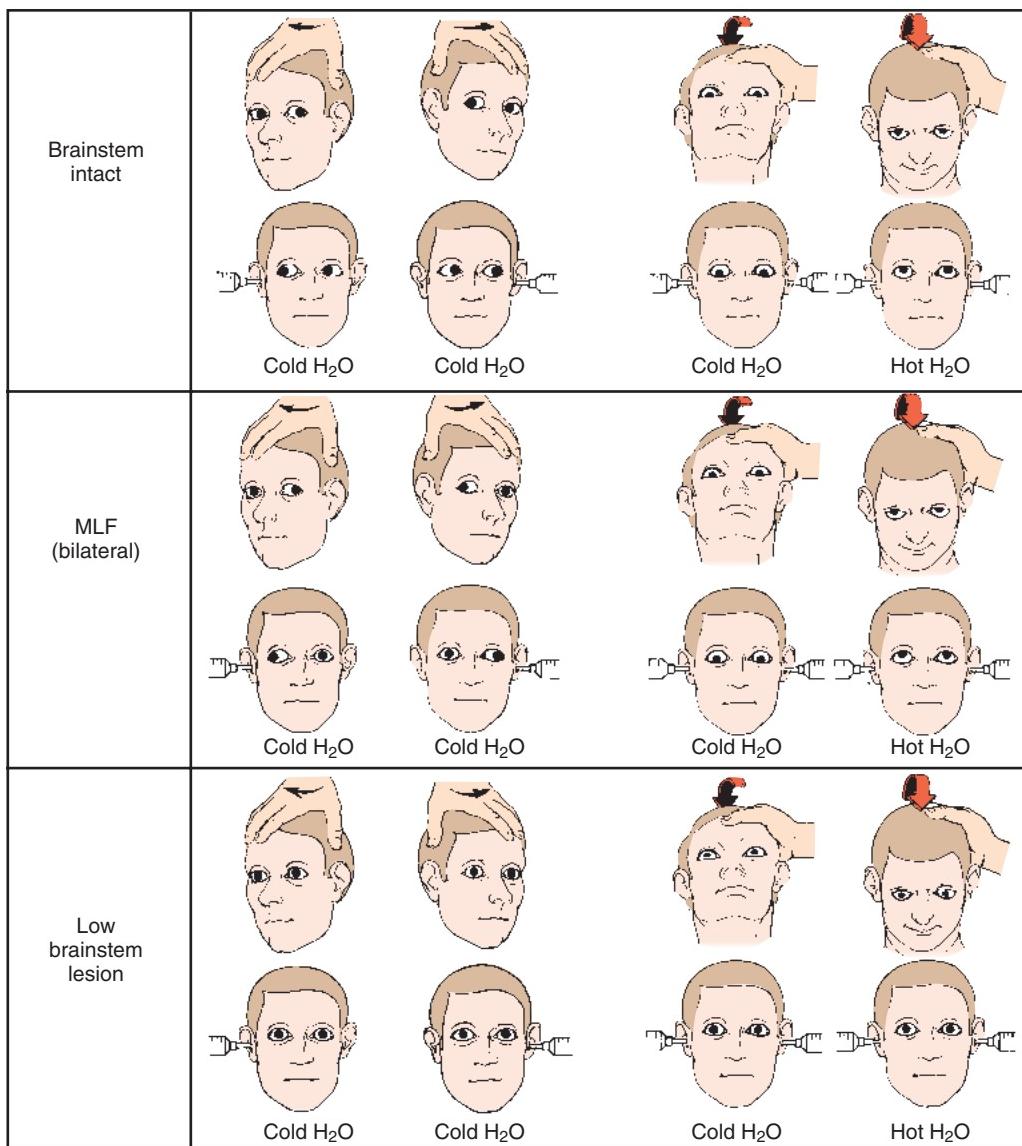
A patient's breathing pattern is also helpful in localizing the area of CNS dysfunction. **Hyperventilation** can be observed not only in midbrain structural lesions but also in toxic-metabolic encephalopathies as a primary response to stimulation of the respiratory center (salicylate, theophylline, hepatic coma) or as a compensatory response to a metabolic acidosis. This pattern is also seen with raised intracranial hypertension, as may occur in a child with meningitis. **Hypoventilation** with a normal rhythm, particularly if associated with a symmetrically depressed motor examination, usually implies global CNS depression secondary to drug ingestion.


FIGURE 31.4 Ocular reflexes. MLF, medial longitudinal fasciculus.

Further laboratory assessment depends on clinical suspicions formulated from the detailed neurologic exam described earlier (Table 31.17). Patients with suspected anatomic causes of coma should undergo emergency head CT imaging, whereas those with a suspected CNS infection should undergo lumbar puncture. Other studies to consider are electrocardiography to rule out conduction abnormalities, seen with many drugs; liver function studies including coagulation factors; blood ammonia determination; measurement of calcium, magnesium, and phosphorus; and serum osmolality measurement. An osmolal gap, as well as an anion gap should be calculated. The osmolal gap is the difference between the measured and calculated serum osmolality (normal is <5-10 mOsm/kg H_2O). Table 31.18 summarizes the differential diagnoses of an elevated anion or osmolal gap. Toxicology screens may be of value with suspected ingestions; however, the results must be interpreted cautiously. Because toxicology screens are not standardized, a "negative" result does not rule out an undetermined ingestion. Screening for certain agents, such as methanol and ethylene glycol, needs to be requested specifically, whereas tests for

other compounds may yield false-negative results. Patients with a history of constitutional symptoms such as headache, emesis, or upper respiratory illness that proceed to have psychiatric symptoms, language disintegration, and catatonia should be evaluated for anti-NMDA (*N*-methyl D-aspartate) receptor encephalitis with a lumbar puncture, brain imaging and antibody testing.

If physical examination and laboratory studies do not yield a diagnosis, a head CT scan should be obtained to rule out anatomic or vascular causes. Further diagnostic evaluation with magnetic resonance imaging (MRI) may be necessary to evaluate parenchymal abnormalities. Imaging may reveal subtle signs of edema, ischemia, or demyelination before these signs are visible on CT scan. Large tumefactive T2 lesions of similar age with variable enhancement in either the brain or spine, with MRI scanning, are consistent with acute disseminated encephalomyelitis (ADEM), an inflammatory demyelinating condition that can present with fever, headache, vomiting, meningeal signs, and seizures resulting in encephalopathy. Neuromyelitis optica (NMO) can occasionally present with encephalopathy similar to that

seen in ADEM, although it more commonly presents with optic neuritis, transverse myelitis, or focal brainstem findings. Brain imaging in a patient with NMO will typically have less defined hemispheric lesions.

If MRI results are normal, the most likely causes of coma are intoxication, psychologic factors, or related to seizure. An electroencephalogram is indicated if encephalitis, encephalopathy, or seizure disorder is suspected.

TOXIC ENCEPHALOPATHY

Toxic compounds are common causes of altered consciousness in children. More than 90% of poisonings in young children are accidental and involve a single substance. Many are prescription medications. Children in certain age groups are statistically at greater risk of being poisoned; 44% and 59% of all cases of poisonings reported to Poison Control Centers occur in children younger than 3 and 6 years of age, respectively. Of these ingestions, opioids, sedative-hypnotic, and cardiovascular medication ingestions are the most common. Intentional ingestions are far more common in adolescents. The clinician's index of suspicion should be dependent not only on the age of the patient but also on the history of the present illness; a poisoning should be suspected in a previously healthy child who presents with a sudden onset of unexplained symptoms (seizures, mental status changes, vomiting, hematemesis) or a gradual onset of symptoms preceded by a period of confusion or delirium. A correct diagnosis is usually established by integrating information from the history, physical examination, and ancillary tests and then identifying a toxidrome, a symptom complex associated with a given class of ingested drug. The most important aspects of the physical examination to identify a toxidrome are the level of consciousness, the pupillary examination, and the vital signs.

Level of Consciousness

Table 31.19 lists common agents responsible for different changes in mental status. Toxic exposures may also occur via routes other than the oral route; organophosphates may be absorbed through the skin, whereas other compounds, such as carbon monoxide, are inhaled.

Pupillary Examination

When the pupils are evaluated for size and reactivity, the presence of nystagmus should also be noted (Table 31.20). Most drugs cause

horizontal nystagmus; however, phenytoin may produce upbeat nystagmus, whereas phencyclidine may cause rotary nystagmus.

Vital Signs

Although fever is typically indicative of infection or a metabolic disturbance, such as the hemorrhagic shock and encephalopathy syndrome, many toxic compounds may induce **hyperthermia** (Table 31.21). The most common causes of fever in intoxicated children include anticholinergic compounds, antihistamines, salicylates, and sympathomimetic agents. **Hypothermia** may also be a sign of drug exposure (Table 31.22). Sedative-hypnotic agents, including ethanol, are common causes of hypothermia.

   Bradycardia or **tachycardia** may result directly from the autonomic effect of a drug or may be a reflex response to a change in blood pressure. Intoxication with a β blocker, calcium channel blocker, α_2-adrenergic agonist (clonidine), or cholinergic agonist (organophosphate) characteristically manifests with bradycardia with or without hypertension. In mild clonidine ingestions or in the early stage of clonidine intoxication, the patient may be hypertensive as a result of the partial α_1-agonist effect of the drug. Bradycardia may be a reflex response to the precipitation of hypertension by a vasoconstrictor agent, such as an ergotamine or an α-adrenergic agonist, such as phenylpropanolamine. On the other hand, a β-adrenergic agonist or anticholinergic agent intoxication usually manifests with tachycardia as part of the symptom complex. Intoxication with drugs that possess both α- and β-adrenergic agonist properties may manifest with both tachycardia and hypertension, whereas several classes of compounds may cause hypotension with a reflex tachycardia. Examples of the latter include direct vasodilators or α-adrenergic blockers (hydralazine, phenothiazines, tricyclic antidepressants) and compounds that cause 3rd-space fluid losses (acute iron intoxication). The anticholinergic properties of the phenothiazines and tricyclic antidepressants contribute to the tachycardia seen with these agents. Cholinergic compounds, such as organophosphates and carbamates, may cause tachycardia

Jaundice	Acetaminophen

instead of bradycardia because acetylcholine is the neurotransmitter found at nicotinic receptors in the sympathetic chain ganglion.

Tachypnea or hyperpnea may result from a central effect of a drug (salicylates, methylxanthines) or from a metabolic acidosis (salicylates, alcohols) in addition to structural CNS lesions or cardiopulmonary compromise. Slow or shallow breathing should always raise the suspicion of drug ingestion, particularly with CNS depressants, such as narcotics and sedative-hypnotics. Hypoventilation may also be a presenting symptom of a clonidine overdose as a result of its opiate-like effects. In addition, organophosphate or carbamate intoxications may manifest with hypoventilation as a primary symptom as a result of weakness of respiratory muscles.

Odors emanating from the breath or clothing may offer invaluable clues as to the diagnosis. Not only do certain metabolic diseases, such as diabetic ketoacidosis and hepatic failure, produce characteristic breath odors but so also do a number of chemical compounds, including cyanide (bitter almonds); isopropyl alcohol, methanol, salicylate (acetone); methyl salicylate (wintergreen); arsenic, thallium, organophosphates (garlic); and turpentine (violets). Inspection of the skin and mucous membranes may also be helpful (Table 31.23).

Although a single sign or symptom may be attributable to many classes of drugs, combinations of symptoms (toxidrome) enable the clinician to narrow down the number of possible agents. Sympathomimetic agents, anticholinergics, and tricyclic antidepressants all cause mydriasis and tachycardia. If these symptoms occur in a patient with a prolonged QRS interval on an electrocardiogram, the most likely cause is a tricyclic compound, whereas if the former symptoms occur

in a diaphoretic, tremulous patient, a sympathomimetic agent would be suspected. Table 31.24 outlines toxidromes of common classes of compounds ingested by children.

Management of most ingestions includes prevention of further absorption and supportive therapy. Activated charcoal is the preferred method for decreasing absorption of stomach contents. Gastric decontamination should be withheld if a nontoxic substance is ingested, if a nontoxic quantity of a toxic compound is ingested, if absorption is complete, or if a caustic agent is ingested. Under these circumstances, gastric decontamination carries risks but no benefits. Induction of emesis is contraindicated in patients with a depressed mental status or who are at risk for a sudden deterioration of their mental status.

Very few specific antidotes exist for substances that are ingested. If an antidote exists, its use depends on the patient's prognosis if it were not administered. For example, not all children require treatment with *N*-acetylcysteine after acetaminophen poisoning. If the patient is asymptomatic and has a serum acetaminophen concentration in a nontoxic range when plotted on the Rumack-Matthew nomogram, *N*-acetylcysteine therapy is not indicated. Table 31.25 is a partial list of available antidotes. Although not a true antidote, sodium bicarbonate is included as an antidote for salicylate and tricyclic antidepressant ingestions because its use can reduce symptoms by reducing tissue distribution of these compounds.

Some drugs lend themselves to procedures aimed at enhancing drug elimination from the body. These procedures include changing urinary pH (alkalinization to enhance salicylate excretion), using multiple doses of charcoal (theophylline, phenobarbital, carbamazepine), and performing extracorporeal drug removal (peritoneal or hemodialysis, charcoal hemoperfusion, exchange transfusion). Either patient-related or drug-related criteria should be met before the institution of extracorporeal drug removal (Table 31.26). When the management approach is not known, a resource such as a poison control center or a clinical pharmacologist should be consulted.

TRAUMA

Infants with head trauma may have evidence of intracranial hypertension: bulging fontanel, decerebrate posturing, and tachypnea. The clinical picture in a young infant may be confused with meningitis. In the absence of a febrile illness, trauma should be suspected, and the patient should be treated as if there is a rapidly progressive intracranial process.

Abusive head trauma, formerly referred to as shaken baby syndrome or nonaccidental trauma, describes a collection of abusive mechanisms that can result in pediatric neurotrauma. The 1st 2 years of life present a high risk period with an estimated incidence of 16-33 cases/100,000 children affected. Injury occurs by many different mechanisms including blunt force, acceleration/deceleration, penetrating trauma, or asphyxiation. Presenting symptoms can include lethargy (77%), respiratory depression or seizure (43-50%), developmental delay (12%), or nonspecific findings such as irritability, decreased oral intake, and vomiting (15%). The key to diagnosis is to maintain a high index of suspicion. In suspected cases of abusive trauma, utilizing a multidisciplinary care team including the primary physician, a child advocacy specialist, appropriate surgical providers (e.g., ophthalmology, neurosurgery, or orthopedic surgery) and social work can assist in making the correct diagnosis and treatment.

METABOLIC DISORDERS

Inborn errors of metabolism are complex and encompass many conditions. Table 31.27 is a partial list of inborn errors of metabolism that

(See *Nelson Textbook of Pediatrics,* p. 634.)

TABLE 31.24 Toxidromes of Common Classes of Drug

Drug Class	Level of Consciousness	Pupils	Vital Signs	Other
Sympathomimetics (amphetamines, cocaine, ephedrine, methylphenidate [Ritalin])	Agitation; psychosis	Dilated	↑ HR; ↑ BP; ↑ T	Tremors, sweating, arrhythmias; seizures
Anticholinergics (antihistamines, scopolamine, atropine, jimson weed, nightshade, phenothiazines, tricyclics)	Confusion; hallucinations	Dilated	↑ HR; ↑ T; ±↑ BP	Flushed; dry skin and mucous membranes; urinary retention; decreased bowel sounds
Opiates	Euphoria; coma	Pinpoint	↓ RR; ±↓ HR; ±↓ BP	Shallow respirations; dry mucous membranes
Cholinergic syndrome (organophosphates; carbamates, bethanechol, *Amanita* mushrooms)	Coma	Miosis	↓ or ↑ HR; ↓ or ↑ BP	Salivation, lacrimation, urination, defecation, bronchorrhea; muscle twitching before flaccidity; seizures
Sedative-hypnotics (alcohol, barbiturates, benzodiazepines)	Coma	± Miosis	↓ RR (shallow); hypothermia; ↓ BP	Ataxia; nystagmus; slurred speech
Neuroleptics (phenothiazines, butyrophenones)	Coma	Miosis (except thioridazine [Mellaril])	↑ HR; ↓ BP; ↓ or ↑ T	Dystonic reactions; ataxia; neuroleptic malignant syndrome; prolonged Q-T interval
Tricyclic antidepressants	Confusion; agitation; coma	Dilated	↑ HR; ↓ or ↓ BP; ↑ T; ↓ RR	Quinidine-like effect: prolonged QRS or Q-T interval and ventricular arrhythmias; seizures; anticholinergic effects (see above)
Salicylates	Disorientation; hyperexcitability; coma (severe)	—	↑ T; ↓ or ↑ RR + depth	Vomiting; tinnitus; metabolic acidosis; hypokalemia
Carbon monoxide	Lethargy; coma	—	—	Headache, nausea, flulike syndrome, dizziness, blurred vision
Theophylline	Agitation	—	↑ HR; ↓ BP; ±↑ RR; ± ↑ T	Protracted vomiting; tremors, seizures, arrhythmias
Phencyclidine	Delirium; combativeness; catatonia; coma	Miosis	—	Rotary nystagmus; seizures
SSRIs	Drowsiness; agitation; delirium; coma	Dilated or unreactive	↑ HR, ↑ T, ↓ BP	Nausea, vomiting, tremor, rigidity, myoclonus, hyperreflexia, diaphoresis

BP, blood pressure; HR, heart rate; RR, respiratory rate; SSRI, selective serotonin reuptake inhibitor; T, temperature.

TABLE 31.25 Specific Toxins and Their Antidotes

Toxin	Antidote	Toxin	Antidote
Acetaminophen	N-Acetylcysteine	Iron	Deferoxamine
Anticholinergics	Physostigmine	Lead	EDTA; dimercaprol; dimercaptosuccinic acid; penicillamine
Arsenic	Dimercaprol		
Benzodiazepines	Flumazenil	Mercury	Dimercaprol
β-Blockers	Glucagon*	Methanol	Ethanol or fomepizole
Calcium channel blockers†	Calcium	Narcotics	Naloxone
Carbamate insecticides	Atropine	Nitrites	Methylene blue
Carbon monoxide	Oxygen	Organophosphates	Atropine; pralidoxime
Cyanide	Amyl nitrite or sodium nitrate plus sodium thiosulfate	Phenothiazines‡	Diphenhydramine or benztropine
		Salicylates	Sodium bicarbonate
Digitalis	Digoxin-specific antibody fragments	Tricyclic antidepressants	Sodium bicarbonate
Ethylene glycol	Ethanol or fomepizole	Warfarin	Vitamin K
Heparin	Protamine		

*May reverse cardiac toxicity.
†Usually requires saline infusion as well for bradyarrhythmias or conduction abnormalities.
‡Dystonic reactions only.
EDTA, ethylenediaminetetraacetic acid.

TABLE 31.26 Indications for Extracorporeal Drug Removal*

Patient Related

Severe intoxication refractory to medical management (e.g., refractory seizures)

Impairment of normal excretion routes that may lead to prolonged intoxication

Drug Related

Ingestion and probable absorption of a potentially lethal dose determined after gut decontamination

Documentation of a potentially lethal drug level

Presence of a significant quantity of a compound that is metabolized to a toxic metabolite (e.g., methanol)

*Patient- and drug-related criteria for extracorporeal drug removal. Only 1 criterion needs to be met.

TABLE 31.27 Inborn Errors of Metabolism Manifesting with Seizures, Lethargy, and Coma in the Neonatal Period

Disorders of Carbohydrate Metabolism	Disorders of Amino Acid Metabolism	Organic Acidemias	Urea Cycle Defects	Lysosomal Storage Disorders	Other
Fructose-1,6-biphosphatase deficiency	Maple syrup urine disease	Methylmalonic acidemia	Carbamyl phosphate synthetase deficiency	Farber disease	Congenital adrenal hyperplasia
Galactosemia	Hypervalinemia	Propionic acidemia (ketotic hyperglycinemia)	Ornithine transcarbamylase deficiency	Fucosidosis	Hypophosphatasia
Hereditary fructose intolerance	Periodic hyperlysinemia	Isovaleric acidemia	Citrullinemia		Menkes kinky hair syndrome
Glycogen storage disease, types I and II	Hyper-β-alaninemia	3-Methylcrotonyl CoA carboxylase deficiency	Argininosuccinic aciduria		Hereditary orotic aciduria
Pyruvate carboxylase deficiency	Nonketotic hyperglycinemia	Multiple carboxylase deficiency			Fatty acyl-CoA dehydrogenase deficiencies
Phosphoenolpyruvate carboxykinase deficiency	Pyroglutamic aciduria	Multiple acyl-CoA dehydrogenase deficiencies			Primary systemic carnitine deficiency
	Hyperornithinemia-hyperammonemia-homocitrullinuria (HHH)	Hydroxymethylglutaryl (HMG)–CoA lyase deficiency			Zellweger syndrome
		2-Methyl-3-hydroxybutyric acidemia			Neonatal adrenoleukodystrophy
		D-Glyceric acidemia

may manifest in the neonate with lethargy, seizures, and coma. Many of these conditions relate to defective enzymes that lead to accumulation of a toxic product. Newborn screening has increased the number of infants diagnosed and effectively treated during the asymptomatic phase of a disease. The clinical manifestations of metabolic disease in the neonate can be nonspecific (Table 31.28). The infants are often thought to have sepsis and are evaluated and treated for presumptive infection. The presence of a documented infection does not preclude metabolic disease because some of these infants are prone to infection (e.g., galactosemia and *Escherichia coli* sepsis). A family history of a previous infant dying from an unexplained illness or other children in the family with neurologic disorders may provide clues to a metabolic cause. Laboratory abnormalities that may be seen in metabolic disease are listed in Table 31.29.

Infants with urea cycle defects often manifest altered mental status, coma (recurrent), and emesis. They cannot metabolize waste nitrogen to urea; this leads to accumulation of ammonia in the blood. These disorders are inherited as autosomal recessive traits, except for ornithine transcarbamylase deficiency, which is X-linked. The keys to the diagnosis of inborn errors of metabolism in the neonate are a high

degree of suspicion, the appropriate screening studies (see Table 31.29), and if the results are positive, a more detailed laboratory evaluation under the guidance of a specialist in metabolic diseases (Table 31.30).

Metabolic encephalopathy resulting from inborn errors of metabolism (partial, incomplete, stress, or fasting exacerbated) or from renal, hepatic, or toxic causes may also manifest in older children or adolescents. There may or may not be a family history or personal history of recurrent lethargy, emesis, repeated hospitalizations, or personality changes. Encephalopathy in older patients that results from endogenous substances (ammonia, organic acids, hypoglycemia, urea) or exogenous substances (opiates, barbiturates) may manifest within a wide range of symptoms (Table 31.31) and an electroencephalograph may be of added value.

SUMMARY AND RED FLAGS

Delirium and coma are common and potentially serious manifestations of a diverse group of life-threatening but potentially reversible disorders. Common causes vary by age, but toxic ingestion, trauma, seizures (postictal), infections, and metabolic disturbances, including inborn errors of metabolism, must be considered. Red flags include family or personal histories compatible with these disorders, signs of increased intracranial pressure, and rapidly progressive rostral-caudal deterioration.

Eye Disorders

Deborah M. Costakos

EYE AND VISUAL SYSTEM ANATOMY

The anatomies of the eye and visual system are shown in Figs. 32.1 and 32.2. The optic nerves, made up of the converging nerve fiber layer of the retina, have intraocular, intraorbital, intracanalicular, and intracranial portions. Partial decussation of the optic nerve fibers occurs in the chiasm, which gives binocular visual input to each side of the brain. The visual cortex is where the conscious process of seeing occurs.

DEVELOPMENT OF THE EYE AND VISUAL SYSTEM

The eyes and vision of a newborn are immature and require several years to reach adult proportions and functional status. By the 9th month of gestation, the retinal vessels have reached the periphery of the retina (an important factor in the pathogenesis of retinopathy of prematurity [ROP]), the optic nerve has completed myelination, and the pupillary membrane has disappeared. Postnatal reorganization of neuron-to-neuron connections in the visual cortex improve the poor visual acuity and other visual processes, which are not fully developed at birth. The visual acuity of the newborn has been estimated to be 20/400-20/600 and may reach the normal 20/20 level as early as 6-12 months of age as tested with visual evoked cortical responses. Acuity of 20/20 is not reached with other types of testing such as preferential looking with Teller acuity cards until ages 3-5 years. Visual acuity measured with conventional letter or symbol recognition methods does not reach 20/20 until 6 years of age because of cognitive factors. Binocular vision, including establishment of normal ocular alignment and depth perception, and improved facility of accommodation, the ability to focus on images at different distances, develop rapidly in the 1st year of life. The rapid maturation of visual function in the 1st year of life accounts for the critical period of visual development and the extreme sensitivity of the visual system to abnormal visual input from strabismus or cataracts. Children deprived of vision in this critical period will have limited visual potential and may develop nystagmus (abnormal eye movements).

The majority of newborns are moderately hyperopic. Heredity contributes to the refractive status of the eyes and the environment and visual experience also plays a role.

AMBLYOPIA AND VISION SCREENING

Amblyopia is defined as a unilateral or, less commonly, bilateral reduction in visual acuity that cannot be immediately corrected with glasses or surgery. In children in whom visual acuity can be accurately measured, a practical definition of amblyopia is a 2-line or greater difference between the best-corrected visual acuity of the eyes. For preverbal children, differences between the eyes in fixation and following behavior or fixation preference are used to diagnose amblyopia. Automated photoscreeners can aid in the diagnosis of risk factors for amblyopia and strabismus, particularly in preverbal children who perform poorly on subjective testing. Amblyopia results from abnormal visual experience early in life during the critical period for visual development. The sensitive period for amblyopia starts in early infancy and continues to at least the age of 6 years and often beyond the age of 8 years. There is a suggestion of cortical plasticity in adults that may allow for some vision improvement into adulthood. The prevalence of amblyopia in the North American population is 2-4%.

Unilateral amblyopia results from 3 types of abnormal visual experience: strabismus, anisometropia (unequal refractive errors), and monocular visual deprivation (e.g., cataract, corneal opacity, hemangioma (severe ptosis). **Bilateral amblyopia** results from bilateral media opacities or significant bilateral refractive errors (ametropia). Nearly all amblyopia is reversible if discovered at an early age and treated appropriately. Treatment effectiveness, however, declines after the age of 5 years.

Detection strategies for amblyopia can involve early recognition of factors that give rise to amblyopia or actual measurement of reduced visual acuity that may be caused by amblyopia. Most amblyopia risk factors can be detected through routine pediatric screening such as ocular history, red reflex evaluation, ocular motility, and vision assessment. Recommended screening and referral guidelines are shown in Table 32.1. Whenever possible, a line of symbols or isolated symbols with surrounding crowding bars is recommended for screening (Fig. 32.3). Isolated symbols can lead to overestimates of the visual acuity of an eye with amblyopia due to a crowding phenomenon or contour interaction in which symbols of a given size are more difficult to recognize if they are surrounded by similar symbols. Hence, visual acuity obtained with single optotypes without crowding bars can result in failure to detect amblyopia.

The treatment of amblyopia involves eliminating amblyopia risk factors, providing a focused retinal image with appropriate optical correction, and forcing use of the amblyopic eye through occlusion of the sound eye or blurring the image it receives. For patients with visual deprivation amblyopia, the depriving factor must be addressed medically or surgically. Optical correction including a bifocal is required for patients who have had cataract surgery. Intraocular implants are not generally placed in children under 1 year of age due to the high postoperative complication rates. For patients with anisometropic amblyopia, optical correction usually involves spectacles or, less commonly, contact lenses.

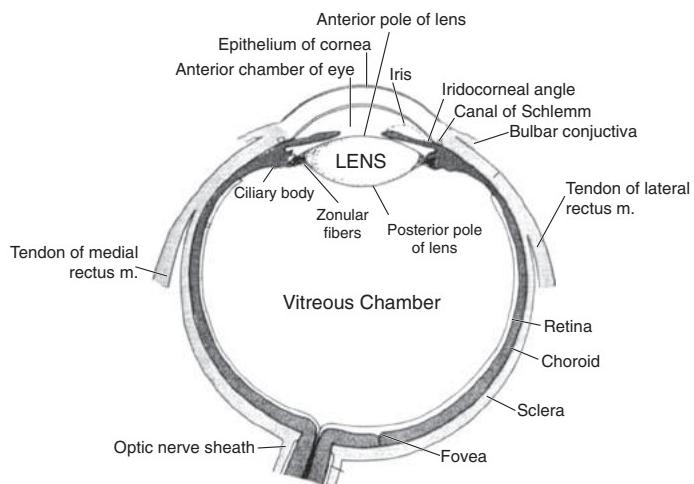
An adhesive patch worn over the sound eye most commonly achieves enforced use of the amblyopic eye. Occlusive devices can be


FIGURE 32.1 Anatomy of the eye as seen in cross section. (Modified from Reilly BM. *Practical Strategies in Outpatient Medicine*. 2nd ed. Philadelphia: WB Saunders; 1991:36.)

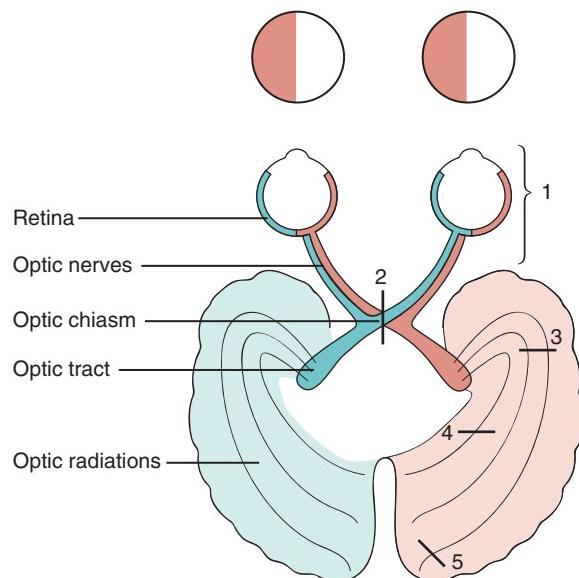
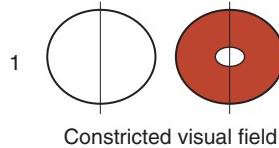
attached to glasses but may be less reliable since the child can peek over the glasses or around the occlusive device. The use of the potent cycloplegic agent atropine sulfate may also be used to encourage use of the amblyopic eye. A drop of atropine is applied to the sound eye each day; this temporarily impairs its accommodative ability and, in the presence of sufficient hyperopia, prevents that eye from obtaining a clear retinal image. Atropine "penalization" for amblyopia works best in hyperopic patients with mild to moderate amblyopia (visual acuity of 20/100 or better). Close follow-up of patients being treated for amblyopia is important for monitoring compliance with treatment and for preventing the development of iatrogenic reverse amblyopia in the sound eye from excessive occlusion or penalization.

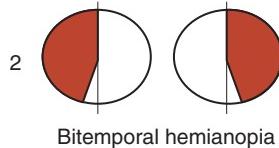
VISUAL FIELDS

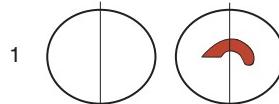
Quantitative testing of the visual field of most children is difficult before the age of 10 years (see Fig. 32.2). Confrontation field tests can be performed to detect gross abnormalities of the visual field (hemianopsias) but even these are not reliable and need to be confirmed at an older age. Visual field defects in children are uncommon despite parental concerns about a child who seems to bump into objects frequently. Unilateral retinal or optic nerve disease can produce unilateral visual field defects, but these are almost always associated with reduced visual acuity in the involved eye. Bilateral visual field defects, particularly if symmetric (homonymous), indicate disease of the optic radiations or visual cortex. Visual acuity may be entirely normal. Causes of bilateral visual field defects in children include cerebrovascular accidents, pituitary or hypothalamic tumors, or congenital central nervous system (CNS) abnormalities.

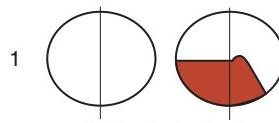
STRABISMUS

Strabismus is derived from the Greek word *strabismos*, "to squint to look obliquely or askance." It implies misalignment of the eyes in such a way that they are not simultaneously viewing the same object. Terms to describe eye alignment and movement are noted in Table 32.2. Strabismus can be constant or intermittent and can be the same in all directions of gaze (comitant) or greater in 1 direction of gaze than in others (incomitant). Furthermore, it can be categorized as congenital or acquired, monocular or alternating. The direction of misalignment










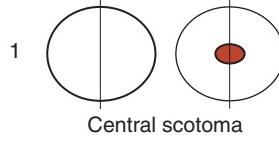


FIGURE 32.2 Anatomy of the visual pathways. The anatomy of the visual pathways appears at the top of the figure, the *pink shading* indicating how visual information from the left visual space eventually courses to the right brain. Visual field defects are at the bottom of the figure. Anterior defects (labeled *1* from disease of the optic nerve or retina) characteristically affect 1 eye and cause defects *(red shading)* that may cross the vertical meridian (i.e., the vertical meridian is the vertical line bisecting each visual field). Chiasmal defects (labeled *2*) and postchiasmal defects (labeled *3* for a lesion in the anterior temporal lobe, *4* for the parietal lobe, and *5* for the occipital cortex) characteristically affect both eyes and respect the vertical meridian. (Modified from McGee S. *Evidence-Based Physical Diagnosis*. 3rd ed. Philadelphia: Elsevier; 2012:514.)

TABLE 32.1	**Vision Screening Recommendations**	
Age	**Tests**	**Referral Criteria Comments**
Newborn to 12 mo	• Ocular history • Vision assessment • External inspection of the eyes and lids • Ocular motility assessment • Pupil examination • Red reflex examination	• Refer infants who do not track well after 3 mo of age. • Refer infants with an abnormal red reflex or history of retinoblastoma in a parent or sibling.
12-36 mo	• Ocular history • Vision assessment • External inspection of the eyes and lids • Ocular motility assessment • Pupil examination • Red reflex examination • Visual acuity testing • Objective screening device "photoscreening" • Ophthalmoscopy	• Refer infants with strabismus. • Refer infants with chronic tearing or discharge. • Refer children who fail photoscreening.
36 mo to 5 yr	• Ocular History • Vision assessment • External inspection of the eyes and lids • Ocular motility assessment • Pupil examination • Red reflex examination • Visual acuity testing (preferred) or photoscreening • Ophthalmoscopy	• Visual acuity thresholds • Ages 36-47 mo: Must correctly identify the majority of the optotypes on the 20/50 line to pass. • Ages 48-59 mo: Must correctly identify the majority of the optotypes on the 20/40 line to pass. • Refer children who fail photoscreening.
5 yr and older* *Repeat screening every 1-2 yr after the age of 5 yr	• Ocular history • Vision assessment • External inspection of the eyes and lids • Ocular motility assessment • Pupil examination • Red reflex examination • Visual acuity testing • Ophthalmoscopy	• Refer children who cannot read at least 20/30 with either eye. Must be able to identify the majority of the optotypes on the 20/30 line. • Refer children not reading at grade level.

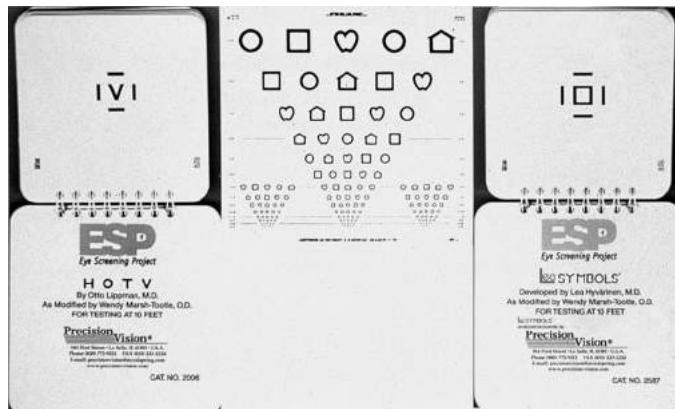
From American Academy of Pediatric Ophthalmology and Strabismus techniques for Pediatric Vision Screening. May, 2014.


FIGURE 32.3 The Lea symbols in chart format *(middle)* and the Lea symbols and HOTV tests with crowding bars *(right and left)*. All tests should be administered at a distance of 10 feet.

can be vertical or horizontal. Vertical strabismus is referred to as a hypertropia of the higher eye. Horizontal strabismus can be convergent (esotropia) or divergent (exotropia). The importance of strabismus detection derives primarily from the fact that it is the leading cause of amblyopia. Other reasons for detecting strabismus are the possibility of being able to restore normal binocular use of the eyes, improving depth perception, and minimizing the social and economic drawbacks to strabismus in society.

Strabismus detection can be simple, as in patients with a large angle of deviation (Fig. 32.4), or difficult, as in patients with more subtle deviations or no deviation at all (pseudostrabismus) (Fig. 32.5). Evaluation of the symmetry of the corneal light reflexes from a penlight directed at the eyes can reliably detect many cases (see Fig. 32.4). With smaller angles of strabismus or when the results of the corneal light reflex are in doubt, the cover test should be performed (Fig. 32.6). It is important to provide attractive fixation targets for the child to view during the test.

Infantile esotropia is defined as convergent strabismus with onset within the 1st 6 months of life (see Fig. 32.4). Transient crossing or divergence of the eyes is common in newborns and is probably not significant unless it persists beyond 3 months of age. In the classic form of infantile esotropia, there is a large-angle, constant deviation. The child may alternate fixation (cross fixate) in which case the visual acuity is usually good in both eyes. Cross fixation may mimic bilateral 6th nerve palsy. If the crossing is present in only 1 eye, amblyopia occurs. The cause of infantile esotropia is not known, but hereditary factors play a definite role. The incidence of infantile esotropia is less than 1% among neurologically normal infants.

Early correction of infantile esotropia may result in full or nearly full restoration of normal binocular function, a result not believed to be obtainable with correction of misalignment at older ages. The ideal

FIGURE 32.4 Corneal light reflex test reveals an asymmetrically placed reflex that is laterally displaced in the right eye. This indicates an inward deviation of the eye (esotropia). (From Lavrich JB, Nelson LB. Diagnosis and treatment of strabismus disorders. *Pediatr Clin North Am.* 1993;40:739.)

timing of surgery for infantile esotropia is not known, although usually done between 6 and 24 months to optimize binocularity. However when early surgery is done, there is a higher chance of needing further surgery. Early detection and prompt referral of infants with suspected esotropia are indicated.

A second category of esotropia occurs in children whose eyes are initially straight but start to cross, usually intermittently at first, at 1-3

FIGURE 32.5 A child with pseudoesotropia. Note that the wide nasal bridge and prominent epicanthal folds create the illusion of an esotropia. The corneal light reflexes are centered in each eye; therefore, the eyes are straight. (From Lavrich JB, Nelson LB. Diagnosis and treatment of strabismus disorders. *Pediatr Clin North Am.* 1993;40:741.)

years of age. These children have excessive hyperopia and an abnormal relationship between accommodation and convergence. This type of esotropia is called **accommodative esotropia**. Amblyopia frequently develops. Treatment consists of correcting amblyopia and providing spectacles to correct hyperopia, thereby modulating the amount of accommodation required by the child (Fig. 32.7). Bifocal spectacles may also be necessary for some forms of accommodative esotropia.

Esotropia caused by paralysis of a lateral rectus muscle, a 6th cranial nerve palsy, occurs much more frequently in children than in infancy (Fig. 32.8). Approximately 30% of children will have an intracranial lesion. Other causes include head trauma or a recent viral illness. The 6th nerve palsy may resolve spontaneously if the cause is benign. An older child may present with complaints of diplopia or a face turn or closure of 1 eye to avoid diplopia, whereas a younger child may present with only the esotropia because of rapid development of suppression to eliminate diplopia. Neurologic investigation is indicated if the history does not support a benign etiology or the paralysis does not spontaneously abate in a few weeks (a so-called benign 6th nerve palsy believed to be postviral in origin) or if the child demonstrates other neurologic impairment or has papilledema.

Infantile exotropia is much less common than infantile esotropia. Infantile exotropia presents as a large deviation of the eyes prior to 6 months of age. Infantile exotropia is uncommon in otherwise healthy infants. It is, however, commonly associated with craniofacial disorders or neurologic impairment. Surgery may be done early in life, but these patients are less likely to obtain good binocular vision than infantile esotropes.

Intermittent exotropia is the most common type of exotropia. This usually manifests by 5 years of age. Parents will notice that the eyes deviate out at times and yet not at others. The deviation is most likely to occur when the child is tired or ill. Because the child maintains the ability to keep the eyes aligned part of the time, amblyopia is uncommon. Diplopia is prevented by active cortical suppression of input from the portion of the retina of the deviated eye that overlaps the central view of the fixating eye. When the eyes are straight, the child generally maintains normal binocular function, including stereopsis. The clinical management of intermittent exotropia is not clear. Treatment options include part-time patching, additional minus power spectacles in patients with myopia, orthoptic exercises, and surgery.

Primary vertical strabismus is far less common than horizontal strabismus. A small vertical deviation in association with a larger amount of horizontal strabismus, however, is common, and is managed in conjunction with the horizontal deviation. A common cause of

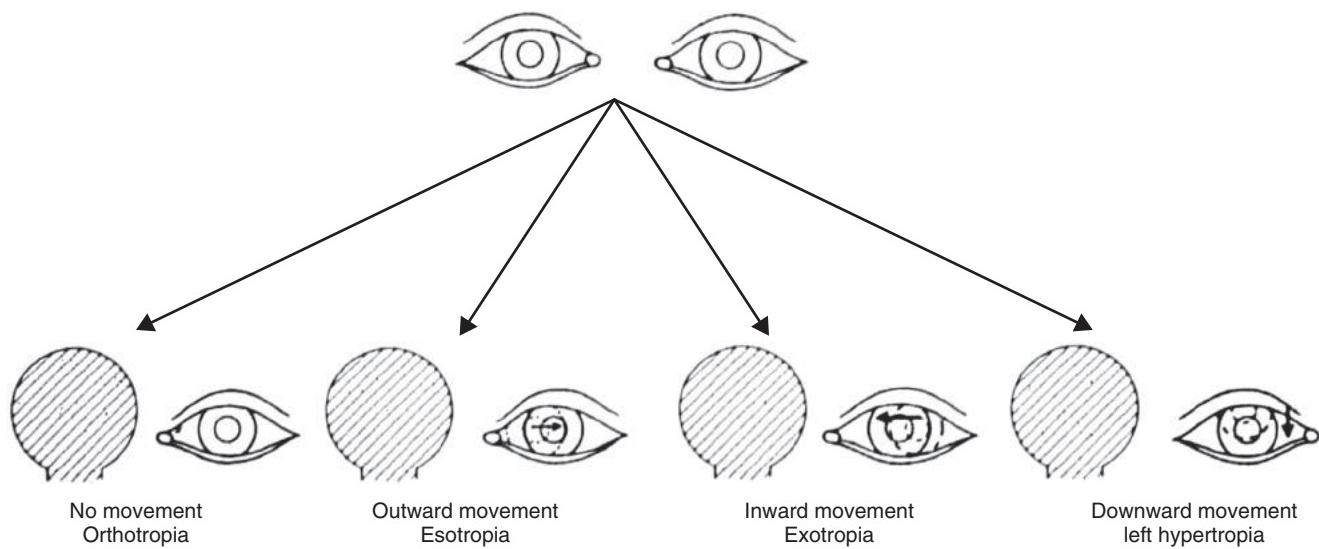
No movement   Outward movement   Inward movement   Downward movement
Orthotropia   Esotropia   Exotropia   left hypertropia


FIGURE 32.6 The cover test. In each instance, the occluder is placed over the right eye while the patient is viewing a fixation target and the examiner is watching for movement of the patient's left eye. If the left eye is not aligned, it will need to move to look at the fixation target. If there is no movement of the left eye, the test needs to be repeated by occluding the left eye and watching for movement of the right eye.
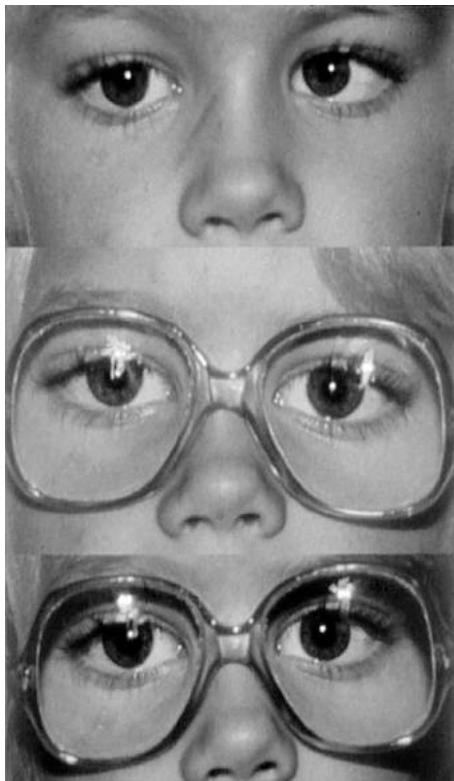

FIGURE 32.7 Accommodative esotropia *(top)*. The deviation is completely controlled with glasses at both distant *(middle)* and near *(bottom)* fixation distances.
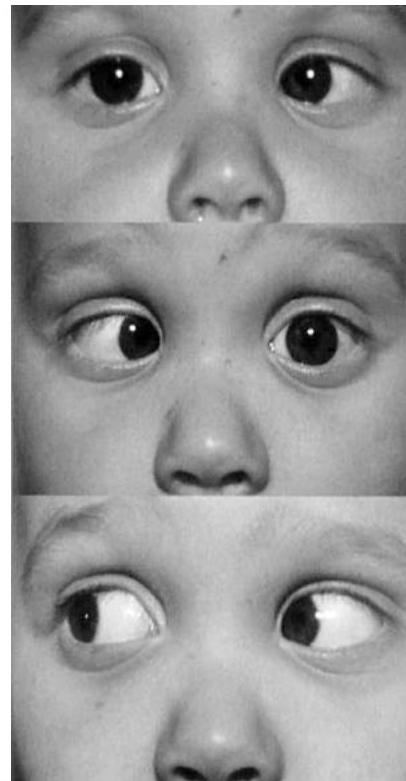

FIGURE 32.8 Left 6th cranial nerve palsy in a 4-year-old. A large manifest esotropia is present when the child looks straight ahead *(top)*. The left eye does not abduct beyond the midline in gaze to the left *(middle)*. Gaze to the right is normal *(bottom)*.

hypertropia in children is congenital paralysis of the superior oblique muscle, a 4th cranial nerve paralysis. In some children, the "paralysis" is actually caused by an anatomic abnormality of the superior oblique tendon. Acquired causes of a superior oblique palsy include trauma, central nervous system abnormalities, or brain tumors. Children with a superior oblique paralysis of any cause frequently present with a head tilt and face turn toward the side opposite the paralyzed superior oblique muscle. If there is a question as to the timing of the onset of the superior oblique palsy, a review of pictures at a younger age may be helpful in determining chronicity. Superior oblique paralysis is 1 of the more common causes of ocular torticollis. An eye muscle disorder needs to be ruled out in any child with a chronic abnormality of head position. The anomalous head position and hypertropia caused by a superior oblique paralysis can be improved by eye muscle surgery in most instances. An approach to the evaluation of strabismus is noted in Fig. 32.9 and less common forms of strabismus are listed in Table 32.3.

REFRACTIVE ERRORS

Refractive errors include myopia (nearsightedness), hyperopia (farsightedness), and astigmatism. Refractive errors may be similar (isometropia) or different (anisometropia) between the 2 eyes. Bilateral amblyopia may result from a high refractive error that is isometropic. Full-time spectacle correction will often correct bilateral amblyopia. Unilateral amblyopia may result from anisometropia. Patching or atropine penalization may be necessary in these children.

Myopia

In patients with myopia, the parallel rays of light in the resting (nonaccommodating) eye are focused in front of the retina. The symptoms of myopia are squinting, holding or viewing an object more closely than normal, and complaining of blurred far vision.

The incidence and degree of myopia increase with age, especially during growth spurts, as in adolescence. There is a complex interaction between genetic and environmental factors in the development of myopia. The incidence of myopia varies with ethnicity and geographic regions and has been increasing in prevalence over the past 50 years. There have been several genetic markers linked to myopia but the increasing frequency among younger generations suggests environment plays an important role. The increase in prevalence from 10-90% in some populations is a public health concern, particularly with high myopia. Myopia can be associated with increased risk of retinal detachment, early cataract, and glaucoma. In very high myopia there can be thinning of the retina and retinal degeneration. This can result in decreased vision even with spectacle or contact lens correction.

Myopia may be associated with other ocular abnormalities, such as keratoconus (central conical protrusion of the cornea), cataracts, ectopia lentis (dislocated lens), spherophakia (overly spherical lens), glaucoma, and medullated (myelinated) nerve fibers. There is an increased prevalence of myopia in premature infants, especially with ROP. Children with high degrees of myopia may have an underlying systemic association, such as Marfan, Stickler, Noonan, or Down syndromes. If myopia is sufficient to produce visual symptoms, spherical concave (minus) lenses in the form of spectacles or contact lenses are prescribed to correct the refractive error. Prescription changes may be needed every 1-2 years and more often during growth spurts.

Hyperopia

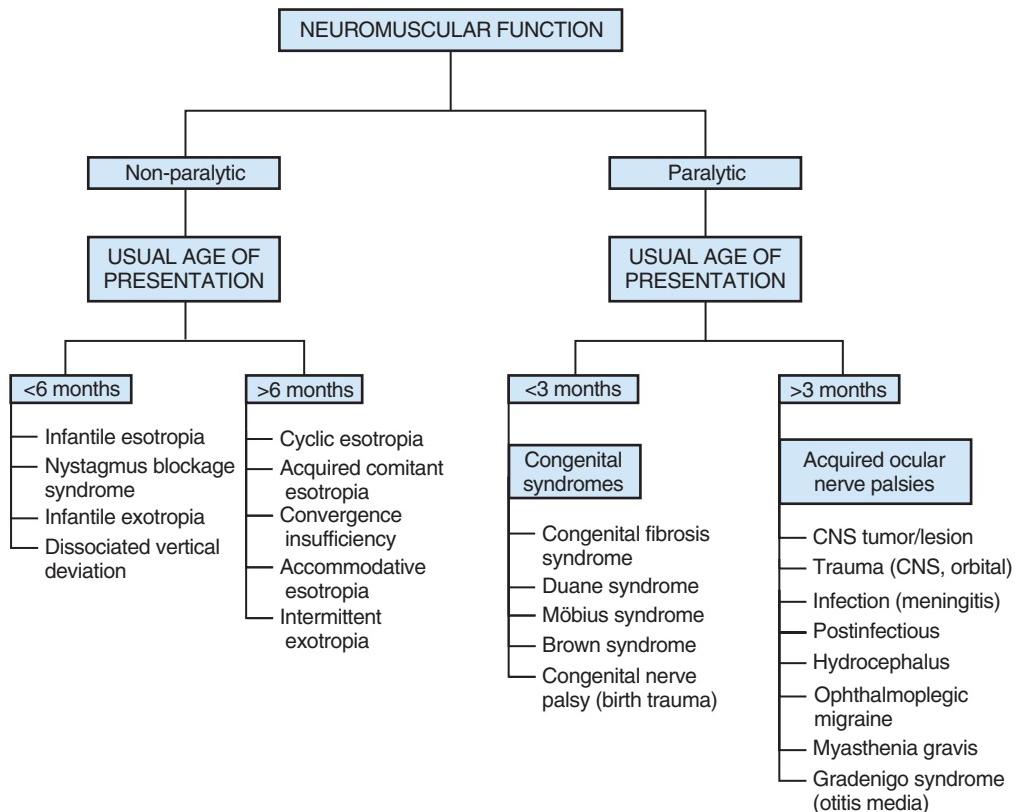
In patients with hyperopia (farsightedness), parallel rays of light in the nonaccommodating eye would, if possible, be focused behind the


FIGURE 32.9 Evaluation of strabismus. CNS, central nervous system.

TABLE 32.3	Less Common Forms of Strabismus		
Type of Strabismus	**Presenting Symptoms and Signs**	**Cause**	**Treatment**
Duane syndrome	Esotropia with deficient abduction or exotropia with deficient adduction of 1 eye; head turn	Absence of 6th nerve nucleus and aberrant innervation of lateral rectus muscle from 3rd cranial nerve	Strabismus surgery for correction of large deviations or abnormal head position
Dissociated vertical deviation	One eye turns up intermittently, especially with fatigue	Eye movement abnormality related most commonly to congenital esotropia	Eye muscle surgery on superior rectus and inferior oblique muscles
Brown syndrome	Head tilt; inability to elevate eye in adduction	Restriction of free passage of superior oblique tendon through trochlea	Observation if not severe; superior oblique tendon surgery if severe
Möbius syndrome	Masklike facies; inability to abduct both eyes; difficulty closing eyes	Bilateral 6th and 7th nerve palsies	Protect corneas from exposure; strabismus surgery
Congenital fibrosis syndrome	Chin-up head position; inability to elevate eyes; ptosis	Autosomal dominant gene on chromosome 16 in some patients; superior division of 3rd nerve in others	Surgical release of tight extraocular muscles
3rd nerve palsy	Exotropia and hypertropia; ptosis; dilated, nonreactive pupil	Congenital absence of 3rd nerve; trauma; or tumor	Ptosis and strabismus surgery
Double elevator palsy	Chin-up head posture; inability to elevate 1 eye	Paresis of superior rectus muscle	Transposition strabismus surgery
Orbital floor fracture	Vertical diplopia; chin-up head position	Entrapment of orbital tissues in fracture	Repair of floor fracture; release of inferior rectus muscle restriction
Myasthenia	Variable ptosis and eye movement abnormalities	Blockage of acetylcholine receptor sites by immune complexes	Treatment of systematic myasthenia; strabismus surgery if patient is stable

retina. The process of accommodation (focusing), which alters the shape of the lens, can compensate for some degrees of hyperopia. Because most children have a tremendous range of accommodation, mildly hyperopic children can see clearly without any visual symptoms. Moderate to severely hyperopic children may be unable to fully compensate through accommodation. The greater accommodative effort may lead to symptoms of "eyestrain," which consist of headaches, fatigue, or eye rubbing. These symptoms may lead to a lack of interest in reading or in prolonged close work. Some children may also develop accommodative esotropia. Some children have a decreased ability to accommodate, or accommodative insufficiency, and are symptomatic even with low degrees of hyperopia. If hyperopia produces symptoms or causes esotropia, spherical convex (plus) lenses usually in the form of glasses are prescribed to correct the refractive error.

Astigmatism

In the patient with astigmatism, the refractive power differs in various meridians of the eye. In most cases, astigmatism is caused by abnormal curvature of the cornea; in rare cases, lens abnormalities may cause astigmatism. Infants and children with corneal distortion secondary to scarring (trauma or infection) or to external compression (ptosis or hemangioma of eyelid) are at an increased risk for astigmatism. Moderate levels of astigmatism may produce blurring of vision (far and near), leading to squinting, fatigue, headaches, and lack of interest in close-up work in older children and amblyopia in younger children. Cylindric or spherocylindric lenses (usually glasses) are used to improve vision and comfort.

Anisometropia

In patients with anisometropia, the refractive error of 1 eye differs significantly from that of the other eye. The difference in refraction can be spherical (hyperopia or myopia) or cylindric (unequal amounts of astigmatism). Mild degrees of anisometropia usually cause no visual symptoms and do not lead to amblyopia. Amblyopia develops with higher degrees of anisometropia because the child uses the less ametropic eye and suppresses vision in the other. Strabismus frequently coexists with anisometropia, and both conditions may be involved in the pathophysiologic mechanisms of amblyopia. Anisometropia may initially be detected by comparison of the red reflex between the 2 eyes (Brückner test). The affected eye has the duller red reflex. Early detection and treatment of anisometropia are essential for the development of optimal visual function.

VISION IMPAIRMENT IN CHILDREN

Vision impairment is formally defined as best-corrected visual acuity of 20/70 or worse in both eyes. Impairment of vision exists as a continuum from 20/70 to no light perception. Unrestricted driver's license has a requirement of best-corrected vision of 20/40 or better in 1 eye in all but 3 states (New Jersey and Wyoming have a requirement of 20/50 best-corrected vision in 1 eye and Georgia has a requirement of 20/60 best-corrected or better in 1 eye). Legal blindness is said to be present when best-corrected visual acuity is 20/200 or less in each eye. Constricted visual fields may also play a role in the diagnosis of vision impairment or legal blindness. An infant or child whose visual acuity and visual field cannot be quantitated may be judged visually impaired on the basis of inability to fixate on and follow movement of the examiner's face or other objects or even, in severe instances, inability to perceive light. Milder vision impairment may be suspected on the basis of associated eye signs but can be difficult to confirm in a preverbal child because of compensatory behavior (holding objects close, a face turn) that allows the child to have relatively normal overall function and development. Observation of the child's behavior in the examination room, examination of the eyes (Table 32.4), and a detailed history (Table 32.5) taken from the parents about the child's visual behavior at home can be important in establishing the degree of impairment. Many visually impaired infants and children have objective signs such as nystagmus, sluggish pupillary light reflexes, or

TABLE 32.4 Red Flags in Inspection and Direct Ophthalmoscopy in Evaluating Visual Impairment

Physical Findings	Possible Pathologic Process
Inspection	
Globe	
Small	High hyperopia, persistent hyperplastic primary vitreous, phthisis bulbi (shrinkage related to deteriorating eye disease)
Large	Glaucoma, high myopia
Red eye	Inflammatory disease (infection, uveitis), trauma, tumor, glaucoma
Protrusion	Retrobulbar or orbital infection/tumor, hyperthyroidism
Sunken	Orbital fracture, Horner syndrome, atrophy, microphthalmia
Misalignment	Impairment of extraocular muscles: congenital weakness, muscle entrapment (tumor/trauma), cranial nerve palsy (infection, tumor, stroke, congenital)
Ophthalmoscopy	
Cloudy cornea	Anterior segment dysgenesis (Peter anomaly), glaucoma, trauma, infection, metabolic storage diseases (mucopolysaccharidoses)
Lens	
Cloudy	Cataracts (congenital vs systemic diseases)
Dislocated	Homocystinuria, Marfan syndrome
Cloudy vitreous	Retinoblastoma, detached retina, endophthalmitis, uveitis, hemorrhage
Optic disk	
Pale	Optic atrophy (congenital, trauma, tumor, hydrocephalus, degenerative neurologic disease)
Swollen	Increased intracranial pressure, optic neuritis
Hemorrhage	Optic neuritis, increased intracranial pressure
Retina/choroid	
Abnormal color	Retinitis pigmentosa (spicule pattern), chorioretinitis (atrophy with hyperpigmentation), Tay–Sachs disease (cherry-red macula)
Exudates	Diabetes mellitus, Coats disease, increased intracranial pressure
Hemorrhage	Hypertension, diabetes mellitus, increased intracranial pressure, trauma, blood disorders
Phakomata	Tuberous sclerosis (yellow plaques, nodules), von Hippel–Lindau disease (reddish globular mass), Sturge–Weber syndrome (choroidal hemangioma), neurofibromatosis (yellow plaques)
Blood vessels	
Constricted	Hypertension
Microaneurysm	Diabetes mellitus

TABLE 32.5 Red Flags in History for Visual Impairment

Manifestation	Possible Pathologic Process
Child's Complaint	
Generalized blurred vision	
Far vision only	Myopia
Near vision only	Hyperopia, disorder of accommodation
Both far and near	Astigmatism or defect of visual pathways
Focal blurred vision (veil, shadow)	
Unilateral	Ipsilateral retinal or optic nerve
Bilateral	Chiasmal, postchiasmal, or bilateral prechiasmal lesion
Ghost/double vision	
With binocular vision	Cranial nerve or extraocular muscle
With monocular vision	Ocular media or macular disease
Changes in special visions	
Poorer color vision	Retinal or optic nerve disease
Poorer night vision	Retinal disease (retinitis pigmentosa)
Visual sensations	
Floaters, spots	Uveitis, retinal detachment, or hemorrhage
Shimmering lines or scotoma	Migraines
Visual hallucinations	Cerebral lesion, psychogenic
Parents' Observations	
Age-appropriate infant does not track	Severe ocular (myopia, cataracts) or systemic (meningitis) pathologic process
Objects viewed too closely	Decreased visual acuity related to refractive error; ocular or neurologic disorder
Squinting	Decreased visual acuity related to refractive error; ocular or neurologic disorder
Roving or wandering eyes	Nystagmus or strabismus; rule out ocular or neurologic disorder
Head tilting	Compensatory posturing for nystagmus, strabismus, astigmatism, or visual field defect
Bumping into objects	Visual field defect, decreased visual acuity
Reading problems	Visual impairment, visual processing disorder

anatomic abnormalities such as optic nerve hypoplasia or chorioretinal scarring.

Visual inattentiveness in an infant deserves special attention because of the possibility that the child has a treatable but not obvious form of vision impairment such as bilateral congenital cataracts. Even if the cause of impairment is not remediable, early diagnosis is important for referral of the infant for physical and occupational therapy for visual impairment since these children have very specific needs. Vision impairment (monocular or binocular) acquired after infancy obligates the physician to search for a cause such as a retinal degeneration because some causes are treatable (Tables 32.6 to 32.8).

TABLE 32.6 Childhood Amaurosis (Blindness): Principal Neurologic Considerations

Congenital Malformations
Optic nerve hypoplasia
Congenital hydrocephalus
Hydranencephaly
Porencephaly
Microencephaly
Encephalocele, particularly occipital type

Phakomatoses
Tuberous sclerosis
Neurofibromatosis (special association with optic glioma)
Sturge–Weber syndrome
von Hippel–Lindau disease

Tumors
Retinoblastoma
Optic glioma
Perioptic meningioma
Craniopharyngioma
Cerebral glioma
Posterior and intraventricular tumors when complicated by hydrocephalus

Neurodegenerative Diseases
Cerebral storage disease
Gangliosidoses, particularly Tay–Sachs disease (infantile amaurotic familial idiocy), Sandhoff variant, generalized gangliosidosis
Other lipidoses and ceroid lipofuscinoses, particularly the late-onset amaurotic familial idiocies such as those of Jansky–Bielschowsky and of Batten–Mayou–Spielmeyer–Vogt
Mucopolysaccharidoses, particularly Hurler syndrome and Hunter syndrome
Leukodystrophies (dysmyelination disorders), particularly metachromatic leukodystrophy and Canavan disease
Demyelinating sclerosis (myelinoclastic diseases), especially Schilder disease and Devic neuromyelitis optica
Special types: Dawson disease, Leigh disease, Bassen–Kornzweig syndrome, Refsum disease
Retinal degenerations: "retinitis pigmentosa" and its variants, and Leber congenital type
Optic atrophies: congenital autosomal recessive type, infantile and congenital autosomal dominant types,
Leber disease, and atrophies associated with hereditary ataxias: the types of Behr, of Marie, and of Sanger–Brown

Infectious Processes
Encephalitis, especially in the prenatal infection syndromes due to *Toxoplasma gondii,* cytomegalovirus, rubella virus, *Treponema pallidum*
Meningitis; arachnoiditis
Optic neuritis
Chorioretinitis

Hematologic Disorders
Leukemia with central nervous system involvement

Vascular and Circulatory Disorders
Collagen vascular diseases
Arteriovenous malformations: intracerebral hemorrhage, subarachnoid hemorrhage

Trauma
Contusion or avulsion of optic nerves or chiasm
Cerebral contusion or laceration
Intracerebral, subarachnoid, or subdural hemorrhage

Drugs and Toxins

RETINOPATHY OF PREMATURITY

Premature infants are at risk for the development of ROP because the retinal vessels have not yet grown out to the periphery of the retina and are susceptible to a variety of postnatal influences, including oxygen that can adversely affect retinal vessel maturation. In advanced stages of ROP, retinal neovascularization and fibrosis may lead to traction on the retina and result in a retinal detachment, the most common cause of blindness in premature infants. In most cases fortunately, ROP spontaneously resolves.

The international classification system for the acute stages of ROP describes the location, extent, and stage of the disease according to the position of the advancing wave of retinal vessels (Fig. 32.10). The retina is divided into zones I, II, and III. Zone I is centered on the optic nerve, from which the retinal arterioles emerge, and zone III exists as a crescent of retina on the temporal side; zone II occupies the midportion of the retina in all 4 quadrants. The severity is indicated by stages 1-5 with stage 1 representing mild ROP and stage 5 representing a total retinal detachment.

The management of ROP begins with a systematic program of eye examinations at well-defined times in infants judged to be at risk for developing ROP. The frequency of examinations is dependent on the findings and progression of the disease. Infants with a birth weight of less than 1500 g are 1st examined 4-6 weeks after birth. Follow-up examinations are performed at regular intervals until the retina is fully vascularized. If treatment is required laser ablation of immature retina or intravitreal injections of anti-vascular endothelial growth factor (VEGF) medication such as bevacizumab are options. The choice of treatment depends on the zone and the rate of progression of disease. Insulin-like growth factor (IGF)-1 supplementation or alterations may be a means to prevent ROP in the future.

LEUKOCORIA AND RETINOBLASTOMA

Leukocoria or "white pupil" is a sign, not a specific disease (Table 32.9). True leukocoria mandates prompt referral to an ophthalmologist as the causes may threaten either vision and/or life. Retinoblastoma is the most feared cause of leukocoria because of its potential to metastasize and cause death. It is the most common malignant ocular tumor of childhood, with an incidence of about 1/15,000. Leukocoria, the most common presenting sign, is caused by light reflection from the tumor's white surface (Fig. 32.11) as opposed to the usual red reflex from the retina. Approximately 25% present with strabismus. Less common presentations include periocular inflammation, glaucoma, and proptosis. Imaging is helpful to evaluate for calcifications that occur in retinoblastoma and to help confirm the diagnosis as well as to evaluate for pinealoblastoma and extension of the tumor into the orbit. Magnetic Resonance Imaging (MRI) should be done since computed tomography (CT) scan poses concern for radiation exposure and the development of secondary cancers for which patients with retinoblastoma are at increased risk. Referral of a patient with suspected retinoblastoma to an ophthalmologist experienced in its diagnosis and management is critical. Genetic counseling is indicated, as is examination of parents and siblings. In about 1% of cases a parent will have a regressed retinoblastoma or retinocytoma. Treatment options include ophthalmic artery chemosurgery, laser photocoagulation, cryotherapy, intravitreal chemotherapy, systemic chemotherapy, and enulceation depending on laterality, location, extent of tumor, and vision potential. There is concerted effort to save the globes through advances in therapies.

TABLE 32.7 Causes of Monocular Visual Loss

Disorder	Timing	Pattern of Loss	Other Clues	Fundus Appearance	Pupil
Refractive error	Gradual*	Varies	Improves with pinhole	Normal	Normal
Cataract	Very gradual	Tunnel?	Opacity visible	Normal	Normal, but red reflex decreased
Corneal disease	Acute or chronic	Murky	Opacity visible or positive fluorescein	Normal	Normal but red reflex decreased
Iritis	Acute or chronic	Murky	Pain Ciliary flush	Normal	Small Disfigured?
Open-angle glaucoma	Gradual	Varies	Elevated pressures	Normal	Normal
Angle-closure glaucoma	Acute	Varies	Pain Steamy cornea Patient ill	Normal	Dilated Fixed
Central retinal occlusion	Acute	Varied	Painless Abrupt	Pale with cherry-red macula	Normal
Retinal detachment	Acute	Varies	Painless Floaters	Unremarkable or diagnostic	Afferent pupillary defect if extensive
Vitreous hemorrhage	Acute	"Dark"	Cannot see in the eye	Obscured	Normal, but red reflex decreased
Amaurosis fugax	Acute Transient	5-10 min	Carotid or heart disease, migraine	Normal	Normal
Migraine	Acute Transient	5-30 min	Headache History Scintillations	Normal	Normal
Optic neuropathy	Gradual or acute	Central scotoma	Toxins? Multiple sclerosis? Pituitary tumor? Virus?	Normal Pale optic disk?	Afferent defect
Diffuse retinopathy	Gradual	Varies	Genetic? AIDS?	Retinal lesions	Afferent defect?
Papilledema (chronic)	Late	Varies	CNS tumor? Pseudotumor cerebri Hypertensive crisis?	Diagnostic	Normal
Endophthalmitis	Varies	Varies	Corneal infection? Penetrating injury? Systemic injury? Hypopyon	Varies Often obscured	Varies

*Refractive error may be more acute when caused by diabetes mellitus.
AIDS, acquired immunodeficiency syndrome; CNS, central nervous system.
Modified from Reilly BM. *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:60.

CHILDHOOD CATARACTS

Congenital cataracts are a common cause of unilateral or bilateral vision loss in children, usually resulting from irreversible amblyopia in 1 or both eyes and occasionally from other accompanying structural ocular abnormalities (Table 32.10). Many infants with cataracts have leukocoria, but all visually significant cataracts can be detected by careful evaluation of the red reflex (Fig. 32.12). Infants with bilateral, visually significant cataracts may present with visual inattentiveness or nystagmus, signs that significant impairment of vision has already occurred.

Most cases of unilateral cataract are idiopathic in origin or associated with other ocular anomalies (persistent hyperplastic primary vitreous, anterior segment dysgenesis). Bilateral cataracts have a known genetic basis in about 60-70% of the cases but this is increasing as novel mutations continue to be described. Cataracts are commonly inherited in an autosomal dominant manner but may be inherited in an autosomal recessive or X-linked pattern. They can be associated with metabolic disease such as galactosemia or Fabry syndrome. Cataracts found to be a result of a metabolic disease may be reversible by removal of the offending agent; galactosemic cataracts are potentially reversible if lactose is eliminated from the diet promptly. Intrauterine TORCH(S) infections (*T*oxoplasmosis, *R*ubella, *C*ytomegalovirus, *H*erpes simplex and *S*yphilis) can also cause cataracts. Usually these are bilateral but in the case of congenital rubella infection unilateral cataract may occur (Table 32.11). Evaluation for a systemic cause should include a pediatric physical examination, ophthalmologic examination of the infant and family members, urine for reducing substances after lactose-containing milk feeding, labs for TORCH(S) infections, calcium, phosphorus, and glucose. Other metabolic studies, chromosomal evaluation, and genetic consultation may be indicated.

TABLE 32.8	**Organic Causes of Vision Loss in Infancy**	
Condition	**Physical Findings**	**Comments**
Corneal Disease		
Corneal forceps injury	Cloudy cornea	May lead to astigmatism and amblyopia; associated with intraocular hemorrhage, retinal detachment
Sclerocornea	Opaque cornea	Scleralization of cornea; familial or sporadic; keratoplasty possibly needed to provide vision
Anterior microphthalmia	Small cornea	Familial inheritance; associated with congenital cataracts, glaucoma, and/or coloboma
Anterior Chamber Diseases		
Peter anomaly	Corneal opacity with iridocorneal/lenticulocorneal adhesions	Maldevelopment of anterior segment of eye; associated with glaucoma and lens abnormalities
Persistent pupillary membrane	Bands or membranes obscuring pupil	Rupture of vessels in membranes may lead to hyphema; membrane may need to be removed to restore vision
Glaucoma	Tearing, enlarged eye, photophobia, cloudy cornea, pale optic disk	Increased intraocular pressure leading to blindness (optic nerve damage) Causes: anomalies of anterior segment, intraocular hemorrhage, ocular inflammatory disease, intraocular tumors Treatment: surgery
Iris and Lens Disorders		
Aniridia	Large, irregular, unreactive pupil	Hypoplasia of iris — may be heritable or sporadic, which is associated with a deletion of chromosome 11 and Wilms tumor or WAGR syndrome
Cataracts	Lens opacity	Multiple causes, ranging from familial inheritance to drugs
Anterior PHPV	Leukocoria (white pupillary reflex), lens opacity, cloudy cornea, small lens and eye	Persistence of fetal hyaloid vascular system, resulting in fibrovascular plaque on back of lens; as plaque contracts, ciliary process and lens become distorted Complications: glaucoma, cataract, intraocular hemorrhage, rupture of posterior capsule. Treatment: removal of membrane, lens aspiration. Prognosis: poor visual outcome
Retinal and Optic Nerve Disorders		
Posterior PHPV	Fibroglial veils around disk/macula, vitreous opacities (membrane, vessels)	Persistence of posterior fetal hyaloid vascular system; remnants of vascular system may cause traction detachment of retina
Chorioretinitis	Diffuse or local retinal atrophy demarcated by hyperpigmentation	Inflammation of posterior uvea with retinal involvement Causes: toxoplasmosis, histoplasmosis, herpes simplex, cytomegalic inclusion virus, syphilis, tuberculosis, and toxocariasis Other complications: glaucoma, detached retina
Retinoblastoma	Leukocoria	Neoplastic tumor with locus on chromosome 13: high incidence of secondary malignancy: poor prognosis with extraorbital metastasis
Retinopathy of prematurity	Leukocoria, cloudy vitreous; retinal white lines and ridges	Abnormal vascularization of retina: associated with retinal traction and detachment
Leber congenital retinal amaurosis	Normal findings to degeneration of retina	Failure of both rods and cones in retina; reduced or absent response to electroretinography; autosomal recessive
Achromatopsia	Color cannot be detected, photophobia	Failure of cone system in retina; autosomal recessive, or X-linked; diagnosed with ERG
Congenital stationary night blindness	Disk anomalies, poor night vision	Defect in rod system of retina; autosomal recessive, dominant, or X-linked recessive
Optic nerve hypoplasia	Pale, small optic disk; peripapillary halo of pigmentation	Secondary to failure in differentiation or degeneration of retinal ganglion cell axons Some causes: septo-optic dysplasia (hypopituitary, midline CNS defects), chromosomal defects (trisomy 13), albinism, fetal drug exposure (phenytoin, ethanol), infant of diabetic mother, CNS defects (hydrocephalus, anencephaly, encephalocele)

Continued

TABLE 32.8   Organic Causes of Vision Loss in Infancy—cont'd

Condition	Physical Findings	Comments
Optic nerve aplasia	Absence of retinal vessels and optic disk	Maldevelopment of optic nerve; associated with severe eye and CNS anomalies
Morning glory disk anomaly	Enlarged, funnel-shaped disk	Associated with retinal detachments and midline defects (cleft palate, encephalocele, agenesis of corpus callosum)
Coloboma	White, wedge-shaped retinal defect; visual field loss	Malclosure of embryonic fissure that leaves a gap in the retina, hence exposing sclera; defect may extend to lens; associated with many congenital syndromes
Aicardi syndrome	Retinal lacunae, coloboma of optic disk	Occurs mostly in girls and women; associated with agenesis of corpus callosum, seizures, intellectual disability, vertebral anomalies
Albinism	Photophobia; blue–gray to yellow–brown iris; macular hypoplasia	Defect in formation of melanin, resulting in lack of pigment in eyes and sometimes skin; increases risk of skin cancer with hypopigmented skin

CNS, central nervous system; ERG, electroretinogram; PHPV, persistent hyperplastic primary vitreous.

TABLE 32.9   Differential Diagnosis of Leukocoria (White Pupillary Reflex)

Common Causes

Cataracts
Cicatricial retinopathy of prematurity
Exudative retinopathy
Fundus coloboma
Larval granulomatosis (toxocariasis)
Persistent hyperplastic primary vitreous
Retinoblastoma

Other Causes

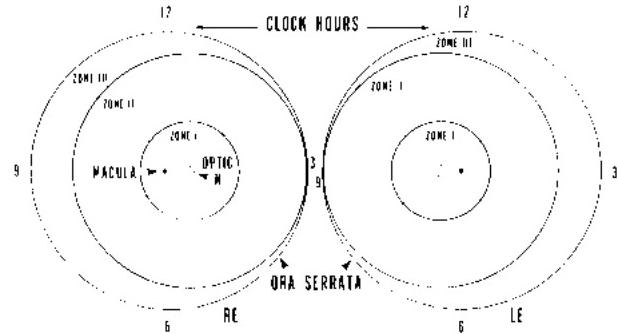
Atrophic chorioretinal scars
Endophthalmitis
Glioneuroma
Hemangioma
Hamartoma
Leukemic ophthalmopathy
Incontinentia pigmenti
Medullated nerve fibers
Medulloepithelioma
Morning glory disk anomaly
Norrie disease
Organized vitreous hemorrhage
Phakomatoses
Retinal gliosis
Retinal dysplasia
Retinoschisis


FIGURE 32.10 The international classification of retinopathy of prematurity (ROP). The stage of ROP is determined by the location, extent, and stage of disease according to the position of the advancing waves of retinal vessels. LE, left eye; RE, right eye.

FIGURE 32.11 Infant with leukocoria of right eye caused by retinoblastoma.

Cataracts in older children may be newly acquired due to a metabolic disease, drug exposure such as steroids, or a manifestation of progressive congenital cataracts. Cataract may rarely be the initial manifestation of diabetes type 1 but can occur as a complication particularly in patients with poor glycemic control. Bilateral cataracts are often the presenting sign in patients with unrecognized cerebrotendinous xanthomatosis (CTX). These patients usually have had chronic diarrhea without a known cause. Unfortunately, CTX is often diagnosed late after mental and neurodegeneration has started to occur. Since chenodeoxycholic acid can be used to prevent mental and neurologic deterioration, CTX should be considered in the presence of a juvenile-onset cataract and chronic diarrhea. Occasionally cataracts, unilateral or bilateral, are caused by an underlying congenital lens defect, which develops into a visually significant cataract at a later age. Trauma is a common cause of an acquired unilateral cataract.

Ideally, unilateral cataracts must be removed and amblyopia treatment begun in the 1st or 2nd month of life. Bilateral cataracts judged to be visually significant must be treated in the 1st 3 months of life to facilitate an optimal outcome. After this critical period maximum visual potential is decreased. Aphakic correction in infants younger than 6-12 months with bilateral cataracts is generally provided with extended-wear contact lenses or spectacles. Unilateral aphakia in this age group is best managed with a contact lens. A posterior chamber intraocular lens may be placed in children over the age of 1 year unless the child has an underlying inflammatory condition such as juvenile

TABLE 32.10 Differential Diagnosis of Cataracts

Developmental Variants
Prematurity ("Y" suture vacuoles) with or without retinopathy of prematurity

Genetic Disorders
Simple Mendelian Inheritance
Autosomal dominant (most common)
Autosomal recessive
X-linked

Major Chromosomal Defects
Trisomy disorders (13, 18, 21)
Turner syndrome (45X)
Deletion syndromes (11p13, 18p, 18q)
Duplication syndromes (3q, 20q, 10q)

Multisystem Genetic Disorders
Alport syndrome (hearing loss, renal disease)
Alström disease (nerve deafness, diabetes mellitus)
Apert syndrome (craniosynostosis, syndactyly)
Cockayne syndrome (premature senility, skin photosensitivity)
Conradi syndrome (chondrodysplasia punctata)
Crouzon syndrome (dysostosis craniofacialis)
Hallermann–Streiff syndrome (microphthalmia, small pinched nose, skin atrophy, and hypotrichosis)
Hypohidrotic ectodermal dysplasia (anomalous dentition, hypohidrosis, hypotrichosis)
Ichthyosis (keratinizing disorder with thick, scaly skin)
Incontinentia pigmenti (dental anomalies, intellectual disability, cutaneous lesions)
Lowe syndrome (oculocerebrorenal syndrome: hypotonia, renal disease)
Marfan syndrome
Meckel–Gruber syndrome (renal dysplasia, encephalocele)
Myotonic dystrophy
Nail–patella syndrome (renal dysfunction, dysplastic nails, hypoplastic patella)
Marinesco–Sjögren syndrome (cerebellar ataxia, hypotonia)
Nevoid basal cell carcinoma syndrome (autosomal dominant, basal cell carcinoma erupts in childhood)
Peter anomaly (corneal opacifications with iris–corneal dysgenesis)
Reiger syndrome (iris dysplasia, myotonic dystrophy)
Rothmund–Thomson (poikiloderma: skin atrophy)
Rubinstein–Taybi syndrome (broad great toe, intellectual disabilty)
Smith–Lemli–Opitz syndrome (toe syndactyly, hypospadias, intellectual disability)
Sotos syndrome (cerebral gigantism)
Spondyloepiphyseal dysplasia (dwarfism, short trunk)
Werner syndrome (premature aging in 2nd decade of life)

Inborn Errors of Metabolism
Abetalipoproteinemia (absent chylomicrons, retinal degeneration)
Fabry disease (α-galactosidase A deficiency)
Galactokinase deficiency
Galactosemia (galactose-1-phosphate uridyltransferase deficiency)
Homocystinemia (subluxation of lens, intellectual disability)
Mannosidosis (acid α-mannosidase deficiency)
Niemann–Pick disease (sphingomyelinase deficiency)
Refsum syndrome (phytanic acid α-hydrolase deficiency)
Wilson disease (accumulation of copper leads to cirrhosis and neurologic symptoms)

Endocrinopathies
Hypocalcemia (hypoparathyroidism)
Hypoglycemia
Diabetes mellitus

Congenital Infections
Toxoplasmosis
Cytomegalovirus infection
Syphilis
Rubella
Perinatal herpes simplex infection
Measles (rubeola)
Poliomyelitis
Influenza
Varicella–zoster

Ocular Anomalies
Microphthalmia
Coloboma
Aniridia
Mesodermal dysgenesis
Persistent pupillary membrane
Posterior lenticonus
Persistent hyperplastic primary vitreous
Primitive hyaloid vascular system

Miscellaneous Disorders
Atopic dermatitis
Drugs (corticosteroids)
Radiation
Trauma

Idiopathic

FIGURE 32.12 *Left,* Fundus reflex of an eye with a visually significant congenital cataract. The lens opacity is seen as black against the lighter fundus reflex. *Right,* Fundus reflex of a small, visually insignificant cataract. Nonetheless, this child requires referral for ophthalmologic evaluation.

TABLE 32.11 Childhood Glaucomas

I. Primary Genetically Determined Glaucoma	II. Secondary Glaucoma
A. Congenital open-angle glaucoma	A. Traumatic glaucoma
B. Juvenile glaucoma	1. Acute
C. Primary angle-closure glaucoma	a. Angle concussion
D. Primary glaucomas associated with systemic or ocular abnormalities	b. Hyphema
1. Associated with systemic abnormalities	2. Late onset with angle recession
a. Sturge–Weber syndrome	3. Arteriovenous fistula
b. Neurofibromatosis	B. Intraocular neoplasm
c. Pierre Robin anomalad	1. Melanoma
d. Oculocerebrorenal syndrome (Lowe syndrome)	2. Melanocytoma
e. Rieger syndrome	3. Juvenile xanthogranuloma
f. Hepatocerebrorenal syndrome	4. Retinoblastoma
g. Marfan syndrome	5. Leukemia
h. Rubinstein–Taybi syndrome	C. Uveitis
i. Infantile glaucoma associated with intellectual disabilty and paralysis	1. Open angle
j. Oculodentodigital syndrome	2. Angle blockage
k. Syndrome of microcornea, absent frontal sinuses, and open-angle glaucoma	a. Synechial angle-closure
l. Mucopolysaccharidosis	b. Iris bombé with pupillary block
m. Trisomy 13	D. Lens-induced glaucoma
n. Hurler disease	1. Subluxation-dislocation and pupillary block
o. Cutis marmorata telangiectasia	2. Spherophakia and pupillary block
2. Associated with ocular abnormalities	3. Phacolytic glaucoma
a. Aniridia	E. Glaucoma after surgery for congenital cataract
b. Congenital ocular melanosis	1. Lens material blockage of trabecular meshwork
c. Sclerocornea	2. Pupillary block
d. Familial hypoplasia of iris	3. Chronic open-angle glaucoma
e. Anterior chamber cleavage syndrome	F. Steroid glaucoma
f. Iridotrabecular dysgenesis and ectropion uveae	G. Glaucoma secondary to rubeosis
g. Posterior polymorphous dystrophy	1. Retinoblastoma
	2. Coats disease
	3. Medulloepithelioma
	H. Secondary angle-closure glaucoma
	1. Retinopathy of prematurity
	2. Microphthalmos
	3. Nanophthalmos
	4. Congenital iris–lens membrane
	I. Glaucoma associated with increased venous pressure
	1. Idiopathic
	2. Orbital disease

idiopathic arthritis (JIA). An intraocular lens may be placed in a child with a traumatic cataract if the intraocular structures that support the lens are intact. The management of a cataract goes well beyond cataract surgery. Amblyopia must be treated with occlusion of the sound eye, often for several years, until stable visual acuity can be demonstrated. Children who have had cataract surgery must be monitored indefinitely to evaluate for delayed complications such as glaucoma and retinal detachment.

GLAUCOMA IN CHILDHOOD

Pediatric glaucomas result from abnormalities of the aqueous outflow pathways (primary congenital glaucoma) or abnormalities that affect other parts of the eye (secondary glaucoma). Several genes causing primary congenital glaucoma, usually autosomal recessive, have been identified. Primary congenital glaucoma is bilateral in about 65% of

patients. This presents as a classic triad consisting of blepharospasm, photophobia, and epiphora (Fig. 32.13). The cornea may be cloudy due to edema resulting from elevated intraocular pressure. The cornea also enlarges and the axial length of the eye may increase with elevated intraocular pressure. Onset usually occurs in the 1st year of life; only 25% are present at birth. If glaucoma presents after the age of 5 years, it is known as primary juvenile open-angle glaucoma. The natural history of untreated primary congenital glaucoma is blindness resulting from progressive corneal opacification and optic nerve damage. Treatment is surgical although eye pressure lowering medications such as topical β blockers and topical or oral carbonic anhydrase inhibitors may be used as temporizing measures. Even with treatment final visual acuity is worse than 20/50 in more than 50% of the patients.

Secondary glaucoma may present similarly to primary glaucoma but is associated with other factors such as ocular trauma, inflammation, prolonged steroid use, or cataract. Some systemic conditions such

FIGURE 32.13 Bilateral congenital glaucoma in a 4-month-old infant. Note the large corneas and epiphora.

as neurofibromatosis are also associated with secondary glaucoma. The differential diagnosis of congenital glaucoma includes conditions that demonstrate corneal opacities (Table 32.12) or an enlarged cornea (Table 32.13). Epiphora also occurs with conjunctivitis, corneal trauma, and nasolacrimal duct obstruction (NLDO). Photophobia is observed in infants with corneal trauma, corneal deposits, cystinosis, and inflammation (uveitis). Corneal opacification can also be found in infants with corneal dystrophies, metabolic storage diseases such as mucopolysaccharidoses, and forceps-related obstetric trauma.

The diagnosis of primary congenital glaucoma or secondary glaucoma is generally confirmed by performing an examination with the patient under anesthesia. The child needs to be quiet and very cooperative in order to get an accurate intraocular pressure reading and a careful examination of the cornea and anterior segment structures. The diagnosis rests on a constellation of abnormal ocular findings, including elevated intraocular pressure, corneal enlargement, anomalies of the drainage angle, and signs of damage to the optic nerve in conjunction with medical history.

CHILDHOOD UVEITIS

Uveitis is defined as inflammation of the uveal tissue of the eye, which includes the iris, ciliary body, and choroid. Inflammation can involve any or all of these structures, and terms such as iritis, iridocyclitis, choroiditis, and chorioretinitis are used to designate which portion of the uveal tissue is involved. Anatomic location such as anterior, posterior, intermediate, or panuveitis are useful in determining etiology (Table 32.14). JIA is the most common cause of childhood anterior uveitis. JIA uveitis is most common in the pauciarticular form, when the onset occurs before the age of 7 years, and when the antinuclear antibody blood test is positive. Girls are at higher risk than boys; 10-15% of children with JIA develop uveitis and 10% of those who develop uveitis do so prior to the diagnosis of JIA. It is common for children with JIA to have no symptoms of inflammation in the eye. Despite the lack of symptoms, uveitis can cause severe vision loss due to the development of edema or deposition of calcium (band keratopathy) in the cornea or retinal edema (Fig. 32.14). A cataract and/or glaucoma may result from inflammation in the eye or chronic use of steroids used to quiet the inflammation. The pupil may have an irregular shape as a result of adhesions to the underlying lens (posterior synechiae). Visual impairment occurs in up to 40% of children with JIA uveitis and blindness occurs in 10% of affected eyes. For this reason there are screening guidelines for the recommended frequency of eye exams based on the risk factors that predispose patients with JIA to uveitis including category of arthritis (oligoarthritis vs polyarthritis), age of onset of arthritis, presence of ANA positivity, and duration of disease (Table 32.15).

The diagnosis of uveitis can be made from an eye examination. Because uveitis can be caused by infections, trauma, autoimmune disorders, and may be idiopathic, evaluation of the cause of the uveitis requires a thorough pediatric physical examination as well as supplementary radiologic and laboratory testing. A chest radiograph may demonstrate tuberculosis and sarcoidosis. Serologic evaluation may include tests for syphilis, sarcoidosis, JIA, Lyme disease, herpes, measles, and toxoplasmosis. In boys, haplotype testing for human leukocyte antigen B27 may be indicated because of the association between iritis and pauciarticular arthritis that may later evolve into ankylosing spondylitis.

The management of iritis in children is the elimination of intraocular inflammation. In some cases of noninfectious uveitis, local treatment with topical corticosteroid drops or periocular corticosteroid injections may control the inflammation. In many cases, local corticosteroids are not sufficient to control chronic uveitis. Immunomodulatory agents such as oral corticosteroids and corticosteroid-sparing agents, including nonsteroidal antiinflammatory drugs (NSAIDs), antimetabolites, T cell inhibitors, alkylating agents, and antitumor necrosis factor biologic agents are options. Short courses of corticosteroids may be used, but corticosteroid-sparing drugs are the 1st-line therapy for long-term use due to the many side effects of corticosteroids. Mydriatic drops are used to prevent the formation of posterior synechiae.

Toxoplasmosis caused by the intracellular parasite *Toxoplasma gondii* is the most common cause of posterior uveitis in children. Most ocular toxoplasmosis in the pediatric age group is probably acquired from the mother during pregnancy. In some instances, the infection is inactive at birth and goes unrecognized until inflammation occurs. Toxoplasmosis that is active at birth may result in widespread fetal tissue damage or may be associated with chorioretinitis, encephalomyelitis, and visceral disease. The diagnosis of toxoplasmosis is based on clinical findings, intracranial calcification in some children, and laboratory tests for specific immunoglobulin G and immunoglobulin M antibodies. Treatment of isolated ocular toxoplasmosis does not require treatment unless it threatens vision. When treatment is indicated, it involves the use of 1 or more antimicrobial drugs. The most common therapy consists of combination therapy with pyrimethamine and sulfadiazine. Steroids may be given in combination with antibiotics. Intravitreal clindamycin with dexamethasone may be as effective as systemic therapies. Several other entities can simulate uveitis in children and must be considered. These entities include retinoblastoma, leukemia, lymphoma, juvenile xanthogranuloma, and an intraocular foreign body.

NASOLACRIMAL PROBLEMS IN CHILDHOOD

The nasolacrimal system consists of tear-secreting glands and a drainage system. The lacrimal gland, located in the superotemporal orbit, is the primary producer of tears; accessory lacrimal glands in the upper eyelid supplement its output. The lacrimal drainage apparatus begins with puncta on the nasal aspect of the upper and lower eyelid margins. The puncta continue as canaliculi that course nasally to empty into the lacrimal sac. The lacrimal sac in turn drains inferiorly through the nasolacrimal duct just under the inferior turbinate in the nose (Fig. 32.15).

The most common developmental anomaly of the nasolacrimal drainage system is **NLDO**, which occurs in up to 20% of infants. A thin

TABLE 32.12	STUMPED: Differential Diagnosis of Neonatal Corneal Opacities					
Diagnosis	**Laterality**	**Opacity**	**Ocular Pressure**	**Other Ocular Abnormalities**	**Natural History**	**Inheritance**
S – Sclerocornea	Unilateral or bilateral	Vascularized, blends with sclera, clearer centrally	Normal (or elevated)	Cornea plana	Nonprogressive	Sporadic
T – Tears in endothelium and Descemet membrane						
Birth trauma	Unilateral	Diffuse edema	Normal	Possible hyphema, periorbital ecchymoses	Spontaneous improvement in 1 mo	Sporadic
Infantile glaucoma	Bilateral	Diffuse edema	Elevated	Megalocornea, photophobia and tearing, abnormal angle	Progressive unless treated	Autosomal recessive
U – Ulcers						
Herpes simplex keratitis	Unilateral	Diffuse with geographic epithelial defect	Normal	None	Progressive	Sporadic
Congenital rubella	Bilateral	Disciform or diffuse edema, no frank ulceration	Normal or elevated	Microphthalmos, cataract, pigment epithelial mottling	Stable, may clear	Sporadic
Neurotrophic – exposure	Unilateral or bilateral	Central ulcer	Normal	Lid anomalies, congenital sensory neuropathy	Progressive	Sporadic
M – Metabolic (rarely present at birth) (mucopolysaccharidoses IH, IS; mucolipidoses type IV)*	Bilateral	Diffuse haze, denser peripherally	Normal	Few	Progressive	Autosomal recessive
P – Posterior corneal defect	Unilateral or bilateral	Central, diffuse haze or vascularized leukoma	Normal or elevated	Anterior chamber cleavage syndrome	Stable; sometimes early clearing or vascularization	Sporadic, autosomal recessive
E – Endothelial dystrophy						
Congenital hereditary endothelial dystrophy	Bilateral	Diffuse corneal edema, marked corneal thickening	Normal	None	Stable	Autosomal dominant or recessive
Posterior polymorphous dystrophy	Bilateral	Diffuse haze, normal corneal thickness	Normal	Occasional peripheral anterior synechiae	Slowly progressive	Autosomal dominant
Congenital Hereditary stromal dystrophy	Bilateral	Flaky, feathery stromal opacities; normal corneal thickness	Normal	None	Stable	Autosomal dominant
D – Dermoid	Unilateral or bilateral	White vascularized mass, hair, lipid arc	Normal	None	Stable	Sporadic

*Mucopolysaccharidosis IH, Hurler syndrome; mucopolysaccharidosis IS, Scheie syndrome.

mucosal membrane at the distal end of the duct, the valve of Hasner, is the most common cause of obstruction. Typically, the infant has epiphora and a mucopurulent discharge that causes matting of the eyelids beginning at about 1 month of age. Pressure applied to the lacrimal sac with a finger or cotton swab often results in reflux of cloudy fluid from the puncta. The infection is usually polymicrobial, but a bacteriologic diagnosis is not necessary for clinical management. Eyelash washes with dilute baby shampoo can decrease the frequency of infections. Topical antibiotics can be used to decrease purulence but this likely leads to resistant organisms. Recurrent infections may be

considered an indication for early probing. Lacrimal sac massage may push fluid through the mucosal membrane and thereby open the duct, but the pressure applied to the lacrimal sac needs to be forceful. Most NLDOs will spontaneously resolve. If resolution does not occur within the 1st year of life, probing of the duct can be done and is effective in 90% of cases. Effectiveness of nasolacrimal duct probing decreases after the age of 18 months. A silicon stent can be placed to maintain an open duct, which increases the success of long-term patency.

NLDO must be differentiated from atresia of the puncta or canaliculi causing tearing but not infection and lacrimal-cutaneous fistula

TABLE 32.13	**Differential Diagnosis of Enlarged Cornea**		
Anterior	**Primary Infantile Simple Megalocornea**	**Megalophthalmos**	**Glaucoma with Buphthalmos**
Inheritance	Autosomal dominant (?)	X-linked recessive (male preponderance)	Sporadic
Time of appearance	Congenital	Congenital	1st year of life
Bilaterality	Bilateral Symmetric	Bilateral Symmetric	Unilateral or bilateral Asymmetric
Natural history	Nonprogressive	Nonprogressive	Progressive
Symptoms	None	None	Photophobia, epiphora
Corneal clarity	Clear	Clear or mosaic dystrophy	Diffuse edema, tears in Descemet membrane
Intraocular pressure	Normal	Elevated in some adults	Elevated
Corneal diameter	13-18 mm	13-18 mm	13-18 mm
Corneal thickness	Normal	Normal	Thick
Keratometry	Normal	Normal; astigmatism	Flat
Gonioscopy	Normal	Excessive mesenchymal tissue	Excessive mesenchymal tissue
Globe diameter (A scan)	23-26 mm	23-26 mm	27-30 mm
Major ocular complications	None	Lens dislocation; cataract, <40 yr; secondary glaucoma	Optic disk damage, late corneal edema
Associated systemic disorders	None	Occasionally Marfan and other skeletal abnormalities	None consistent

causing tears to drain to the skin surface. These conditions require surgery to re-form the canalicular system and puncta and repair the fistula if present. NLDO should be differentiated from infectious conjunctivitis, especially gonococcal, chlamydial, and herpetic infections. Chronic tearing occurs in congenital glaucoma in addition to blepharospasm and photophobia.

A **dacryocystocele** is a variation of congenital NLDO that occurs in newborns. These infants present with a bluish mass in the nasoorbital region below the medial canthal tendon. This mass is a dilated lacrimal sac that has both distal obstruction from a membrane and proximal obstruction from a 1-way valve effect from an incompetent valve of Rosenmüller (Fig. 32.16). A hemangioma or dermoid cyst may have a bluish hue but hemangiomas typically do not present at birth. An encephalocele or dermoid cyst may also appear to be a bluish mass but will lie above the medial canthus. On occasion, the dilated sac is accompanied by bulging of the nasal mucosa at the distal end of the nasolacrimal duct. The nasal mucocele can compromise the infant's breathing. If the dacryocystocele fails to resolve with topical antibiotics

and massage, or if cellulitis develops, systemic antibiotics and surgical decompression must be considered. Decompression is accomplished by relieving the distal obstruction by probing the nasolacrimal duct, removing any nasal cyst, and possibly placing a stent.

RED EYE

The term *red eye* usually refers to inflammation of the conjunctiva that causes the eye to appear red. Much less commonly (and much more seriously), the sclera is injected. Causes of red eye include infection of the ocular surface (cornea, conjunctiva, and sclera), allergy, intraocular inflammation, glaucoma, foreign body, and trauma. Evaluation must be directed toward discerning whether a child's red eye is caused by a benign condition that will spontaneously resolve (viral conjunctivitis) or easily be treated with topical medication (bacterial conjunctivitis) or whether the cause is potentially vision threatening (iritis, corneal

FIGURE 32.16 Dacryocystocele of the left lacrimal sac in a 2-week-old infant. The dacryocystocele resolved with a probing of the left tear duct.

ulceration, glaucoma) and requires urgent ophthalmologic evaluation (Table 32.16). Signs that should raise concerns for a serious etiology of red eye are in an immunocompromised host, severe pain, proptosis, limitation of eye movements, opacified cornea, abnormal pupil response, or lack of response to therapy.

In taking the history, the examiner should inquire about laterality, onset, associated illnesses, contact with others with "pink eye," the presence of pain or itching, the characteristics of any discharge (watery, mucoid, purulent), and blurring of vision. The examination of the child should start with as precise a measurement of visual acuity as possible. The presence and type of discharge should be noted. Inspection of the surface of the eye with a penlight should determine whether the cornea is clear. Fluorescein staining of the cornea to assess for a corneal abrasion should be done. The red reflex should be checked. The presence of foreign bodies should be considered.

The most common cause of a red eye in a child is infectious conjunctivitis (Table 32.17). *Streptococcus pneumoniae* is the most frequent bacterial pathogen, followed by some *Haemophilus* species and *Moraxella*. However, infections from *Haemophilus* species have decreased because of immunization. In hospitalized patients, staphylococcal infections (including methicillin-resistant *Staphylococcus aureus*) are more common. A bacterial culture is not necessary in mild cases of suspected bacterial conjunctivitis because the infection tends to be self-limiting but may last up to 2 weeks. Treatment with a broad-spectrum *topical* antibiotic may relieve symptoms and shorten the course of infection, allowing the child to return to school or daycare. Topical antibiotic options include trimethoprim–polymyxin B, erythromycin, gentamicin or tobramycin, ciprofloxacin, moxifloxacin, gatifloxacin, azithromycin, and sulfacetamide. Sulfacetamide preparations are inexpensive but have a narrower range of effectiveness and cause a great deal of stinging. Sulfa drugs also have an association with Stevens–Johnson syndrome. Gentamicin can cause redness, which can cause difficulty in determining whether or not the conjunctivitis is treated. The aminoglycosides are less effective with gram-positive organisms, particularly streptococcal species. Trimethoprim sulfate/polymyxin B is bacteriostatic and a 7-10 day course of therapy is recommended. The fluoroquinolones are rapidly effective but have different dosing recommendations. Azithromycin has a very short course but can be costly. Steroid-antibiotic combinations should be avoided because of the risk of worsening a bacterial corneal ulcer or an unsuspected herpes simplex infection.

Viral conjunctivitis tends to be associated with a watery or mucoid discharge. Follicles may be visible with low magnification on the palpebral conjunctiva, and a preauricular lymph node can often be palpated. Adenovirus is common pathogen; epidemic outbreaks are frequent. In children as old as 2 years, adenovirus can manifest with severe periorbital edema and erythema that mimics bacterial preseptal or orbital cellulitis; a conjunctival pseudomembrane is common in this setting. Adenoviruses types 8, 19, 35, enterovirus 70, and coxsackie 24 are associated with subconjunctival hemorrhages or hemorrhagic conjunctivitis. Pharyngoconjunctival fever, conjunctivitis accompanied by a sore throat and fever, is associated with adenovirus types 3 and 7. Cultures are not usually necessary but can be performed if there is a question of etiology. Antibiotics are ineffective in adenovirus infections. Treatment is largely supportive, with cool compresses and artificial tears providing symptomatic relief. Adenovirus is highly contagious so careful attention to hygiene should be taken among family members, caregivers, and contacts to prevent the spread of infection.

Less frequent causes of viral conjunctivitis are herpes simplex and varicella. These may be associated with vesicular involvement of the eyelid and face. Treatment with oral antiviral medications can be used if lesions are very near the cornea or there is corneal involvement. Oral antivirals are also considered in individuals who are immunocompromised. Topical antivirals are also used in patients with corneal involvement. Topical corticosteroid medications are contraindicated in herpetic infections because of the potential for worsening the infection. However the ophthalmologist often uses topical steroids to control inflammation after the viral infection has been treated.

The DNA poxvirus *Molluscum contagiosum* can cause a chronic conjunctivitis when lesions are located on the eyelid margin (Fig. 32.17). The conjunctivitis is caused by release of poxvirus particles into the tear film. Additional waxy, umbilicated lesions are oftentimes found elsewhere on the face. The infection may be self-limited but treatment of more severe cases requires incision and debridement of the central core from each lesion.

Allergic conjunctivitis manifests with a bilateral watery or mucoid discharge and must always be considered in the differential diagnosis of bilateral red eyes. The child may rub the eyes because of pruritus; nasal allergic symptoms may also be present. About 80% of individuals with allergies have ocular symptoms and these may occur in isolation. A more severe form of allergic conjunctivitis, **vernal keratoconjunctivitis (VKC)**, tends to occur in males in the first 2 decades of life and is seasonal, occurring in the spring and fall. Ulceration of the cornea can occur. Usually the ulceration is sterile but it can impair vision. Treatment of allergic conjunctivitis includes topical antihistamines, mast cell stabilizers, or a combination of the 2. Systemic treatment of allergies often improves the ocular symptoms. In severe cases of allergic conjunctivitis or VKC, steroids or cyclosporines can be used.

Systemic syndromes must also be considered in a child with a red eye. In the Stevens–Johnson syndrome, conjunctival inflammation is associated with other mucous membrane or cutaneous involvement. This disease can have severe ophthalmic consequences as a result of conjunctival scarring, changes of the eyelid position, and dry eye syndrome. Kawasaki syndrome is a febrile illness of young children who frequently manifest bilateral nonpurulent conjunctival injection and, in rare cases, iritis. Ophthalmic consultation may be indicated to assist in the diagnosis and management of children with Stevens-Johnson and Kawasaki syndromes.

EYELID ABNORMALITIES

Congenital abnormalities of the eyelids can be severe as in the case of cryptophthalmos, in which there is a failure of differentiation of eyelid structures and the skin passes uninterrupted from the forehead to the cheek. This is often associated with corneal abnormalities and systemic

TABLE 32.16 The Red Eye

Condition	Cause	Signs/Symptoms	Treatment
Bacterial conjunctivitis	*Haemophilus influenzae, H. influenzae aegyptius, Streptococcus pneumoniae, Neisseria gonorrhoeae, Staphylococcus aureus, Yersinia* species, cat-scratch bacillus less common	Mucopurulent unilateral or bilateral discharge, normal vision, photophobia usually absent. Conjunctival injection and edema (chemosis); gritty sensation	Topical antibiotics: systemic ceftriaxone for gonococcus, *H. influenzae*
Viral conjunctivitis	Adenovirus, ECHO virus, coxsackievirus	As above; may be hemorrhagic, unilateral enlarged preauricular lymph nodes	Self-limited
Neonatal conjunctivitis	*Chlamydia trachomatis,* gonococcus, chemical (silver nitrate), *S. aureus*	Palpebral conjunctival follicle or papillae; as above	Ceftriaxone for gonococcus and oral erythromycin for *C. trachomatis*
Allergic conjunctivitis	Seasonal pollens or allergen exposure	Itching, incidence of bilateral chemosis (edema) greater than that of erythema, tarsal papillae	Antihistamines, steroids, cromolyn
Keratitis	Herpes simplex, adenovirus, *S. pneumoniae, S. aureus, Pseudomonas* species, *Acanthamoeba* species, chemicals	Severe pain, corneal swelling, clouding, limbus erythema, hypopyon, cataracts; contact lens history with amebic infection	Specific antibiotics for bacterial/fungal infections; keratoplasty, acyclovir for herpes
Endophthalmitis	*S. aureus, S. pneumoniae, Candida albicans,* associated surgery or trauma	Acute onset, pain, loss of vision, swelling, chemosis, redness; hypopyon and vitreous haze	Antibiotics
Anterior uveitis (iridocyclitis)	JIA, reactive arthritis, sarcoidosis, Behçet disease, Kawasaki disease, inflammatory bowel disease	Unilateral/bilateral; erythema, ciliary flush (in circumcorneal area), irregular pupil, iris adhesions; pain, marked photophobia, small pupil, poor vision, no discharge	Topical steroids, plus therapy for primary disease
Posterior uveitis (choroiditis)	Toxoplasmosis, histoplasmosis, *Toxocara canis*	No sign of erythema, decreased vision, no discharge	Specific therapy for pathogen
Episcleritis/scleritis	Idiopathic autoimmune disease (e.g., SLE, Henoch–Schönlein purpura)	Localized pain, intense erythema, unilateral; blood vessels bigger than in conjunctivitis; scleritis may cause globe perforation, no discharge	Episcleritis is self-limiting; topical steroids for fast relief
Foreign body	Occupational exposure	Unilateral, red, gritty feeling; visible or microscopic size	Irrigation, removal; check for ulceration
Blepharitis	*S. aureus, S. epidermidis,* seborrheic, blocked lacrimal duct: rarely, molluscum contagiosum, *Pthirus pubis, Pediculosis capitis*	Bilateral, irritation, itching, hyperemia, crusting, affecting lid margins	Topical antibiotics, warm compresses
Dacryocystitis	Obstructed lacrimal sac: *S. aureus, H. influenzae,* pneumococcus	Pain, tenderness, erythema and exudate in area of lacrimal sac (inferomedial to inner canthus); tearing (epiphora); possible orbital cellulitis	Systemic, topical antibiotics; surgical drainage
Dacryoadenitis	*S. aureus, Streptococcus* species, CMV, measles, EBV, enteroviruses, trauma, sarcoidosis, leukemia	Pain, tenderness, edema, erythema over gland area (upper temporal lid); fever, leukocytosis	Systemic antibiotics; drainage of orbital abscesses
Orbital cellulitis	Paranasal sinusitis: *H. influenzae, S. aureus, S. pneumoniae,* other *Streptococcus* species. Trauma: *S. aureus.* Fungi: *Aspergillus, Mucor* species if immunodeficient	Rhinorrhea, chemosis, vision loss, painful extraocular motion, proptosis, opthalmoplegia, fever, lid edema, leukocytosis. *S. aureus*	Systemic antibiotics (postseptal cellulitis), drainage of orbital abscesses
Periorbital cellulitis	Trauma: *S. aureus, Streptococcus* species. Bacteremia: *H. influenzae,* pneumococci, *S. pyogenes*	Cutaneous erythema, warmth, normal vision, minimal involvement of orbit, fever, leukocytosis, toxic appearance	Systemic antibiotics (preseptal cellulitis)

CMV, cytomegalovirus; EBV, Epstein–Barr virus; ECHO, enteric cytopathogenic human orphan; JIA, juvenile idiopathic arthritis; SLE, systemic lupus erythematosus.

FIGURE 32.17 Chronic eczematoid and follicular conjunctivitis in only the left eye, caused by *Molluscum contagiosum,* in a 5-year-old. Note the elevated lesions on the lateral aspect of the left upper eyelid.

abnormalities. Colobomas of the eyelid can occur and are usually on the upper lid and can range in severity from a notch to the entire length of the eyelid. Eyelid colobomas are often associated with Goldenhar and CHARGE syndromes. Surgery can be done to reconstruct the eyelids. More common eyelid abnormalities include entropion (inward turning of the eyelid margin), ectropion (eversion of the eyelid margin), epiblepharon (in which a horizontal fold of skin in the lower eyelid causes the lashes to rub against the cornea), and distichiasis (in which an accessory row of eyelashes is more posterior than the normal ones and can rub against the cornea). All these may resolve spontaneously or, if necessary, can be corrected with eyelid surgery. Epiblepharon tends to be well tolerated by patients. Epicanthus, a crescent-shaped

fold of skin, is usually most prominent in the upper eyelid that can make the child appear esotropic by obscuring the underlying sclera.

Congenital ptosis (Fig. 32.18), droopiness of the upper eyelid, is usually caused by abnormal development of the levator muscle. Other causes in children are trauma, congenital 3rd nerve palsy, and congenital Horner syndrome. Acute onset of ptosis in the absence of trauma requires evaluation for new-onset Horner syndrome, which may be associated with neuroblastoma, and evaluation for a 3rd nerve palsy, which may be associated with an intracranial mass. A child with congenital ptosis needs to be monitored for amblyopia. Treatment of ptosis is delayed until the child is several years old unless it is causing amblyopia due to occlusion of the visual axis, an induced astigmatism difficult to treat with glasses, or when severe chin-up head posture is necessary to allow the child to see (Fig. 32.19). Surgical correction consists of resection of the levator muscle or suspension of the upper eyelid to the frontalis muscle with a silicon sling or autogenous or cadaveric fascia lata.

ORBITAL TUMORS

Orbital tumors, either benign or malignant, may occur in children. The space-occupying lesions can present with proptosis, swelling or discoloration of the eyelids, ptosis, or strabismus. Some of the most common benign tumors are vascular lesions. **Hemangiomas** occur in 1-3% of term newborns and are more common in premature infants. Hemangiomas are classified by depth of skin involvement and type of orbital involvement. The natural history involves rapid proliferation over the 1st several months of life. Ulceration, hemorrhage, and occlusion or induced astigmatism of the eye causing amblyopia can occur. After the 1st year of life the lesion begins to regress. Systemic diseases such as

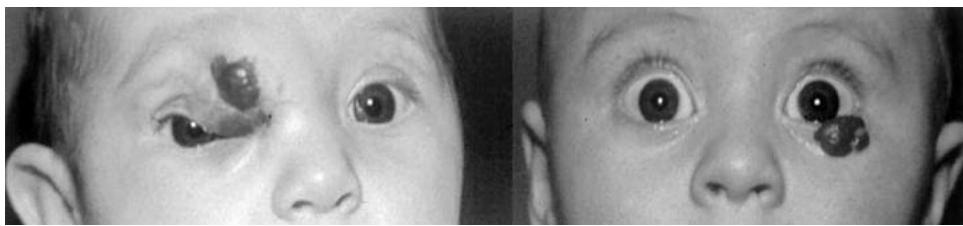
FIGURE 32.18 Congenital ptosis of the right upper eyelid. The child adopted a compensatory chin-up head posture to allow use of both eyes together and did not have amblyopia.


FIGURE 32.19 *Left,* A capillary hemangioma of the right upper eyelid and anterior orbit. This lesion necessitated treatment because it was causing amblyopia from astigmatism as a result of pressure against the globe and by occlusion of the visual axis. *Right,* This capillary hemangioma of the left lower eyelid is not causing amblyopia and does not necessitate treatment unless it grows substantially.

PHACE syndrome (posterior fossa malformations, hemangiomas, arterial anomalies, coarctation of the aorta and cardiac defects, eye abnormalities) and multiple cutaneous hemangiomas with hepatic hemangiomas may have an orbital or eyelid hemangioma as the presenting finding. First-line treatment consists of oral propranolol 1-3 mg/kg/day divided into 3 oral doses. Side effects include bradycardia, hypoglycemia, hypotension, somnolence, bronchospasm, and cough. Treatment initiation is done under medical supervision and care is taken to administer the medicine with feeds to limit the side effects. Topical timolol maleate may be used with minimal side effects for superficial skin lesions but is not effective in deeper or orbital lesions. A pulsed dye laser can also be used to treat the superficial lesions. Propranolol has replaced steroids, vincristine, and interferon alfa-2a due to the unacceptably high side effect profiles of these other medications and the very rapid regression of hemangiomas using propranolol.

Lymphangiomas may cause proptosis. Most commonly these present in the 2nd or 3rd decade but may present in infancy. The size may increase with the onset of an upper respiratory infection. Lymphangiomas are usually managed conservatively but short courses of steroids can be used. Rapid expansion may occur if bleeding into the lesion occurs. This may require surgical intervention if the pressure in the orbit is threatening damage to the optic nerve.

Dermoid cysts are benign choristomas that arise from primitive dermal elements that develop in fetal suture lines. This tissue forms a keratinized epithelium cyst and includes hair follicles, sweat glands, and sebaceous glands. It most commonly occurs superotemporally in the zygomatic frontal suture but may be superonasal in the frontal-nasal suture. Imaging can be valuable in confirming the diagnosis and determining if the dermoid extends into the orbit. If the cyst ruptures, a marked inflammatory reaction ensues so removal is recommended prior to the child becoming very active, which increases the chances of the child rupturing the cyst traumatically.

Malignant tumors of the orbit can rapidly enlarge, which make them difficult to differentiate from inflammatory and infectious causes. Rhabdomyosarcomas are the most common primary pediatric orbital tumor. Average age of onset is 5-7 years. Usually the tumor arises in the orbit but it can arise in the conjunctiva, eyelid, or uveal tissue. Patients present with rapidly progressing proptosis. Tumors need to be removed completely and chemotherapy or radiation may also be needed.

Neuroblastoma is the most common metastatic orbital tumor of childhood. It usually arises from the adrenal gland or sympathetic ganglion chain, hence the association with acquired Horner syndrome. Unilateral or bilateral proptosis and eyelid ecchymosis are the classic presentations. **Opsoclonus** (rapid, multidirectional eye movements) is a paraneoplastic syndrome associated with neuroblastoma and is not related to orbital involvement. The mean age of diagnosis of orbital metastasis of neuroblastoma is 2 years.

Other, less common orbital tumors in childhood are Ewing sarcoma, Burkitt lymphoma, leukemia, and Langerhans cell histiocytosis. Ewing sarcoma is the 2nd most common solid tumor metastatic to the orbit (after neuroblastoma). Orbital involvement occurs in 1-2% of children with leukemia and this must be differentiated from orbital infections.

OCULAR MANIFESTATIONS OF SYSTEMIC DISEASE

Neurologic Disease

Ocular abnormalities frequently accompany neurologic disease, and their detection can help in the localization and diagnosis of a specific condition. Abnormal findings of pupillary reaction, decreased visual acuity, or decreased color vision can indicate abnormities of the optic nerve, which can be associated with other neurologic conditions. An afferent pupillary defect is an important finding that may signify unilateral optic nerve disease. The condition may be intrinsic to the optic nerve such as a glioma in neurofibromatosis type 1, extrinsic such as an orbital tumor, applying pressure on the nerve (Fig. 32.20), or inflammation of the optic nerve as seen with **optic neuritis** in multiple sclerosis, neuromyelitis optica, and acute demyelinating

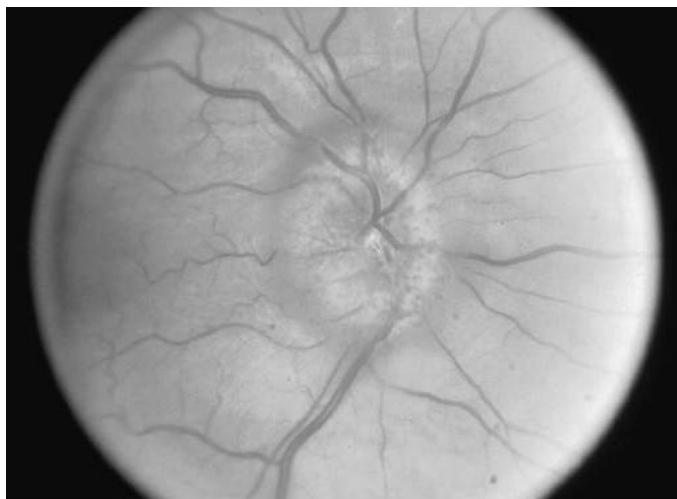
FIGURE 32.20 Left 3rd cranial nerve palsy. The boy has exotropia *(top),* limitation of adduction of his left eye *(middle),* and normal gaze to his left *(bottom).*


FIGURE 32.21 Papilledema of the right optic nerve.

encephalomyelitis (ADEM). Color perception and the visual acuity of the affected eye is usually reduced in comparison with that of the normal eye. The presence of an afferent pupillary defect necessitates a comprehensive eye examination and imaging studies of the orbit and brain.

Optic nerve edema (Fig. 32.21) is a worrisome sign because of its association with conditions that cause increased intracranial pressure. The elevation of the optic nerve and blurring of the disk margins must be differentiated from optic nerve drusen, which can have similar clinical appearances. Papilledema, swelling of the optic nerve as a result of increased intracranial pressure, is almost always bilateral. Visual acuity

may be normal initially but decreases with chronic or severe optic nerve swelling.

Strabismus of truly acute onset is most often incomitant and caused by paralysis of extraocular muscles innervated by the 3rd or 6th cranial nerves. Cranial trauma, brain tumors, and viral infections are the most common causes of acute, incomitant strabismus in children. A 6th nerve palsy is of less localizing value than a 3rd nerve palsy because of the more tortuous intracranial course of the 6th nerve. This nerve can be affected by direct pressure from a mass and indirectly by conditions that cause increased intracranial pressure. A patient with an acute 6th nerve paralysis typically has esotropia that increases when he or she gazes toward the affected side (see Fig. 32.8). The patient may have a compensatory face turn toward the side of the lesion to allow fusion and prevent diplopia. A 3rd nerve paralysis usually causes exotropia and hypotropia of the involved eye (see Fig. 32.20). There may also be ipsilateral ptosis and a dilated, nonreactive pupil. A general approach to an acquired diplopia is noted in Fig. 32.22.

The **neurocutaneous syndromes** are a group of inherited disorders featuring multiple, discrete lesions of 2 or more organ systems, most commonly the skin and brain. These include neurofibromatosis, tuberous sclerosis, angiomatosis of the retina and cerebellum (von Hippel–Lindau disease), and encephalofacial or encephalotrigeminal angiomatosis (Sturge–Weber syndrome). Sometimes ataxia-telangiectasia, incontinentia pigmenti, and racemose angioma are included in neurocutaneous syndromes. Ocular involvement is common and may be a site of comorbidity or may serve as a marker for the overall condition. For example, Lisch nodules are benign tan, smooth-surfaced lesions on the iris surface that look somewhat gelatinous seen in **neurofibromatosis** type 1. They are usually not present until 3 years and thereafter about 10% of patients develop Lisch nodules per year. They do not have malignant potential. Other ocular features of neurofibromatosis type 1 (NF-1) are plexiform neurofibromas of the eyelid that give the eyelid margin a sigmoid shape and cause a variable amount of ptosis, astigmatism, and possibly amblyopia. Glaucoma is a significant problem in patients with NF-1. It is usually unilateral and associated with an ipsilateral plexiform neurofibroma of the upper eyelid. This is generally managed surgically. Visual prognosis in patients who develop glaucoma is poor.

Optic gliomas, such as low-grade pilocytic astrocytomas, have the potential to cause severe vision loss in patients with NF-1. The gliomas can involve 1 or both optic nerves as well as the optic chiasm. They are found prospectively in 15% of patients with NF-1 but cause visual symptoms such as vision loss or proptosis in only 1-5% of patients. Treatment of optic gliomas is reserved for lesions that are documented to be growing and causing visual morbidity, although it is difficult to determine which patients require treatment before vision loss occurs. NF-2 is much less common than NF-1 and involves primarily the acoustic nerves. Ocular involvement can consist of posterior lens opacities and hamartomas of the retina.

Tuberous sclerosis is an autosomal dominant disorder localized to chromosome 9. In children with tuberous sclerosis, angiofibromas of the eyelids and retinal lesions known as astrocytic hamartomas can occur but rarely cause significant problems with vision. The retinal lesions are not pathognomonic of tuberous sclerosis, inasmuch as similar lesions have been reported in NF-1 and in unaffected individuals.

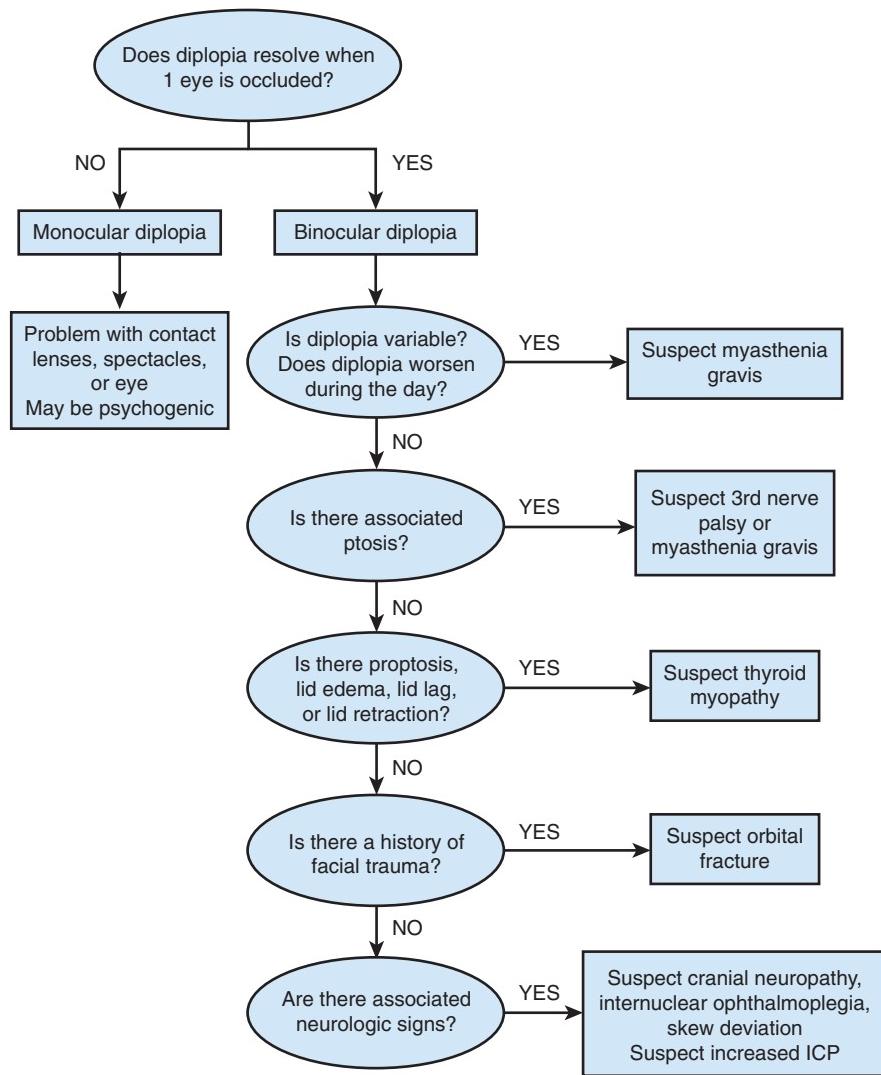
Von Hippel–Lindau disease is autosomal dominant. Both benign and malignant tumors can occur in affected individuals as a result of a mutation in a tumor suppressor gene. Hemangioblastomas of the retina can produce a lipid exudate in the retina as a result of leakage from the thin vessel walls. This can lead to vision loss and ultimately a retinal detachment. Symptoms of vision loss do not


FIGURE 32.22 General approach to diplopia. The clinician should 1st distinguish monocular from binocular diplopia and, in patients with binocular diplopia, address the 5 questions on the right side of the figure. Only then should the clinician identify which muscle is weak, although this is unnecessary if the clinician already suspects myasthenia (from fatigability) or full 3rd nerve palsy (from weakness of the medial rectus, superior rectus, inferior rectus, and inferior oblique muscles, with or without a dilated pupil). Uncommon causes of diplopia and associated ptosis, not presented in the figure, are botulism, the Fisher variant of Guillain-Barré syndrome, and aberrant regeneration of the 3rd nerve. Uncommon causes of diplopia and associated orbital findings (e.g., proptosis) are carotid-cavernous fistula (which causes an orbital bruit), orbital tumor, and pseudotumor. ICP, intracranial pressure. (From McGee S. *Evidence-Based Physical Diagnosis*. 3rd ed. Philadelphia: Elsevier; 2012:522, Fig. 57-1.)

occur until extensive leakage or retinal detachment occurs. More than 65% of lesions can be treated effectively with laser photocoagulation. Because lesions are most effectively treated prior to the development of symptoms, children known to have von Hippel–Lindau disease should have regular eye examinations beginning at the age of 5 years.

Sturge–Weber syndrome is sporadic and ocular involvement is common. Abnormalities of the ocular circulation can occur when the eyelids are affected. These abnormalities range from increased conjunctival vascularity to angiomas of the choroid. Choroidal angiomas usually remain asymptomatic in childhood but can thicken in adolescence and cause degeneration of the overlying retina. Glaucoma is the most serious ocular complication and occurs in 70% of affected patients. Regular eye examinations in infancy are necessary to rule out glaucoma. Treatment of glaucoma associated with Sturge–Weber syndrome may be difficult. Topical drops may be effective in initially lowering eye pressure but the patient may eventually require several surgeries

Ataxia-telangiectasia syndrome is an autosomal recessive disorder. Oculomotor abnormalities may be early manifestations of this syndrome. In 90% of patients, telangiectasia develops in the conjunctiva in children between the ages of 3 and 5 years.

Incontinentia pigmenti syndrome is an X-linked dominant condition in which proliferative retinal vasculopathy develops in about 30% of affected patients. The retinal changes can mimic ROP with incomplete peripheral retinal vascularization. Retinal detachment can occur. Treatment includes laser photocoagulation or cryotherapy but these treatments have varying degrees of success.

In **Wyburn–Mason syndrome,** a racemose angioma can develop in the retina with shunting of blood directly from arteries to veins. Vision can be normal or markedly reduced, depending on the location of the lesion. Treatment is not indicated for primary lesions.

Dermatologic Disease

Albinism is a heterogeneous group of genetic disorders resulting from absence of melanin in the eye, skin, or both. Clinically, albinism is divided into ocular and oculocutaneous forms. Oculocutaneous albinism (OCA) results from mutations in the tyrosinase gene *(TYR)* or *OCA1* gene. There are 2 subtypes and hair color can range from blond to light brown as the most prevalent type of albinism worldwide. Ocular albinism is autosomal recessive or an X-linked mutation in the *OCA1* gene. Ocular albinism mainly affects pigmentation in the visual system and the most common ocular finding is iris transillumination, which may be observable in a darkened room by placing a penlight against the lower eyelid and noting the passage of light from both the pupil and the iris. Other frequent ocular findings are nystagmus, light fundus pigmentation (blonde fundus), and foveal hypoplasia. Visual acuity usually ranges from 20/40 to 20/400. The Chédiak–Higashi and Hermansky–Pudlak syndromes can manifest features of albinism. If either of these conditions is suspected, hematologic consultation is recommended because of the lethal nature of these forms of albinism. All patients with OCA are at an increased risk of skin cancer and should be counseled as such.

Stevens–Johnson syndrome is an acute inflammatory condition affecting skin and mucus membranes. Drugs, particularly sulfonamide medications, are common precipitating factors. Microbial agents, especially *Mycoplasma pneumoniae*, have also been implicated in this condition. Ocular involvement, which occurs in half of the patients, consists of eyelid edema and ulceration, conjunctival injection with vesicle formation and, in severe cases, conjunctival scar formation that may result in adhesions between the palpebral and bulbar conjunctiva (symblepharons). The severity of late ocular complications depends primarily on the extent of conjunctival involvement. Malposition of the eyelids with corneal irritation from inward-turned eyelashes (trichiasis) can occur from severe conjunctival scarring. The most serious complication is dry eye syndrome, caused by damage to the ducts of the lacrimal glands and obliteration of conjunctival mucus-forming cells (goblet cells). Eyelid surgery may be required, and the child with a dry eye may face a lifetime of needing ocular lubrication from artificial tears and ointments. Aggressive lubrication during the acute phase of the disease is recommended to keep tissues moist and prevent conjunctival adhesions. Treatments may include regular debridement of the fornices of the eye or placement of symblepharon rings or amniotic membranes in severe cases.

Hyperkeratotic disorders such as lamellar ichthyosis can cause scaling of the eyelids, ectropion, lagophthalmos, and exposure keratopathy. Although eyelid surgery may be required, the mainstay of treatment is ocular lubrication with artificial tears and ointments. **Connective tissue disorders** such as Marfan syndrome, Stickler syndrome, Ehlers–Danlos syndrome, and pseudoxanthoma elasticum (PXE), are associated with particular ocular abnormalities. Patients with Stickler syndrome, Marfan syndrome, and Ehlers–Danlos syndrome have myopic retinal degeneration and can develop retinal detachment. Lens subluxation is common in Marfan syndrome. Cracks in the Bruch membrane of the retina, known as angioid streaks, occur in 85% of patients with PXE and 70% of these patients experience vision loss from hemorrhage, extension into the macula, choroidal sclerosis and atrophy of the retinal pigment epithelium. Angioid streaks rarely occur before the 2nd decade of life.

Skin disorders causing neoplasia such as juvenile xanthogranuloma can affect the eye, sometimes even in the absence of typical skin lesions. Ocular complications from juvenile xanthogranuloma occur most commonly in infants and consist of nodular tumors of the iris and ciliary body. The iris lesions have thin-walled vessels that are prone to bleeding and to causing a hyphema. Glaucoma and iridocyclitis can also occur. The iris lesions may respond to topical corticosteroids.

Hematologic Disorders

The **hemoglobinopathies** can have direct ocular consequences. Patients with hemoglobin SC or S thalassemia are more prone to retinal vascular occlusive disease because of a higher hematocrit and greater blood viscosity than are patients with hemoglobin SS, but retinal complications are frequently not seen until adolescence or early adulthood. Patients develop hemorrhages, angioid streaks, and arterial occlusions. Patients with sickle cell disease or sickle cell trait are at higher risk of complications of trauma, particularly hyphema. These patients may develop glaucoma, optic nerve damage and artery occlusion in this setting and require close monitoring.

Leukemia in children is usually acute. All ocular structures may be affected by direct infiltration of leukemic cells, hemorrhage, or infection. Conjunctival thickening, hypopyon, corneal ulcers, iris infiltrates, retinal hemorrhages, and neovascularization may occur. Infiltration of the optic nerve can be difficult to distinguish from papilledema secondary to CNS relapse. Infectious processes may present with similar findings as leukemia and can be difficult to discern from leukemic infiltrates. Papilledema and intraocular infection are true emergencies as the findings not only threaten vision but also are highly correlated with CNS involvement. Prompt diagnosis and treatment is necessary.

Congenital Heart Disease

Eye disease can be related to congenital heart disease by association, which is not surprising because there is a temporal relationship between the embryogenesis of the heart and that of the eyes; an embryopathic insult may result in malformations of both systems. CHARGE syndrome, a constellation of *C*oloboma, *H*eart defects, choanal *A*tresia, *R*etardation, and *E*ar abnormalities is a result of a mutation in the CHD7 transcription regulator of tissue-specific genes. The effects are tissue and developmental stage dependent. Colobomas of the eyelid, iris, retina, choroid, and optic nerve occur. They are usually bilateral and the effects on vision are determined by the location of the coloboma. If the macula is involved the visual prognosis is poor. Congenital heart disease can be a cause of eye disease as a direct effect of complications such as cyanosis or systemic hypertension. Severe hypoxia can cause cortical visual impairment or damage to the optic nerve resulting in optic atrophy.

Gastrointestinal Disorders

Ocular manifestations of inherited metabolic abnormalities of the gastrointestinal system occur primarily in the cornea and retina. **Wilson disease** is an autosomal recessive disorder of copper metabolism. The excess copper is deposited in the liver, basal ganglia, cornea, and kidney. Liver damage, neurologic, and psychiatric disorders result at a young age. The deposition of copper in the Descemet membrane of the cornea is the Kayser–Fleischer ring, which is pathognomonic of the disease. Copper may also be deposited in the lens. The corneal deposition of copper is not generally symptomatic but lens deposition may adversely affect vision.

Alagille syndrome, an autosomal dominant condition with intrahepatic bile duct hypoplasia, is associated with a peripheral corneal finding known as posterior embryotoxon. This finding consists of thickening and anterior displacement of the Schwalbe line, which is

the peripheral extent of the Descemet membrane of the cornea. It can best be seen with a slit-lamp biomicroscope. Posterior embryotoxon occurs in more than 90% of patients with Alagille syndrome, but because it also occurs in 15% of normal individuals, it is not pathognomonic for this syndrome.

Inflammatory bowel disease also can be associated with ocular disease. Anterior uveitis occurs in both Crohn disease and ulcerative colitis. Uveitis is diagnosed in almost half of cases of Crohn disease and fewer in ulcerative colitis. In turn, untreated chronic uveitis can lead to cataracts, glaucoma, and retinal edema. Conjunctivitis, keratitis, and retinal vasculitis are less frequent complications of these diseases.

Genitourinary Disease

Oculorenal syndromes may result from chromosomal abnormality syndromes or from inherited metabolic or developmental defects. The **Wilms tumor** gene *WT1* lies near the *PAX6* gene locus on 11p13. A chromosomal deletion of both results in Wilms tumor and aniridia. A larger deletion may result in WAGR syndrome (*W*ilms tumor, sporadic *A*niridia, *G*enitourinary malformations, and mental *R*etardation). Any child with nonfamilial aniridia is at risk for Wilms tumor and needs appropriate genetic evaluation.

The **Bardet–Biedl syndrome** is an autosomal recessive disorder combining retinal dystrophy, polydactyly, obesity, renal abnormalities, and hypogenitalism. An electroretinogram may be the earliest means of detecting the cone-rod dystrophy in suspected cases. Visual acuity and the funduscopic appearance may be normal in early childhood. Vision may then decrease and pigmentary retinopathy, which appears around the age of 8 years, becomes more prominent with age.

Cystinosis is also an autosomal recessive disorder of cystine transport from lysosomes that leads to intracellular accumulation of cystine in many tissues, including the eyes and kidneys. Cystine crystals accumulate in the anterior layer of the cornea beginning in the 1st year of life. This can cause photophobia, which can be severe. Retinal deposits of cystine can lead to focal degeneration of the retinal pigment epithelium. Frequent topical administration of cysteamine drops (6-12 times per day) can clear the cornea of cystine crystals and relieve ocular discomfort.

Alport syndrome is an X-linked syndrome characterized by nephritis, hearing loss, and ocular signs, particularly of the lens. An "oil droplet" appearance can be seen in the pupil with an ophthalmoscope. This represents an abnormality in the anterior capsule of the lens, anterior lenticonus, which can sometimes be associated with a cataract. Perimacular flecks are frequently present in the retina but do not tend to reduce visual acuity.

The **Lowe oculocerebrorenal syndrome** is also an X-linked disorder comprising congenital cataracts, intellectual disability, and renal tubular dysfunction. Glaucoma develops in a high proportion of affected boys and men. The carrier state can frequently be detected in girls and women by the appearance of numerous punctate opacities of the lens.

Endocrine Disease

Optic nerve hypoplasia is the most common congenital optic nerve anomaly. It can involve only a segment of the optic nerve. A superior segmental hypoplasia sometimes occurs in children of diabetic mothers. Optic nerve hypoplasia can occur with other CNS abnormalities. Patients with optic nerve hypoplasia may have septo-optic dysplasia, which denotes the absence of the septum pellucidum and agenesis of the corpus callosum or additional findings including pituitary abnormalities and cerebral hemisphere abnormalities. Evaluation of hypothalamic and pituitary functions is indicated in patients found to have pituitary abnormalities on imaging or if there is clinical suspicion of endocrine abnormalities such as neonatal jaundice, hypoglycemia, or difficulty with temperature control.

Diabetes mellitus results in retinopathy at some point in nearly all persons with insulin-dependent type I diabetes. The prevalence of retinopathy is directly proportional to the duration of disease after puberty. It rarely occurs within 5 years of diagnosis, occurs in about 50% of patients at 7 years after diagnosis, and is seen in 90% at 15 years after diagnosis. Funduscopic signs of diabetic retinopathy are microaneurysms, retinal hemorrhages, cotton wool spots, and hard exudates. Proliferative diabetic retinopathy with neovascularization is uncommon in children. Intensive glucose control as monitored by hemoglobin A_{1c} decreases the incidence and progression of diabetic retinopathy. Diabetic cataracts caused by sorbitol accumulation in the lens are also complications of diabetes mellitus in children. Refractive changes such as myopia can occur with rapid rises in blood sugar because of osmotic changes in the lens.

Thyroid ophthalmopathy related to **Graves disease** occurs in children much less frequently than in adults. It can be a cause of proptosis, lid edema, eyelid retraction, or restrictive strabismus due to lymphocytic infiltration of the muscles.

Infectious Diseases

Intrauterine or maternally transmitted infections can cause tissue damage or malformation. The common types of congenital infections are the **TORCH(S)**. The infectious agent, *T. gondii*, is acquired transplacentally or postnatally and has particular affinity for the central nervous system, including the retina. Chorioretinitis and uveitis may occur and resolution leaves scarring. Reactivation can occur and thus serial eye examinations are necessary. The macula is commonly involved and vision can be quite poor. Intrauterine rubella infection has become a rarity in the United States because of immunization with the measles-mumps-rubella vaccine. A fetus infected transplacentally in the 1st trimester of pregnancy is prone to multiple congenital defects, including heart disease, microcephaly with intellectual disability, and deafness. Ocular sequelae include cataracts, glaucoma, and chorioretinitis. Cataracts may be unilateral. Permanent visual impairment despite cataract surgery is common in these children. **Cytomegalovirus** (**CMV**) is the most common congenital infection in humans occurring in 1% of infants, although over 90% are asymptomatic and may not require treatment. Ophthalmic manifestations include retinochoroiditis, optic nerve anomalies, microphthalmos, cataract, and uveitis. CMV retinitis can be acquired in children who are immunocompromised.

Herpes simplex virus (**HSV**) may be acquired during passage through the birth canal or by close contact. Skin lesions on the eyelids (Fig. 32.23), keratoconjunctivitis, uveitis, or retinitis may occur. Acute retinal necrosis may occur in conjunction with CNS involvement. Keratitis is treated with topical antivirals, while systemic disease or retinitis is treated with oral or intravenous antiviral therapy. **Congenital syphilis** may occur following maternal infection. Early eye involvement is rare and symptoms may occur as late as adolescence. Chorioretinitis appears as a salt-and-pepper granularity. Uveitis, glaucoma, or interstitial keratitis may occur. Affected children are treated with intravenous penicillin G and monitored until serologic tests become nonreactive or the titer has decreased 4-fold.

Ophthalmia neonatorum is defined as conjunctival infection or inflammation occurring in the 1st month of life. Almost any bacterial pathogen can cause conjunctivitis in a newborn, but infection with *Neisseria gonorrhoeae* is of particular concern because it produces a hyperacute, profusely purulent conjunctivitis that can lead to corneal perforation and blindness. The US Preventative Services Task Force recommends prophylactic topical 1% tetracycline or 0.5%

FIGURE 32.23 Vesicular eruptions of the right lower eyelid and the right side of the nose, caused by primary herpes simplex infection. The cornea was not involved.

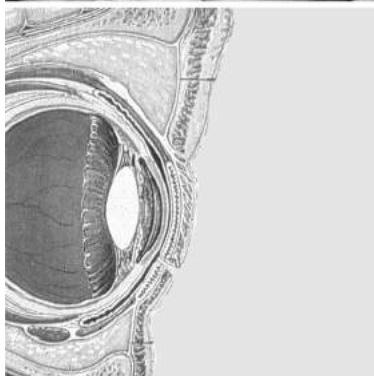

FIGURE 32.24 Preseptal cellulitis in a young girl. The infection is confined to the space anterior to the superior and inferior orbital septa and does not involve the orbit.

FIGURE 32.25 A subperiosteal abscess of the left orbit *(top image)*. Note the limitation of upward movement of the left eye *(middle image)*. The computed tomographic scan shows ethmoid sinusitis and a subperiosteal abscess bowing the left medial rectus muscle laterally *(bottom image; arrow)*.

erythromycin ointment, administered within 24 hours after birth for prevention of gonococcal neonatorum. A 2.5% solution of povidone-iodine is used effectively and inexpensively in other countries but has not been approved for this use in the United States at this time. *Chlamydia trachomatis* (also known as trachoma–inclusion conjunctivitis or TRIC) is a common cause of neonatal conjunctivitis and is acquired from an infected cervix during delivery. Because this organism can also cause pneumonia, systemic treatment with oral erythromycin is indicated for treatment. In a child presenting with ophthalmia neonatorum it is important to obtain the history of whether prophylaxis has been given, particularly in cases of home births where this is unlikely. Evaluation with Gram and Giemsa stains and bacterial cultures are indicated. Polymerase chain reaction (PCR) testing can be done for suspicion of HSV infection. *Chlamydia* can be diagnosed by culture, fluorescent antibody-staining techniques, or enzyme immunoassays.

Preseptal cellulitis, defined as infection confined to the eyelid tissues anterior to the orbital septum, is a common infection in children and needs to be distinguished from infection involving the orbit (Fig. 32.24). Preseptal infections may result from trauma and insect bites involving the eyelids, severe conjunctivitis, primary bacteremia,

upper respiratory infection or they may spread to the eyelids from the paranasal sinuses. The affected eyelids are swollen and red, and the infection can spread further into the eyebrow, forehead, and cheek. Proptosis and limitation of eye movements do not occur in preseptal cellulitis, but confirmation of this can be problematic because of the difficulty of opening the eye. *S. aureus,* group A streptococcus, and *S. pneumoniae* are the most common pathogens. Patients with signs and symptoms of systemic toxicity should be hospitalized for intravenous antibiotics; milder cases of preseptal cellulitis may be managed with oral antibiotics as long as appropriate follow-up is ensured.

Orbital cellulitis is an infection of the orbit that involves the tissues posterior to the orbital septum. Most frequently, this is a result of spread of infection from the ethmoid or frontal sinuses. Ocular signs include eyelid edema and erythema, proptosis, and inferior and lateral displacement of the globe with limited eye movements. Ocular movement is painful; visual activity may be reduced. If orbital cellulitis is suspected, computed tomography of the orbit and sinuses is indicated. Children younger than 9 years are more likely to have an infection caused by a single aerobic pathogen, whereas children older than 9 years may have complex infections with multiple pathogens. Often, orbital cellulitis begins as a subperiosteal abscess that forms in the potential space between the periorbital (analogous to the periosteum of long bones) and the orbital bones (Fig. 32.25). Left untreated, this space-occupying mass can apply pressure to the optic nerve and cause permanent damage to vision. It can also spread into the intracranial space and result in a cavernous sinus thrombosis, a subdural empyema, or cerebral abscess. Systemic toxicity is quite common and severe with orbital cellulitis. Most children younger than 9 years who have small to medium-sized subperiosteal abscesses can be treated successfully with broad-spectrum intravenous antibiotics (ceftriaxone and vancomycin, ampicillin/sulbactam, or piperacillin/tazobactam). Close observation with periodic checks of vision and pupillary function is important in the 1st 24-48 hours of treatment. Older children, those with large subperiosteal abscesses, and children who fail to respond to intravenous antibiotics within 48 hours require surgical drainage of

the abscess. Emergency drainage is indicated in a patient of any age where there is compromise of the optic nerve.

NYSTAGMUS

Nystagmus is defined as an involuntary rhythmic, to-and-fro movement of the eyes. Horizontal nystagmus is the most common form of nystagmus, but vertical nystagmus and torsional nystagmus also occur (Table 32.18). Nystagmus may be congenital or acquired. Gaze positions can affect the eye movement. Congenital nystagmus is somewhat of a misnomer because the abnormal eye movements are generally not noted until an infant is 1 or 2 months of age, when the fixation reflex becomes established. Non-nystagmus eye movements are noted in Table 32.19.

Congenital motor nystagmus is often idiopathic; in this case, visual acuity is only moderately impaired, and the fundus examination findings and the electroretinogram are normal. Usually an affected individual will have a null point or a preferred position in which the eye movements are minimized. This may affect the head position as the patient tries to keep the eyes in the null point. In patients with congenital motor nystagmus there is often dampening or quieting of the nystagmus with convergence. Vision may be quite good (20/40 or better) in the patient's preferred gaze and head position. Sometimes surgery is done on the eye muscles to move them into a position such

that the head is straighter. A family history of nystagmus can frequently be ascertained.

Congenital sensory nystagmus occurs with disorders that impair normal image formation (bilateral congenital cataracts) or image processing in both eyes (a retinal dystrophy or bilateral optic nerve atrophy or hypoplasia). Eye movements may be searching and there is no null point. Visual acuity is more severely impaired than in idiopathic congenital nystagmus (20/200 or less), and visual loss may be progressive in some instances. The evaluation of a child with congenital nystagmus entails a thorough health and family history, a general physical examination, and an eye examination by an ophthalmologist with expertise in pediatric eye disorders. A cranial magnetic resonance imaging scan is indicated when the hallmark signs of congenital motor nystagmus such as a null point and dampening of nystagmus on convergence are not yet identifiable and there are no eye findings to suggest a specific pathology such as cataract. Electroretinography, visual evoked potentials (VEPs), or optical coherence tomography (OCT) may be useful in establishing a specific diagnosis.

Acquired nystagmus is less common than congenital nystagmus. Nystagmus that is truly acquired beyond the 1st few months of life is of concern and may represent a significant neurologic abnormality. It may be caused by central nervous system disorders, particularly of the cerebellum, brainstem, or suprasellar region. In children, the most common tumor causing acquired nystagmus is a craniopharyngioma.

TABLE 32.18 Specific Patterns of Nystagmus

Pattern	Description	Associated Conditions
Latent nystagmus	Conjugate jerk nystagmus toward viewing eye	Congenital vision defects, occurs with occlusion of eye
Manifest latent nystagmus	Fast jerk to viewing eye	Strabismus, congenital idiopathic nystagmus
Periodic alternating	Cycles of horizontal and horizontal-rotary movements that change direction	Caused by both visual and neurologic conditions
Seesaw nystagmus	One eye rises and intorts as other eye falls and extorts	Usually associated with optic chiasm defects
Retraction nystagmus	Eyes jerk back into orbit or toward each other	Caused by pressure on mesencephalic tegmentum (Parinaud syndrome)
Gaze-evoked nystagmus	Jerk nystagmus in direction of gaze	Caused by medications, brainstem lesion, or labyrinthine dysfunction
Gaze-paretic nystagmus	Eyes jerk back to maintain eccentric gaze	Cerebellar disease
Downbeat nystagmus	Fast-phase beating downward	Posterior fossa disease, drugs
Upbeat nystagmus	Fast-phase beating upward	Brainstem and cerebellar disease, and some visual conditions
Vestibular nystagmus	Horizontal-torsional or horizontal jerks	Vestibular system dysfunction
Asymmetric or monocular nystagmus	Pendular vertical nystagmus	Disease of retina and visual pathways
Spasmus nutans	Fine, rapid, pendular nystagmus	Torticollis, head nodding; idiopathic or gliomas of visual pathways

TABLE 32.19 Specific Patterns of Non-Nystagmus Eye Movements

Pattern	Description	Associated Conditions
Opsoclonus	Multidirectional conjugate movements of varying rate and amplitude	Hydrocephalus, diseases of brainstem and cerebellum, neuroblastoma
Ocular dysmetria	Overshoot of eyes on rapid fixation	Cerebellar dysfunction
Ocular flutter	Horizontal oscillations with forward gaze and sometimes with blinking	Cerebellar disease, hydrocephalus, or central nervous system neoplasm
Ocular bobbing	Downward jerk of eyes from primary gaze; eyes remain for a few seconds, then drift back	Pontine disease
Ocular myoclonus	Rhythmic to-and-fro pendular oscillations of the eyes, with synchronous nonocular muscle movement	Damage to red nucleus, inferior olivary nucleus and ipsilateral dentate nucleus

Vertically oriented nystagmus is also of concern; it may be associated with the Arnold-Chiari malformation or with pharmacologic agents such as lithium, tranquilizers, or anticonvulsants.

Spasmus nutans is a special form of acquired nystagmus with onset in the 1st 2 years of life. The usual triad of findings consists of nystagmus (often a shimmering type of nystagmus that is frequently asymmetric or even monocular), head nodding, and torticollis. This form of nystagmus is generally benign and disappears by the age of 3-4 years. In some cases, spasmus nutans can be associated with chiasmal or suprachiasmal or retinal dystrophies. Neuroradiologic investigation is indicated.

Opsoclonus is a special form of eye movement abnormality that is not truly nystagmus in that the bizarre, seemingly random oscillations of the eyes are not rhythmic and are frequently multivectorial. The most common cause of opsoclonus in children is acute cerebellar ataxia. The child presents with "dancing eyes and dancing feet." Opsoclonus can occur also with occult neuroblastoma, as a paraneoplastic phenomenon, viral encephalitis, and hydrocephalus.

OCULAR TRAUMA

Trauma is a major cause of acquired visual loss in children. Ninety percent of trauma cases are preventable and 50% occur in the home. The nature of the traumatic injury varies by age but there is a persistent male preponderance. In school-aged children, sports-related injuries are the most common cause of ocular injury accounting for 25% of hospitalizations. There is some effort to reduce injuries by legislation. For instance, the incidence of eye injuries from ice hockey are almost zero since the institution of mandatory face masks in children playing organized hockey. Projectile injuries from firearms, air guns, and fireworks are relatively frequent in the United States, however, these injuries are very rare in countries without easy access to guns or fireworks.

The extent of the eye examination is determined by the child's level of cooperation. If the circumstances of the injury suggest a high likelihood of a perforating injury (from a sharp object that could go through the cornea or sclera), the eye should not be forced open but rather, should be covered with a protective shield to prevent further injury until the child can be seen by an ophthalmologist and an exam under anesthesia can be done if necessary. If a perforating injury is considered unlikely (a blunt or scratching type of injury), a sterile, topical ophthalmic anesthetic agent can be applied to the eye to reduce surface pain, which is a major cause of the child's reluctance to open the eye. The eye can then be inspected for foreign bodies or corneal abrasion. Fluorescein dye may be of help in diagnosing a corneal abrasion. The fluorescein may have linear pattern of staining that suggests a foreign body may be on the tarsal conjunctiva under the upper eyelid and during an eye blink the cornea is being abraded. Lid eversion is needed to investigate this possibility. The inferior fornix should also be inspected for foreign bodies.

Corneal or conjunctival foreign bodies can sometimes be irrigated out of the eye. Otherwise the foreign body may be removed at a slit lamp using topical anesthesia if the patient is cooperative. If not, the patient will require anesthesia. Management of a corneal abrasion entails relief of pain, prevention of infection, and promotion of healing of the corneal epithelium. Ibuprofen or similar analgesics are usually sufficient for pain relief. Topical anesthesia, while used in the office, should not be used at home as it prevents epithelial healing and can be toxic to the cornea with longer-term use. A drop of a cycloplegic agent (cyclopentolate) may provide comfort by relieving ciliary spasm. Application of a topical antibiotic ointment such as erythromycin helps prevent infection and provides lubrication to the ocular surface

to allow the new epithelium to form and adhere to the basement membrane of the cornea. Patching the eye has not been shown to be of benefit. Close follow-up is indicated to make sure that the cornea is healing and has not developed an infection that could lead to a corneal ulcer. Most abrasions heal completely within 24-48 hours.

Hyphema

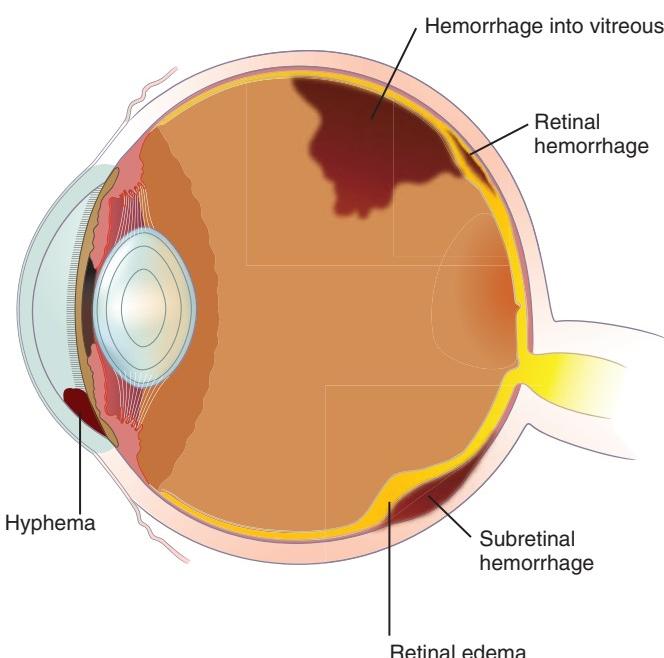
Any child with blunt trauma to the eye should be evaluated for blood in the anterior chamber of the eye, known as a hyphema (Fig. 32.26). The visual acuity of the injured eye should be measured as possible. The anterior segment and pupillary function should be assessed if the hyphema only partially fills the anterior chamber. Funduscopy should be attempted to look for associated retinal hemorrhage, edema (Fig. 32.27), or detachment. The view of the retina may be obscured by


FIGURE 32.26 Various types of ocular hemorrhage after blunt trauma to the globe. (From Reilly BM. *Practical Strategies in Outpatient Medicine.* 2nd ed. Philadelphia: WB Saunders; 1991:68.)

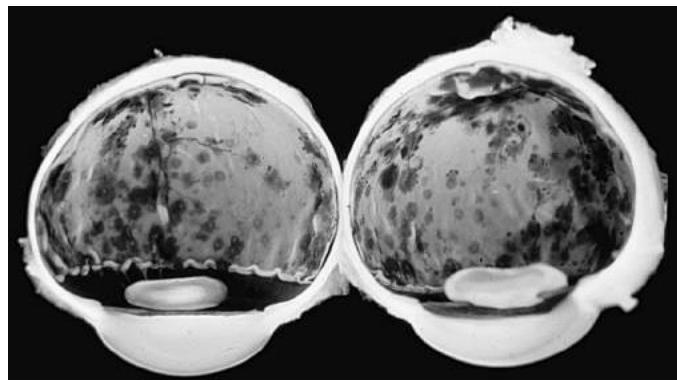
FIGURE 32.27 Hemorrhage and edema of the retina from blunt ocular trauma (commotio retinae).

blood. If necessary, ultrasound can be used to determine if the retina is attached. Usually the blood will resolve if the patient can limit his or her activity. The complications of hyphema include glaucoma, corneal blood staining, and rebleeding. The glaucoma may be managed initially with topical medications but the blood may need to be washed out of the anterior chamber surgically if the intraocular pressure cannot be controlled, blood is not resolving, or corneal blood staining is severe and threatening vision.

Eye Injuries in Child Abuse

In cases of child abuse, the presenting sign may involve the eye. Ocular injuries are also detected in the course of examining many other child abuse injuries. Blunt injuries to the eyelids and anterior segment of the eye from fingers, fists, or belts may cause eyelid ecchymosis, subconjunctival hemorrhage, hyphema, cataract, and lens dislocation. The finding of such an injury should alert the physician to the possibility of child abuse. Abusive head trauma is caused by forceful acceleration and deceleration motion such as shaking, which results in subdural hemorrhage and retinal or vitreous hemorrhages (Fig. 32.28). The vitreous is adherent to the retina and the traction of the moving vitreous results in multiple retinal hemorrhages, often in all layers of the retina. In severe cases, the optic nerve may be avulsed. Vitreous or retinal hemorrhage may take a long time to resolve and the child is at risk for amblyopia during the time the vision is obscured by blood. In cases of persistent hemorrhage, a vitrectomy may need to be done to clear the blood in the visual axis. Cortical brain damage also has a role in limiting visual function. Fewer than half of the patients diagnosed with abusive head trauma with retinal or vitreous hemorrhage see better than 20/40 after recovery.

Functional Vision Loss

Some patients complain of vision loss or blurring or other visual disturbances (seeing spots, colors, or patterns) while the eye exam is normal. Functional visual disturbances occur most commonly in girls of ages 8-15 years. The key to confirming functional vision loss is to demonstrate objective findings that indicate better vision than the subjective responses. The patient's responses to visual acuity testing are frequently inconsistent. Stereoacuity testing may demonstrate better visual acuity than the patient is reporting. There are several examining techniques that the ophthalmologist can employ to get this information. There are also objective tests available to further delineate etiologies of possible vision loss; however, these are rarely needed. These include imaging tests such as OCT, fluorescein angiogram, electroretinogram (ERG), or VEPs. The relationship of functional vision loss


to true psychologic disease is unclear but it is worth keeping in mind that there is a higher incidence of functional vision loss in children who are experiencing psychologic stressors. Some children willfully complain of vision loss because they want glasses. The treatment should consist of reassurance. It may be of benefit to refer the patient to a psychiatrist if the symptoms do not subside.

VISUAL COMPLAINTS FROM CHILDREN

Frequently, a child is brought to the pediatrician because of a subjective visual complaint from the child rather than because of an abnormality observed by a parent. Symptoms associated with reading are common and include seeing blurred print, words "swimming" together, and skipping words or lines. Other children complain primarily of blurred distance vision. Uncommon visual phenomena may include seeing colored lights, objects appearing larger or smaller, seeing spots, and double vision. Eye pain localized to 1 or both eyes is also common. There may be physiologic explanations for each of the complaints, and the child is usually interested in an explanation of the reason proposed for his or her complaint. A careful history of the exact nature of the complaint and any associated concerns should be sought and a screening eye examination performed. Specifically, distance and near visual acuity should be measured in each eye. A cover test or stereopsis test rules out manifest strabismus. An external eye examination may reveal a reason for eye pain (conjunctival injection, tearing, corneal abrasion, foreign body). Pupillary reactions should be assessed. Funduscopy should be done to evaluate optic nerve and retinal status. A color vision test may be helpful. Having the child read an age-appropriate passage may reveal information about the child's reading ability and the

FIGURE 32.28 Gross pathologic specimen from an infant who died of shaken baby syndrome. Note the diffuse retinal hemorrhages.

TABLE 32.20 Concerning Symptoms and Signs That Should Raise Red Flags	
Symptom or Sign	**Most Worrisome or Urgent Cause**
Leukocoria	Retinoblastoma
Acute onset of strabismus	Cranial nerve palsy from brain tumor, ↑ICP
Acute vision loss	Compression or infiltration of optic nerve by an orbital or intracranial lesion
Proptosis	Rhabdomyosarcoma
Sudden onset of ptosis	3rd nerve palsy from tumor, ↑ICP
Severe headaches	↑ICP
Black eye	Trauma with associated hyphema
Light sensitivity	Uveitis
Head tilt or turn	Cranial nerve palsy causing strabismus, ↑ICP
Loss of corneal luster	Corneal edema from glaucoma or uveitis
Purulent conjunctivitis in a newborn	Gonococcal infection
Acquired anisocoria	Horner syndrome caused by neuroblastoma, ↑ICP
Bilateral cataracts in a newborn	Galactosemia
Retinal hemorrhage in an infant or toddler	Shaken baby syndrome
Onset of nystagmus after early infancy	Brainstem or posterior fossa tumor

↑ICP, increased intracranial pressure.

severity of the reading complaint. If the examination is normal, simple reassurance may ease the concerns of the child and parent, particularly if combined with an offer to follow up on the complaint if it persists or if the parent notes objective changes in the child's eyes. If difficulty reading persists despite correction of any refractive error and an otherwise normal eye exam, the child may have learning disabilities that warrant further evaluation. Behavioral vision therapy has not been proven to improve reading skills, learning disabilities, or dyslexia.

SUMMARY AND RED FLAGS

Ocular manifestations of vision loss, strabismus, and nystagmus may be caused by isolated ocular pathologic processes or by significant systemic disease. Vision screening and basic evaluations done in the pediatrician's office are important for detection of vision loss. Impaired visual function resulting from strabismus, cataracts, or other conditions may produce amblyopia and blindness. It is important to detect amblyopia because in most cases, amblyopia is reversible if discovered early and treated appropriately. Symptoms and signs that suggest potentially life- or vision-threatening diseases are listed in Table 32.20.

Arthritis

James Nocton and Dominic Co

INTRODUCTION

Although children with musculoskeletal complaints may present with what appears to be an isolated, localized problem, complaints involving the musculoskeletal system (e.g., arthralgia, myalgia, joint swelling, poorly localized extremity pain, limping, refusal to walk) may be associated with a long list of potential illnesses. Children or their parents rarely arrive in the clinic with a complaint of arthritis or patellofemoral syndrome. Instead, they have symptoms such as extremity pain, joint swelling, or limitations of activity and function. These children may have chronic inflammatory arthritis or an associated systemic rheumatic disease, a traumatic condition, a mechanical problem, or a pain syndrome, among other possible explanations.

The differential diagnosis of extremity pain is extensive (Table 33.1). For many of these diagnoses, the history and physical examination are sufficient to confirm a diagnosis; for others, specific laboratory tests or imaging studies will confirm a suspected diagnosis. Musculoskeletal symptoms may indicate pathologic processes localized and restricted to a single extremity or joint, or localized symptoms may be a component of a systemic illness.

Arthritis is a specific sign indicating objective inflammation of the joint, and can be defined as (1) swelling of the joint or (2) limitation of motion combined with 1 of the following: pain on motion, tenderness, or warmth. Arthritis should be distinguished from arthralgia (Table 33.2), bone pain, myalgia, and neuralgia, because if arthritis is present, the diagnostic possibilities are limited to more specific categories of disease (Fig. 33.1). Arthritis is not a specific disease; there are infectious, postinfectious/reactive, hematologic, metabolic, oncologic, and rheumatic causes of arthritis. The precise diagnosis is determined by 1st establishing the characteristics of the arthritis with respect to the number and location of joints involved, severity, degree of disability, and chronicity. The clinician combines these characteristics with the history and the pattern of any associated systemic signs and symptoms to determine the specific cause of arthritis.

◆ History

Although the parents and child are usually the principal historians, it is often helpful to determine whether other adults have seen signs or have been aware of the child's symptoms. Have daycare providers reported problems to the parents? Has the school staff, coach, or physical education teacher noticed any problems similar to those seen at home? Obtaining consistent information from several observers in different settings determines the frequency and consistency of the symptoms, how disabling the symptoms have been, and the reliability of the history. Adolescents have a tendency to either underreport or overreport their symptoms, making the history especially challenging within this age group. If there are inconsistencies, it becomes increasingly difficult to formulate a diagnosis, and information from the physical examination, along with potential laboratory and imaging studies, may be needed to resolve the inconsistencies.

Pain Location

There are several possible sources of extremity pain (Fig. 33.2). Pain directly over a joint or joints may indicate synovial inflammation, arthralgia secondary to viral infection, or mechanical joint problems such as ligament trauma, meniscal tears, or hypermobility. Pain near a joint may represent disease in the muscle, bone, tendon, enthesis (tendon insertion sites), or bursa, or may be referred from a nearby joint. Pain may involve a whole limb or limbs, or isolated regions thereof, in which case it may reflect neuropathy, myalgia, or a regional pain syndrome. On occasion, children complain of pain "all over," which may suggest diffuse myalgia related to a systemic infection, or if chronic, a myofascial pain syndrome. Intense pain localized to a single small area is seen with infection, trauma, fracture, or tumor. Migrating arthritis or arthralgia is more suggestive of diagnoses such as acute rheumatic fever or immune complex–mediated disease, and is less consistent with trauma, tumors, osteomyelitis, or septic arthritis, with the exception of septic arthritis secondary to *Neisseria gonorrhoeae* infection.

Pain Character

Arthritis is an aching discomfort that is usually not severe enough to cause crying or screaming. Some children with arthritis may not complain of pain at all. Very severe pain should increase the suspicion of a pain syndrome or bone disease such as osteomyelitis, leukemia, metastatic neuroblastoma, fracture, or bone tumors. Sporadic episodes of extreme pain interspersed with pain-free intervals are seen with pain syndromes such as growing pains, myofascial pain, and complex regional pain syndrome, or in situations in which psychogenic and behavioral factors contribute to the pain. With some pain syndromes, children often rate their pain as 10 on a scale of 0-10 and also may state that the pain is constant. Some patients may demonstrate "la belle indifference," an incongruity between their affect and their complaint; they may be smiling or laughing while they are describing the presence

(See *Nelson Textbook of Pediatrics,* p. 1162.)

TABLE 33.1 Conditions Causing Arthritis or Extremity Pain

Rheumatic and Inflammatory Diseases
Juvenile idiopathic arthritis
Systemic lupus erythematosus
Juvenile dermatomyositis
Polymyositis
Polyarteritis nodosa
Scleroderma
Sjögren syndrome
Behçet disease
Overlap syndromes
Granulomatosis with polyangiitis
Microscopic polyangiitis
Sarcoidosis
Kawasaki disease
Henoch–Schönlein purpura
Chronic recurrent multifocal osteomyelitis

Infectious Illnesses
Bacterial arthritis (e.g., *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Kingella kingae*, *Neisseria gonorrhoeae*, *Haemophilus influenzae*)
Lyme disease
Viral illness (e.g., parvovirus, rubella, mumps, Epstein–Barr virus, hepatitis B, Chikungunya fever)
Fungal arthritis
Mycobacterial infection

Hematologic Disorders
Hemophilia
Hemoglobinopathies (including sickle cell disease)

Immunodeficiencies
Hypogammaglobulinemia
Immunoglobulin A deficiency
Human immunodeficiency virus
Common variable immunodeficiency

Congenital and Metabolic Disorders
Gout
Pseudogout (calcium pyrophosphate dihydrate crystal deposition disease)
Mucopolysaccharidoses
Glycogen storage diseases
Thyroid disease (hypothyroidism, hyperthyroidism)
Hyperparathyroidism
Vitamin C deficiency (scurvy)
Vitamin D deficiency (rickets)
Hereditary connective tissue disease (Marfan syndrome, Ehlers–Danlos syndrome)
Fabry disease
Farber disease

Orthopedic Disorders
Trauma
Patellofemoral syndrome
Hypermobility syndrome
Osteochondritis dissecans
Avascular necrosis (including Legg–Calvé–Perthes disease)
Hypertrophic osteoarthropathy
Slipped capital femoral epiphysis
Osteolysis
Benign bone tumors (including osteoid osteoma)
Histiocytosis

Neuropathic Disorders
Peripheral neuropathies
Carpal tunnel syndrome
Charcot joints (neuropathic osteoarthropathy)

Neoplastic Disorders
Leukemia
Neuroblastoma
Lymphoma
Bone tumors (osteosarcoma, Ewing sarcoma)
Histiocytic syndromes
Synovial tumors

Reactive Arthritis
Acute rheumatic fever
Postinfectious
Serum sickness
Transient synovitis of the hip
Postimmunization

Pain Syndromes
Fibromyalgia
Growing pains
Depression (with somatization)
Anxiety
Stress
Complex regional pain syndrome
Myofascial pain syndromes

Miscellaneous Disorders
Pigmented villonodular synovitis
Plant-thorn synovitis (foreign body arthritis)
Myositis ossificans
Eosinophilic fasciitis
Tendonitis (overuse injury)
Raynaud phenomenon
Erythromelalgia

TABLE 33.2 Distinguishing Characteristics of Arthritis and Arthralgia

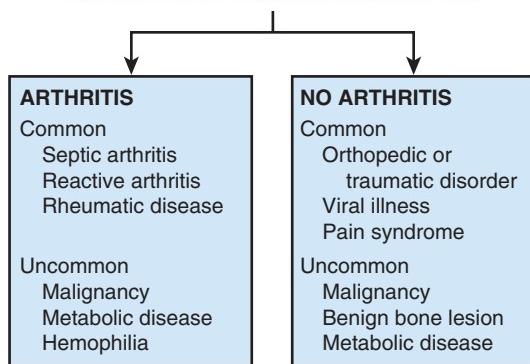
Arthritis	Arthralgia
Prominent swelling	Minimal or no swelling
Morning stiffness	No morning stiffness
Symptoms improve with activity	Symptoms are exacerbated by activity
Stiffness follows rest	Pain constant or improves with rest
Limited range of motion	Normal or excessive range of motion
Warmth of joint	No warmth
Symptoms usually daily, consistent	Symptoms variable, constant, or intermittent


FIGURE 33.1 Algorithm for determining the cause of extremity pain based on the presence or absence of arthritis.
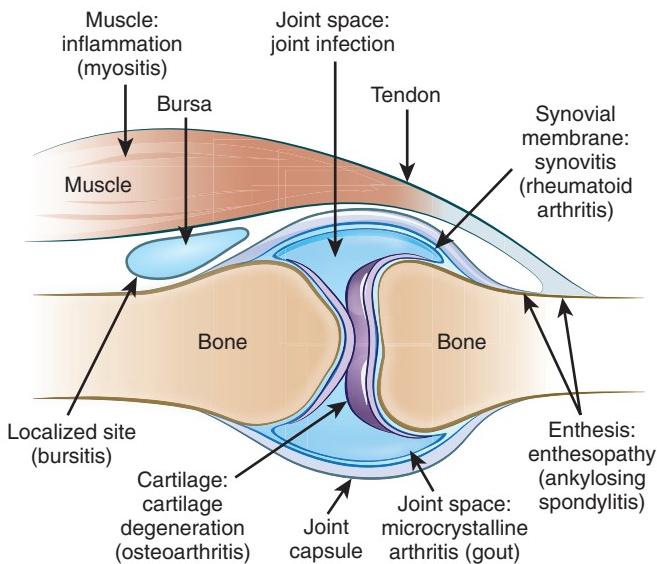

FIGURE 33.2 Location of musculoskeletal disease processes by site, pathophysiologic process, and typical disease *(parentheses)*. (From Fries JF. Approach to the patient with musculoskeletal disease. In: Wyngaarden JB, Smith LH, Bennett JC, eds. *Cecil Textbook of Medicine.* 19th ed. Philadelphia: WB Saunders; 1992:1488.)

of excruciating discomfort. Sharp, radiating, or throbbing pain is very unusual for arthritis and suggests an alternative explanation such as neuropathic pain, trauma, or psychogenic pain.

Pain Timing

Arthritis usually causes consistent patterns of discomfort. Symptoms are present daily, though with day-to-day variability in severity.

Stiffness or pain-related discomfort occurs on awakening in the morning or after other periods of inactivity, such as prolonged sitting in class or taking a long car ride. The stiffness may last for hours, but generally improves with activity during the day. Some forms of arthritis, such as Lyme arthritis or enthesitis-related arthritis, may be more episodic. Lyme arthritis classically causes symptoms for days to weeks, usually in a single knee, interspersed with periods of improvement. Enthesitis-related arthritis can cause sudden increases in swelling and discomfort of 1 or more joints for several weeks to months at a time, followed by gradual spontaneous improvement.

Discomfort that occurs with activities and improves with rest is more suggestive of mechanical pain such as that associated with patellofemoral syndrome, hypermobility, tendonitis, overuse, or muscle strain. Affected children do not have significant symptoms in the morning or after naps, and these conditions are generally not associated with signs of significant inflammation such as warmth, prominent swelling, or limited range of motion.

Nocturnal pain that wakes children from sleep may be seen in potentially serious conditions such as leukemia, bone tumors (including benign tumors such as osteoid osteoma), or infections, but may also occur with benign conditions such as growing pains, muscle cramps, or behaviorally mediated pain. Children with benign causes of pain tend to lack systemic symptoms, are well during the day, and have normal physical examination findings, whereas those with more serious illnesses typically have additional symptoms to suggest the diagnosis.

Pain Acuity

Most chronic arthritis is insidious, and affected children often have symptoms for weeks to months before they seek medical attention. If the onset is sudden and severe, the evaluation should focus on excluding diagnoses that require urgent treatment, such as trauma, fracture, septic arthritis, or osteomyelitis. Acute rheumatic fever, reactive arthritis, and viral-associated arthritis or myositis may also manifest suddenly.

Children who describe having extremity pains "for years" often have mechanical causes of their discomfort such as hypermobility syndrome or patellofemoral syndrome, psychogenic or behavioral causes of pain, or other relatively benign conditions such as growing pains. It is very rare for such children to have an unrecognized arthritis.

Signs of Inflammation

The swelling and warmth of arthritis are often apparent to the child and parents. Exceptions may include the shoulder and hip, in which the joints are too deep for these signs to be visible, and the spinal, temporomandibular, and sacroiliac joints, in which the articular surfaces are small in relation to the surrounding soft tissues. In these areas, physical examination may reveal tenderness or limitation of motion in the absence of reported signs of inflammation.

Disability

The chief complaint may often be a disability such as limping, trouble climbing stairs, or difficulty writing. Some children will have associated pain and signs of inflammation, whereas others have little or no discomfort and it may be that they or their family have simply noticed a decrease in functional ability.

If the chief complaint is the disability, it is helpful to localize the source of the disability to the joint, the bones, the muscles, or the nerves. Muscle or nerve disease manifests primarily as weakness, although some children with sensory neuropathies or myositis, particularly acute viral myositis, will also have pain. Dermatomyositis and polymyositis cause symmetric proximal weakness in the upper and lower extremities. The characteristic symptoms are difficulties

climbing stairs, rising from the floor, taking the big step onto a bus or into the family minivan, and washing or combing the hair, as well as fatigue and poor endurance. Isolated lower extremity or asymmetric weakness should increase suspicion of neurologic disease.

Disabilities from arthritis are caused by limited range of motion or discomfort in the joint rather than weakness. Limping, particularly in the mornings, toe-walking because of inability to extend the knee or Achilles tendon, and having difficulty running and jumping are seen with lower extremity arthritis. The child with hand or wrist arthritis has difficulty opening bottles, turning doorknobs, manipulating buttons or snaps on clothing, and gripping pencils or utensils.

Medical History

Numerous genetic syndromes and metabolic diseases are associated with arthritis and arthropathy (see Table 33.1). Endocrine disorders such as diabetes, hyperparathyroidism, and hypothyroidism are associated with arthropathy, periosteal inflammation, and muscle weakness, respectively. Arthritis is more frequent in patients with psoriasis and inflammatory bowel disease. Bone pain is common in hemoglobinopathies such as sickle cell disease. Cystic fibrosis and other chronic pulmonary diseases increase the likelihood of painful hypertrophic osteoarthropathy: the clinical triad of arthritis, digital clubbing, and ossifying periostitis of the long bones. Arthritis or arthralgia may occur after viral diseases or immunization, particularly with immunization against rubella and hepatitis B, presumably secondary to immune complex deposition in the joint.

Medications

Medications may directly cause symptoms, either via serum sickness-like reactions or swelling related to anaphylaxis. Response to medications may also provide further insight into the etiology of arthritis. In most children, an adequate dose of nonsteroidal antiinflammatory drugs (NSAIDs) improves the discomfort of arthritis to some degree. In rheumatic fever, NSAIDs often result in dramatic improvement in symptoms. Conversely, the patient who continues to have severe pain despite adequate doses of antiinflammatory and analgesic medication is more likely to have an infection, a fracture, a tumor, or psychogenic pain.

Family History

For some diseases, a positive family history increases the likelihood that other individuals in the family have that disease, but the genetics of the rheumatic diseases are complex, and none of the genetic associations are strong enough to confirm or eliminate a diagnosis solely on the basis of the family history. Within the rheumatic diseases, the family history is most helpful when diagnostic possibilities include enthesitis-related arthritis, psoriatic arthritis, or lupus. Ankylosing spondylitis, reactive arthritis, or inflammatory bowel disease in the family increases the likelihood that the child's arthritis is related to 1 of these entities. The presence of the human leukocyte antigen (HLA)-B27 in these family members may increase the likelihood of enthesitis-related arthritis in the child. Approximately 30% of patients with lupus will have a 1st-degree relative affected by lupus. Less common familial illnesses that may cause rheumatic complaints include familial Mediterranean fever, mucopolysaccharidoses, hemophilia, and muscular dystrophies. A family history of adults with osteoarthritis or other forms of degenerative arthritis is generally not helpful, since these entities are relatively common and very rarely relevant to a child's joint symptoms.

Social History

Determining the extent to which the problem has limited usual activities helps to gauge the severity of the problem. Has the child missed school because of their symptoms? Has the child been able to participate in physical education, organized sports, or other physical activities such as dancing, swimming, and gymnastics? Is the older child participating in social activities with friends? In some instances, the limitations are directly related to discomfort or disability from arthritis, but school absences and the discontinuation of sports and social activities may also be secondary to depression or psychogenic pain. It is helpful to ask the parents whether the child's mood or personality has changed recently and whether there have been any recent known psychosocial stressors such as problems at school or with friends or discord within the family. Chronic pain syndromes in children are frequently associated with a history of psychosocial stress as well as depression.

Travel history is important in considering Lyme disease because the causative agent, the spirochete *Borrelia burgdorferi*, is transmitted by the bite of a deer tick that has a restricted geographical distribution. Lyme arthritis characteristically causes episodic joint effusions in 1 or several large joints, most commonly the knee. A small percentage of patients develop chronic arthritis. In the United States, endemic regions include the northeast (Connecticut, Rhode Island, and Massachusetts), mid-Atlantic (Long Island, New York City suburbs, New Jersey, southeastern Pennsylvania, Delaware, and Maryland), and the upper Midwest (parts of Minnesota and Wisconsin). Although these endemic areas may be gradually expanding, a child who has not traveled to these areas is unlikely to have Lyme disease. Arthritis may be the only symptom of Lyme disease, and may not appear until up to 2 years after the tick bite; a history of the classic rash (erythema migrans) is helpful but not necessary for a diagnosis of Lyme disease.

Review of Systems
Constitutional Symptoms

Some rheumatic diseases, including several forms of childhood arthritis, are systemic illnesses and cause fevers, poor appetite, weight loss, and fatigue. The absence of these symptoms helps eliminate specific illnesses as diagnostic possibilities. When fevers are present, establishing the pattern of fever is important. Systemic juvenile idiopathic arthritis (JIA) typically produces 1 or 2 high temperature spikes each day, with many afebrile hours in between (Fig. 33.3). More persistent fevers tend to be seen with infections or Kawasaki disease. A periodic fever pattern, in which fevers occur for several days, followed by weeks without fever, is seen in familial Mediterranean fever, cyclical neutropenia, the syndrome of periodic fever, aphthous stomatitis, pharyngitis, and adenopathy (PFAPA), and other autoinflammatory syndromes. Systemic lupus erythematosus (SLE), vasculitis, rheumatic fever, serum sickness, inflammatory bowel disease, sarcoidosis, leukemia, and neuroblastoma may cause fevers associated with arthritis or extremity pains. These illnesses do not cause specific patterns of fever.

A decline in appetite is common in many arthritides, though when associated with documented weight loss may indicate more severe or systemic illness. Although most children with JIA do not have significant appetite changes, those with systemic JIA may have substantial appetite and growth disturbances. Severe polyarticular JIA may cause some appetite changes and mild weight loss. Children with Crohn disease or ulcerative colitis, both of which are often accompanied by abdominal pain and diarrhea, may demonstrate poor appetite and failure to thrive. SLE, vasculitis, scleroderma, malignancies, and chronic infections such as tuberculosis are additional causes of significant weight loss. An increase in weight should raise the suspicion of hypothyroidism or fluid retention.

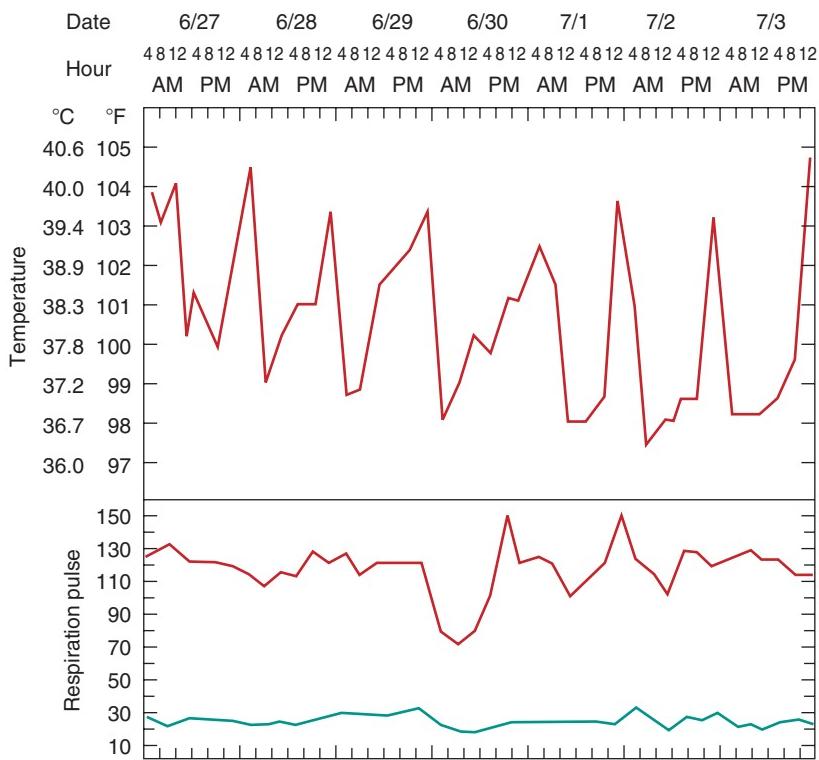
Fatigue is common with any systemic illness, and it may be present in systemic or polyarticular JIA, SLE, hypothyroidism, rheumatic fever, and chronic pain syndromes. The clinician should attempt to


FIGURE 33.3 Pattern of high, intermittent fever in a 3-year-old girl with systemic juvenile idiopathic arthritis (JIA). Most febrile spikes in this patient occurred in the late evening to early morning hours and were accompanied by a systemic JIA rash. (From Cassidy JT, Petty RE, Laxer RM, et al., eds. *Textbook of Pediatric Rheumatology.* 6th ed. Philadelphia: Elsevier; 2011:238.)

distinguish between generalized fatigue and specific muscle weakness. The presence of proximal muscle weakness, often associated with fatigue and poor endurance, is characteristic of polymyositis and dermatomyositis.

Skin Changes

Systemic JIA is nearly always accompanied by evanescent pink or salmon-colored macules, often a few centimeters in diameter or smaller but sometimes coalescing to form larger patches (Fig. 33.4). These may be generalized or localized to the trunk or extremities. The macules are usually not pruritic, appear with the fever spikes, and may resolve completely when the fever is absent. Sometimes parents do not notice the rash because of its fleeting nature. Acute rheumatic fever is associated with a specific rash, **erythema marginatum**, in only approximately 5% of cases. Erythema marginatum is also a fleeting rash, changing in distribution over time, and consists of erythematous patches with serpiginous borders that tend to migrate, usually over the trunk and proximal extremities. Because of their changes in distribution, families often confuse both of these rashes with urticaria. The **malar rash of SLE** is a fixed, erythematous, nonblanching patch over the cheeks and nasal bridge that tends to spare the nasolabial folds. SLE may also cause vasculitic rashes, as well as nonspecific erythematous macular or papular lesions. Vasculitic rashes consist of palpable purpura and can sometimes be ulcerative. The characteristic skin lesions in dermatomyositis are pathognomonic: a **heliotrope rash** is a purpuric discoloration of the upper eyelid, often accompanied by edema (Fig. 33.5); **Gottron papules** are erythematous plaques or papules that appear on the extensor surface of the metacarpophalangeal and proximal interphalangeal joints of the hands (Fig. 33.6). These are sometimes scaly and can be confused with

psoriasis or eczema, were it not for the distribution. Lesions similar to the Gottron papules occasionally also appear on the extensor surfaces of the elbows and knees and over the medial malleoli at the ankle. In addition, erythematous patches may appear on the shoulders, chest, or face, where the appearance can cause confusion with the malar rash of SLE.

Erythema migrans occurs in up to 80% of cases of Lyme disease, days to weeks after the tick bite. The lesion expands, beginning as a small papule and then forming a large erythematous, circular patch, usually at least 5 cm in diameter and often with some clearing in the center to produce a target-like appearance (Fig. 33.7). If Lyme disease is left untreated, the lesion usually lasts for several weeks and then gradually resolves. If dissemination occurs, some individuals develop multiple secondary lesions that appear similar to the primary lesion.

The history of other types of rashes or skin lesions may suggest other diagnoses. Measles and parvovirus infections, for example, have characteristic rashes. Petechiae may be seen with SLE, vasculitis, immune thrombocytopenia, or leukemia. Pallor or cyanosis of the digits, hands, and feet in association with cold temperature suggests **Raynaud phenomenon**, which is most often seen in those with no underlying systemic illness, but may be associated with several rheumatic diseases, most notably SLE and scleroderma. **Scleroderma** causes tightening, thickening, and the development of a waxy texture to the skin, and it frequently begins on the hands, feet, and face. A history of photosensitivity is suggestive of SLE.

Additional Symptoms

Questioning the parents about cognitive difficulties, including declining school performance or memory loss, helps screen for the possibility of subtle central nervous system involvement that may be associated

FIGURE 33.4 Systemic juvenile idiopathic arthritis rash, a salmon-colored, macular rash that is nonpruritic. The individual lesions are transient, appear in crops, and may be in a linear distribution after minor trauma such as scratching the surface of the skin (Koebner phenomenon). (From Cassidy JT, Petty RE, Laxer RM, et al., eds. *Textbook of Pediatric Rheumatology*. 6th ed. Philadelphia: Elsevier; 2011:238.)

FIGURE 33.5 Heliotrope discoloration and violaceous suffusion with edema of the upper eyelids in acute dermatomyositis. (From Cassidy JT, Petty RE, Laxer RM, et al., eds. *Textbook of Pediatric Rheumatology*. 6th ed. Philadelphia: Elsevier; 2011:384.)

FIGURE 33.6 Symmetric, scaly, erythematous papules over the metacarpopharyngeal and proximal interphalangeal joints of the hand in acute dermatomyositis. (From Cassidy JT, Petty RE, Laxer RM, et al., eds. *Textbook of Pediatric Rheumatology*. 6th ed. Philadelphia: Elsevier; 2011:385.)

FIGURE 33.7 Erythema migrans. Lesions begin as red macules that expand to form large rings that often have a typical "bulls-eye" appearance. (From Cassidy JT, Petty RE, Laxer RM, et al., eds. *Textbook of Pediatric Rheumatology*. 6th ed. Philadelphia: Elsevier; 2011:582.)

with SLE or vasculitis. Seizures or frank psychosis may also occur in these illnesses. Alopecia is frequently seen with SLE and may also occur with hypothyroidism. Ocular symptoms, such as pain or redness of the eye, may occur with uveitis. Acute anterior uveitis (involving the iris and/or ciliary body) can be seen with reactive arthritis and enthesitis-related arthritis. Chronic anterior uveitis is most common with oligoarticular JIA and is usually asymptomatic. Sarcoidosis in children is usually associated with posterior uveitis, although anterior uveitis also occurs. Ulcerations of the nose or hard palate may be present with SLE. Aphthous ulcerations can be seen with inflammatory bowel disease

and Behçet disease. Frequent sinusitis is often a manifestation of granulomatosis with polyangiitis.

Pleuritic chest pain that is worse when the patient lies supine and improves with sitting up and leaning forward may represent pericarditis, which can be seen in systemic JIA and SLE. Dysphagia suggests esophageal dysmotility, which may occur with inflammatory myopathies and scleroderma. Asking whether the child needs to cut food into small pieces, needs to drink an unusual amount of fluid with meals, or takes a long time to complete a meal are helpful ways of assessing dysphagia. Abdominal pain, vomiting, and diarrhea are nonspecific, but if severe or associated with melena or hematochezia, suggest Henoch–Schönlein purpura (HSP), inflammatory bowel disease, polyarteritis nodosa with vasculitis of the intestine, or the rare intestinal vasculitis associated with dermatomyositis. Testicular pain is seen with some forms of vasculitis, particularly HSP and polyarteritis nodosa. A history of recurrent genital and oral ulcerations is highly suggestive of Behçet disease. Peripheral edema, sacral edema, or periorbital edema may be present with illnesses causing glomerulonephritis, such as SLE and some of the vasculitides.

◆ Physical Examination

Observing the child ambulate or explore the examination room provides a sense of the severity of the illness and the degree of disability. Particularly with young, fearful children, this period of observation may give a better sense of the range of motion or the degree of discomfort in the joints than the formal examination, when the child may be uncooperative.

The examination begins by reviewing the vital signs. Fever, especially in the child with arthritis or localized extremity pain, may suggest an infectious process. Tachycardia may be caused by fever, anxiety, pericarditis, or myocarditis. Tachypnea suggests the presence of cardiac or pulmonary disease and hypertension increases the suspicion of renal disease.

In any child with joint complaints, it is important to examine all of the joints because arthritis may be detected in joints that have not had symptoms. The neck and the joints of the upper extremities are best examined with the child in a sitting position. Children with inflammation in the joints of the cervical spine usually have limitations in extension, lateral flexion, and rotation. This is tested by asking the child to look up at the ceiling, touch each ear to the ipsilateral shoulder, and touch the chin to each shoulder.

Arthritis of the temporomandibular joint is common with polyarticular JIA and might easily be overlooked. Children with chronic arthritis of these joints develop micrognathia and often retrognathia as a result of delayed mandibular growth. The oral opening is often decreased, and there may be pain with opening and closing of the jaw, and tenderness to palpation directly over the joint.

Shoulder arthritis is identified by detecting limited range of motion and pain with motion. With the upper arm abducted to 90 degrees and the elbow flexed to 90 degrees, the clinician can then rotate the upper arm superiorly and inferiorly (external and internal rotation of the humerus, respectively), noting any limitation or pain. Alternatively, the patient can be asked to abduct and extend the arm, reaching behind the head to touch the contralateral scapula, and then to adduct and extend the arm, reaching behind the back and upward, again touching the contralateral scapula. The acromioclavicular joints and the sternoclavicular joints are occasionally affected by arthritis and should be palpated, noting any swelling or tenderness.

In the elbow, arthritis often produces detectable swelling and warmth. Elbow extension and flexion should also be tested, along with supination of the forearm and hand. Many children can normally hyperextend their elbows, and the degree of extension is variable; therefore, it is helpful to compare the range of motion of each elbow to the contralateral side.

The wrists are inspected for swelling and palpated for warmth and tenderness. Many children with wrist arthritis develop swelling on the dorsal aspect of the wrist that may be fairly large but is usually nontender. Extension tends to be more limited than flexion in wrist arthritis, and radial deviation tends to be more limited than ulnar deviation. Children with arthritis frequently complain of pain or withdraw their arm with maneuvers to test flexion and extension of the wrist.

The metacarpophalangeal (MCP) joint and the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints should be individually palpated, and any swelling, tenderness, or warmth should be noted (Fig. 33.8). The examiner should flex and extend the MCP joints, looking for limitations. To test the range of motion of the PIP and DIP joints, the child should try to supinate the hand and flex all of the digits, attempting to touch the fingertips to the palm. To examine the 1st MCP and thumb interphalangeal joint, the child should try to touch the tip of the thumb to the base of the 5th finger. Grip strength is determined by having the child tightly squeeze 2 of the clinician's

FIGURE 33.8 The joints of the wrists and hands of a 2-year-old boy are swollen, warm, and painful with limited extension of the fingers. (From Cassidy JT, Petty RE, Laxer RM, et al., eds. *Textbook of Pediatric Rheumatology.* 6th ed. Philadelphia: Elsevier; 2011:221.)

fingers. Arthritis of the wrist or any of the small joints of the hand decreases grip strength.

The child should next lie in a supine position, either in the parent's lap or on the examination table so that the lower extremities can be examined. Each hip is taken through its range of motion, beginning with flexion by trying to bring the knee as close to the chest as possible. Any pain or limitation is noted. With the hip and knee each flexed to 90 degrees, internal and external rotation are tested by keeping the knee in a fixed position and turning the lower leg laterally and medially, thereby rotating the femur. The hip and knee are extended back to a neutral supine position and abduction is tested. With the child in the prone position, the examiner evaluates hip extension by placing a hand on the child's ipsilateral iliac crest and lifting the child's thigh posteriorly with the knee extended. Hip arthritis most often causes limitations with internal rotation and extension, usually in association with pain in the inguinal area.

The knee is inspected for effusions and other obvious deformities. Palpation of the knee assesses for warmth, a common finding in knee arthritis, synovial swelling, or an effusion. Applying pressure in the suprapatellar area with 1 hand while palpating on either side of the patella with the other allows for the detection of effusions more readily because this forces excessive joint fluid that has accumulated in the suprapatellar area into the synovial space. Small effusions may be detected by eliciting a **bulge sign**. This is done by milking the medial and lateral depressions around the patella superiorly in an effort to push the fluid into the suprapatellar space and then gently pushing either medially or laterally just superior to the patella. This releases the fluid back into the synovial space, causing the area medial to the patella to bulge out. The popliteal fossa should be palpated, because fluid within the knee joint tends to track posteriorly as it accumulates, producing fullness in the popliteal fossa and sometimes a frank cyst, identical to the Baker cysts seen in adults with rheumatoid arthritis.

Palpating around the edges of the patella causes pain in many adolescents with **patellofemoral syndrome** (also known as chondromalacia patellae), a common cause of knee pain in active adolescents. In another maneuver that elicits pain in this syndrome, the patient relaxes the quadriceps muscles while the examiner pushes the patella inferiorly. While the examiner maintains pressure on the patella, the patient contracts the quadriceps. In patients with patellofemoral syndrome, pain elicited by this maneuver is referred to as a positive

patellar apprehension test, while a grinding sensation felt by the examiner constitutes a positive **patellar grind sign**. The tibial tubercle and patellar tendon should be inspected and palpated for swelling and tenderness associated with **Osgood-Schlatter disease** and **patellar tendonitis**, respectively.

Flexing and extending the knee tests range of motion. Most young children can touch their heel to their buttocks and hyperextend the knee. The examiner can detect subtle limitations in extension by standing at the foot of the table and lifting the heels of the child off the table as the child holds his or her legs fully extended. If 1 knee is limited with extension, the patella on that side may be slightly more elevated.

Swelling in the ankles is often best seen when inspecting and palpating the posterior aspect of the ankle, where fullness on either side of the Achilles tendon may be appreciated between the tendon and the malleoli. Warmth is common with ankle arthritis. Testing range of motion in the ankle should include both the tibiotalar ankle joint and the subtalar talocalcaneal joint. Cupping the heel with 1 hand and using the other hand to grasp the forefoot allows the examiner to move the forefoot superiorly (dorsiflexion) and inferiorly (plantar flexion). The hand cupping the heel is rocked laterally and medially to check inversion and eversion associated with motion at the subtalar joint. Holding the heel firmly with a cupped hand and gently rotating the forefoot with the other hand tests the joints of the midfoot. Each of the metatarsophalangeal joints is palpated along with each of the toes. The toes are inspected for the presence of swelling. The plantar fascia and the Achilles tendon are palpated, and any tenderness or swelling is noted.

The child should stand so that the examiner can evaluate the back. The sacroiliac joints are palpated, any tenderness is noted, and the child is asked to keep the knees extended and bend forward, touching the hands to the ground if possible. The lumbar spine should curve forward normally without flattening. The **modified Schober measurement**, which reveals whether the lumbar spine flexes normally, is done by marking the lumbar spine at a point where a horizontal line connecting the dimples of Venus intersects the spine. Then the examiner measures 10 cm above and 5 cm below that spot while the child is standing. When the child bends forward, the distance between the top and bottom marks should increase to at least 21 cm as the vertebral bodies separate during flexion. A shorter distance suggests limitation in mobility of the spine and potential spondylitis. Scoliosis is detected by noting any asymmetric elevation of the shoulder and upper back while the child bends forward.

Hypermobility is a very common cause of pain associated with sports and other activities; it tends to improve with rest. Hypermobility, patellofemoral syndrome, frequent ankle sprains, and pes planus are frequently seen together. The hypermobile child or adolescent can hyperextend the knees and elbows, appose the thumb to the forearm while flexing the wrist, hyperextend the MCP joints so that the digits are parallel to the forearm when the wrist is extended, and easily put the palms flat on the floor while bending forward from a standing position with the knees locked. Extreme hypermobility is seen in some individuals with Ehlers–Danlos syndrome or Marfan syndrome.

Myofascial pain syndromes are associated with the presence of **trigger points**, exquisitely tender, well-localized points often detected in the following locations: the occiput, trapezius muscles, medial borders of the scapula, upper outer quadrant of the buttocks, the 2nd cervical space anteriorly, the 2nd costochondral space just distal to the lateral epicondyle on the forearm, the greater trochanter in the proximal leg, and the medial aspects of the knees. Their presence in the older child with diffuse pain, fatigue, and difficulty sleeping is highly suggestive of a myofascial pain syndrome.

Proximal muscle strength testing should be performed in any patient complaining of weakness or fatigue. The deltoids, biceps, triceps, psoas, quadriceps, and hamstrings are tested. Neck flexor weakness is common in dermatomyositis and polymyositis and is tested by having the child lie supine and lift only his or her head. Most children are able to lift and keep the head elevated, even if asked to resist pressure from the examiner's hand against the forehead. To test proximal leg strength, the child rises from a sitting position on the floor. Muscle atrophy should be noted. Chronic knee arthritis or hip disease leads to atrophy of the ipsilateral quadriceps. Similarly, ankle arthritis causes the gastrocnemius to atrophy; wrist arthritis leads to wasting of the forearm muscles; and elbow contractures cause atrophy of the triceps muscle. Atrophy is easily overlooked, and it is sometimes helpful to measure the circumference of the thigh, calf, or upper arm to detect asymmetry.

The skin and mucous membranes should be examined carefully, as there may be clues to the presence of systemic disease (Table 33.3). Systemic JIA, SLE, acute rheumatic fever, and dermatomyositis are associated with characteristic rashes. Petechiae or palpable purpura suggests vasculitis. Nodules are seen with acute rheumatic fever and some forms of JIA. Thickening and tightening of the skin, particularly over the distal extremities and face, are often present in scleroderma. Nasal or palatal ulcers suggest SLE, whereas aphthous ulceration may be seen with inflammatory bowel disease or Behçet disease. Alopecia,

TABLE 33.3 Skin Manifestations of Rheumatic Disease

Physical Finding	Possible Disease
Petechiae, purpura	Vasculitis (if palpable) Leukemia Meningococcemia Other infections SLE
Erythema nodosum	Inflammatory bowel disease Streptococcal infection Sarcoidosis Drugs Tuberculosis Fungal infection
Gottron papules	Dermatomyositis
Alopecia	SLE, hypothyroidism
Calcification	Dermatomyositis, scleroderma
Subcutaneous nodules	Polyarticular JIA, rheumatic fever
Oral ulcers	SLE, Behçet disease, inflammatory bowel disease, reactive arthritis
Genital ulcers	Behçet disease
Digital ulcers	Vasculitis, SLE, scleroderma
Tight, thickened skin	Scleroderma
Livedo reticularis	Antiphospholipid syndrome, SLE, cutaneous polyarteritis nodosa
Nail dystrophy or pits	Psoriasis
Edema	SLE, vasculitis, scleroderma, eosinophilic fasciitis, serum sickness, Henoch–Schönlein purpura
Desquamation	Kawasaki disease, scarlet fever
Cyanosis	Raynaud phenomenon, hypertrophic osteoarthropathy

JIA, juvenile idiopathic arthritis; SLE, systemic lupus erythematosus.

either localized or diffuse, may be apparent to the examiner without being recognized by the patient. The presence of peripheral or periorbital edema increases the suspicion of glomerulonephritis.

◆ Laboratory Studies

Laboratory testing should be considered when the diagnosis is unclear or when there is a suspicion of life- or limb-threatening disease such as leukemia, septic arthritis, or osteomyelitis. Laboratory testing alone does not establish a diagnosis of JIA. Tests frequently seen in "arthritis panels" such as those for antinuclear antibody (ANA), rheumatoid factor (RF), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) are not specific for arthritis. However, if arthritis is detected on physical examination, laboratory testing aids in classifying the specific type of arthritis that is present.

A complete blood count (CBC) with manual differential is useful as a means of decreasing the suspicion of an acute infection or leukemia, which may manifest with bone or joint pain or even frank arthritis. A normal CBC is reassuring, but it is also helpful to compare the platelet count to the ESR. Because platelets are an acute-phase reactant, their number should increase as the ESR increases. A normal or low platelet count in a child with markedly elevated ESR increases the suspicion of leukemia.

An elevated peripheral white blood cell (WBC) count is often present with septic arthritis or osteomyelitis, but it is neither sensitive nor specific enough to change the diagnostic impression formulated after the history and physical examination. In systemic JIA, the WBC count may be markedly elevated at 20,000 WBCs/mm^3 or greater, the hemoglobin may be as low as 6 or 7 mg/dL, and the platelet count is typically significantly elevated. For many of the other inflammatory diseases that are associated with arthritis or extremity pain, a mild to moderate normocytic anemia as well as a mild thrombocytosis are common. SLE may demonstrate anemia, leukopenia, and thrombocytopenia.

The ESR is helpful when the physical examination is inconclusive regarding the presence or absence of an inflammatory condition. In uncooperative or obese children, it may be difficult to detect small effusions or subtle limitation in the range of motion. In these instances, an elevated ESR increases the suspicion of arthritis, although a normal ESR does not rule it out. In children who clearly have rheumatic disease or infection, the ESR is not diagnostically useful, but it may be used to monitor disease activity over time.

Urinalysis is an excellent screen for glomerulonephritis, which may occur in patients with vasculitis or SLE. Proteinuria or red blood cell casts suggest renal involvement. The creatinine level is elevated with renal insufficiency. Severe proteinuria leads to hypoalbuminemia, though hypoalbuminemia without proteinuria may also be seen in systemic JIA. Kawasaki disease is associated with sterile pyuria.

Serum aminotransferases are elevated in patients with hepatitis and occasionally in patients with SLE. In those with myositis, elevated aminotransferases, usually with the asparate aminotransferase (AST) elevated out of proportion to the alanine aminotransferase (ALT), often occurs concomitantly with increased creatine kinase, lactate dehydrogenase, and aldolase levels.

Antinuclear Antibody

The ANA test is a sensitive screen for SLE because it is positive in more than 95% of patients who also usually have high ANA titers, typically with values of 1:640 or higher. Lower ANA titers, usually in the range of 1:40-1:160, are seen in children with JIA, healthy children, or those with cross-reactive antibodies in the setting of a recent infection. The frequency of ANA positivity varies in the different forms of JIA. The pattern of the ANA is rarely helpful. Homogeneous and speckled patterns are the most common and are not specific for any particular illness. A peripheral or "rim" pattern is usually associated with anti–double-stranded DNA (anti-dsDNA) antibodies and is more specific for SLE. A nucleolar pattern suggests the presence of anti–Scl-70 antibodies, which may be seen in patients with scleroderma.

The ANA test is not specific and should not be ordered unless there is a strong suspicion of SLE or an overlap syndrome. It is not sensitive enough or specific enough to be diagnostically helpful for other diseases. A positive ANA finding is present in many asymptomatic healthy children, and in children with viral illnesses, other infections, other rheumatic and inflammatory diseases, and in relatives of those with autoimmune illnesses.

Rheumatoid Factor

The rheumatoid factor (RF) test is not diagnostic. Only 5% of children with JIA have a positive RF result, and this usually occurs in teenagers with adult-like polyarticular disease. RF is an immunoglobulin M antibody directed against immunoglobulin G. In children with polyarthritis, the presence of RF is a poor prognostic factor; these children have a high likelihood of developing chronic, erosive arthritis. A positive test result for RF can be seen with other illnesses associated with the formation of immune complexes, including rheumatic diseases such as SLE or vasculitis, and with infectious diseases such as bacterial endocarditis, infectious mononucleosis, and hepatitis B or C. It should not be ordered, and will not be helpful diagnostically, in individuals who do not have polyarthritis based on the history and physical examination.

Additional Antibody Testing

If the history and physical examination findings are suggestive of SLE, additional autoantibody testing is helpful (Table 33.4). Anti-dsDNA antibodies and anti-Smith antibodies are highly specific for SLE. Anti-ribonucleoprotein (anti-RNP) antibodies may be seen in patients with SLE, and when present in isolation (without anti-dsDNA and anti-Smith antibodies), suggest mixed connective tissue disease, which has clinical features that are often a combination of those seen with SLE, dermatomyositis, and scleroderma. Anti-Sjögren syndrome type A (anti-SSA [also known as anti-Ro]) and anti-Sjögren syndrome type B (anti-SSB [also known as anti-La]) antibodies are occasionally seen in patients with SLE but are not specific. They are seen in Sjögren syndrome, an illness producing chronic inflammation of the salivary and lacrimal glands and resulting in xerostomia and xerophthalmia.

Anticardiolipin antibodies, 1 of several antiphospholipid antibodies, may be present in SLE, but they are also seen in asymptomatic individuals and in those with the antiphospholipid antibody syndrome, in which clinical manifestations are restricted to the complications of the hypercoagulable state associated with these antibodies. These complications include venous and arterial thromboses and recurrent spontaneous abortions. Many patients with SLE have a false-positive Venereal Disease Research Laboratory (VDRL) test result because this is also a test for antiphospholipid antibodies. A positive direct Coombs test result, indicative of an autoimmune hemolytic anemia, is common in patients with SLE, although rarely is the hemolysis clinically significant.

Granulomatosis with polyangiitis (GPA) and the other antineutrophil cytoplasmic antibody (ANCA) associated vasculitides are the only types of vasculitis that can be diagnosed with confidence on the basis of serologic testing. Antiproteinase 3 antibodies, previously identified as cytoplasmic-staining or c-ANCA, are 95% sensitive and specific for GPA. The antimyeloperoxidase antibody (corresponding to peripheral-staining or p-ANCA) is much less specific; it is present with other vasculitides and a variety of infectious and inflammatory illnesses.

TABLE 33.4	**Autoantibodies in Children**
Test	**Characteristics**
Antinuclear antibody (ANA)	99% sensitive in SLE; very nonspecific
Anti–double-stranded DNA (dsDNA)	Up to 80% sensitive for SLE; highly specific (nearly 100%)
Anti-Smith (Sm)	Up to 35% sensitive in SLE; nearly 100% specific
Anti-SSA (Anti-Ro)	50% sensitive in SLE; seen in asymptomatic children; present in Sjögren syndrome and scleroderma; can be associated with neonatal lupus
Anti-SSB (Anti-La)	15% sensitive in SLE; seen in similar conditions as anti-SSA; can be associated with neonatal lupus
Antiribonucleoprotein (RNP)	Up to 40% sensitive in SLE; also seen in mixed connective tissue disease
Antihistone	Drug-induced SLE-like syndromes
Rheumatoid factor (RF)	30% of SLE patients; 5% of JIA; also seen in infections
Antiproteinase 3 (c-ANCA)	90–95% sensitive and specific for granulomatosis with polyangiitis
Antimyeloperoxidase (p-ANCA)	75% sensitive for microscopic polyangiitis; seen in other vasculitides, inflammatory bowel disease, other inflammatory diseases
Anti-RBC membrane (Coombs positive)	Up to 50% sensitive in SLE; nonspecific, seen also in Evan syndrome, isolated hemolytic anemia
Anticardiolipin	Seen in SLE; nonspecific, seen in asymptomatic children and in those with antiphospholipid syndrome

JIA, juvenile idiopathic arthritis; RBC, red blood cell; SLE, systemic lupus erythematosus; SSA and SSB, Sjögren syndrome type A and type B.

TABLE 33.5	**Criteria for Diagnosing Lyme Disease**

Characteristic clinical presentation
- Early localized disease: erythema migrans at the site of a recent tick bite, possible constitutional symptoms (malaise, headache, mild neck stiffness, myalgia, arthralgia), possible fever
- Early disseminated disease: multiple erythema migrans lesions at sites distinct from initial lesion, cranial nerve palsies (particularly cranial nerve VII), lymphocytic meningitis, polyradiculitis, constitutional symptoms, carditis
- Late disease: arthritis, polyneuropathy, encephalopathy, encephalitis

Exposure in an endemic area*

Positive Lyme ELISA, confirmed by positive Western blot

Western blots are considered positive if the following are present:
  For IgM, 2 of the following 3 bands must be present:
  23, 39, 41 kD
  For IgG, 5 of the following 10 bands must be present:
  18, 21, 28, 30, 39, 41, 45, 58, 66, 93 kD

*Mid-Atlantic and southern New England coastal regions, northwestern Wisconsin, and eastern Minnesota are considered the most endemic regions in North America. Even within these regions, the incidence of infection can vary widely.
ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin; kD, kilodaltons.

Viral infections such as human parvovirus B19, Epstein–Barr virus, and rubella may be associated with arthralgia or arthritis, and testing for antibodies to these viruses may be helpful in some clinical situations. For diagnosing Lyme disease, the enzyme-linked immunosorbent assay (ELISA) is a very sensitive, but not specific, screening test. A positive ELISA must be confirmed by Western blot (Table 33.5).

Complement

The complement proteins C3 and C4 are often depressed in patients with active SLE, which indicates consumption of C3 and C4 secondary to the formation of immune complexes. Some patients with hereditary complement deficiencies develop SLE. Low levels of complement can be seen occasionally with the vasculitides and in other illnesses with immune complexes such as bacterial endocarditis. The CH_{50} is a functional assay that measures the activity of the entire classical pathway of complement. If any single complement protein is depressed, this may cause a decrease in the CH_{50}. The CH_{50} is less sensitive and less specific than testing for the individual complement components.

◆ Diagnostic Imaging
Radiographs

Plain radiographs of the limbs are helpful as a means of evaluating children for potential infections, trauma, leukemia, or solid bone tumors. Osteomyelitis usually causes periosteal elevation, which may be seen after approximately 1 week of illness. Chronic osteomyelitis causes abscesses that may be visualized on plain radiographs. Fractures, including stress fractures and small avulsion fractures, are occasionally detected even when the clinical information is not strongly suggestive. Leukemia can cause lucency within the metaphyses of the long bones. Solid tumors, including osteosarcomas, Ewing sarcoma, and the benign osteoid osteoma, may all be identified on plain radiographs. Because knee pain may reflect referred pain from the hip, any child with unexplained knee or thigh pain should have pelvis and hip radiographs, including a "frog-leg" view. The young, limping child may have Legg–Calvé–Perthes disease, an avascular necrosis of the femoral head. A slipped capital femoral epiphysis is classically seen in an overweight patient in his or her early teens (see Chapter 34).

In the child with arthritis, soft tissue swelling or effusions within the joint may be identified on plain radiographs. Chronic arthritis may demonstrate bone erosions and juxta-articular osteopenia. Radiographs can be useful in monitoring the course of the disease and can sometimes help guide management.

In children with suspected SLE, a chest radiograph may reveal an enlarged cardiac silhouette, suggestive of a pericardial effusion or the presence of pleural effusions. If GPA is a consideration, a chest radiograph may reveal bilateral cavitating pulmonary nodules. Pulmonary hemorrhage, with bilateral alveolar infiltrates, can be seen with GPA, SLE, microscopic polyangiitis, and rarely HSP.

Magnetic Resonance Imaging (MRI)

MRI is useful when plain radiographs either are unrevealing or have identified a poorly defined abnormality. MRI, a sensitive test for osteomyelitis and avascular necrosis, can also reveal small joint effusions that are not apparent on physical examination. MRI helps distinguish hemarthrosis from other forms of joint swelling and detects ligamentous and meniscal tears. MRI provides better visualization and characterization of tumors than do plain radiographs. If myositis is suspected, MRI may reveal increased signal within the muscle as a result of inflammation and can help determine a potential biopsy site.

(See *Nelson Textbook of Pediatrics,* p. 1483.)

Bone Scan

A bone scan is useful when plain radiographs are unremarkable and when the source of pain cannot be adequately localized. It is a sensitive test for inflammation in the bones and joints, and it can help distinguish arthritis from osteomyelitis, fractures, and tumors. Bone scans, like plain radiographs, are not as sensitive for osteomyelitis if obtained very early in the disease process, and a 2nd scan should be considered if the initial study is negative. A bone scan may detect osteoid osteomas that are not apparent on plain radiographs. Complex regional pain syndrome (CRPS) usually demonstrates asymmetric increased uptake on the affected side.

Additional Imaging Studies

Ultrasonography helps evaluate the hip for transient synovitis with effusion. Ultrasonography may also help to identify synovitis or effusions in other joints and may also be useful when evaluating tendons for tenosynovitis. Echocardiography is useful when acute rheumatic fever is a consideration. Clinically silent valvulitis with resulting insufficiency is detected only by echocardiography and was recently added as a formal diagnostic criterion for rheumatic fever. The echocardiogram can also detect pericardial effusions in patients with SLE and coronary artery aneurysms in patients with Kawasaki disease.

Conventional angiography, computed tomography (CT) with angiography, and magnetic resonance (MR) angiography are useful for the diagnosis of medium- or large-vessel vasculitis such as polyarteritis nodosa or Takayasu arteritis. High-resolution CT of the chest without contrast is helpful in visualizing pulmonary nodules in patients with GPA and in detecting basilar lung fibrosis in those with scleroderma.

Joint Fluid Aspiration

There are few indications for diagnostic joint fluid aspiration in the child with arthritis. Synovial fluid analysis in childhood is most helpful for confirming or excluding 3 possible problems: (1) infectious arthritis, (2) hemarthrosis (either secondary to trauma or a coagulopathy), and very rarely (3) crystal diseases such as gout or pseudogout. A 4th condition, the rare entity of pigmented villonodular synovitis, is suggested by the aspiration of a "chocolate brown" synovial fluid from the knee.

Among these possibilities, only infection is a common consideration in childhood and is typically suspected on the basis of the history and physical examination findings. The child with septic arthritis is usually febrile and has developed acute joint pain, swelling, warmth, and occasionally erythema, most commonly in a single joint (Table 33.6), over a period of hours to days. When septic arthritis is suspected, arthrocentesis is necessary, and the joint fluid is sent for cell count, protein quantification, glucose measurement, Gram stain, and microbiologic studies, including bacterial culture and polymerase chain reaction (PCR) testing for *Kingella kingae*, an increasingly common cause of septic arthritis in children (Table 33.7). Additional microbiologic assays include fungal culture and mycobacterial testing if suspected. Some infectious arthritides develop more indolently, such as gonococcal arthritis, tuberculous arthritis, and opportunistic infections in immunocompromised hosts. Adolescents with monoarticular arthritis (Table 33.8) or acute polyarthritis should undergo joint aspiration, regardless of other symptoms, if they have risk factors for

TABLE 33.6 Distribution of Affected Joints in 1050 Children with Pyogenic Arthritis

Joint	Number	Percentage of Cases
Knee	467	41
Hip	287	25
Ankle	143	13
Elbow	116	10
Shoulder	53	5
Others*	70	6
Total†	1136	100

*Includes sacroiliac joints, joints of the hands and feet, and sternoclavicular joint.
†Some children had more than 1 joint affected.

TABLE 33.8 Differential Diagnosis of Monoarticular vs Polyarticular Arthritis and Arthralgia

Usually Monoarticular	Often Polyarticular
Common	
Infectious arthritis	Polyarticular JIA
• Bacterial	Psoriatic arthritis
• Mycobacterial	Reactive arthritis
• Fungal	Enthesitis-related arthritis
Avascular necrosis	• Ulcerative colitis
Hemarthrosis	• Crohn disease
Coagulopathy	Serum sickness
Trauma/overuse	Henoch–Schönlein purpura
Oligoarticular JIA	Systemic lupus erythematosus
Congenital hip dysplasia	Viral arthritis
Osteochondritis dissecans	Immune complex–mediated
Complex regional pain syndrome	post-bacteremia (*Neisseria*
Stress fracture	*meningitidis*, *Haemophilus*
Osteomyelitis	*influenzae*)
Metastatic tumor (neuroblastoma,	Hypermobility
leukemia)	Hemoglobinopathies
Rare	
Pigmented villonodular synovitis	Undifferentiated connective tissue
Plant thorn synovitis	disease
Familial Mediterranean fever	Relapsing polychondritis
Synovioma	Whipple disease
Synovial metastasis	Sarcoidosis
Intermittent hydrarthrosis	Hyperlipidemias types II and IV
Pancreatic fat necrosis	Systemic JIA
Gaucher disease	Pyoderma gangrenosum
Behçet disease	Pulmonary hypertrophic
Regional migratory osteoporosis	osteoarthropathy
Sea urchin spine	Chondrocalcinosis-like syndromes
Amyloidosis (myeloma)	caused by ochronosis,
Synovial osteochondromatosis	hemochromatosis, Wilson disease
	Acute rheumatic fever
	Paraneoplastic syndromes
	Dialysis arthropathy
	Crystal-induced arthropathies

JIA, juvenile idiopathic arthritis.

TABLE 33.9 Classification of Childhood Vasculitis

- Predominantly large-vessel vasculitis
  - Takayasu arteritis
- Predominantly medium-vessel vasculitis
  - Childhood polyarteritis nodosa
  - Cutaneous polyarteritis
  - Kawasaki disease
- Predominantly small-vessel vasculitis
  - Granulomatous
    - Granulomatosis with polyangiitis
    - Eosinophilic granulomatosis with polyangiitis
  - Nongranulomatous
    - Microscopic polyangiitis
    - Henoch–Schönlein purpura
    - Isolated cutaneous leukocytoclastic vasculitis
    - Hypocomplementemic urticarial vasculitis
- Other vasculitides
  - Behçet disease
  - Vasculitis secondary to infection (including hepatitis B-associated polyarteritis nodosa), malignancy, and medication (including hypersensitivity vasculitis)
  - Vasculitis associated with connective tissue diseases
  - Isolated vasculitis of the central nervous system
  - Cogan syndrome
  - Unclassified

Modified from Ozen S, Ruperto N, Dillon MJ, et al. EULAR/PReS endorsed consensus criteria for the classification of childhood vasculitis. *Ann Rheum Dis.* 2006;65:936-941.

should be analyzed for crystals. These conditions include leukemia, tumor lysis syndrome, renal failure, Down syndrome, Lesch–Nyhan syndrome, and type I glycogen storage disease (von Gierke disease).

Invasive Testing

If weakness is present, an electromyogram (EMG) and a nerve conduction study distinguish myopathies and myositis from neuropathies. Children with inflammatory myositis have a characteristic, albeit nondiagnostic, abnormal EMG. Peripheral neuropathies confirmed by nerve conduction studies may suggest the presence of a vasculitis or SLE.

Biopsies are most helpful in confirming the presence of vasculitis (Table 33.9) and to determine the extent of renal disease in a child with SLE. Kawasaki disease, GPA, Takayasu arteritis, polyarteritis, and HSP are vasculitides that may be diagnosed on the basis of either clinical criteria alone (Kawasaki disease, HSP), a combination of clinical criteria and arteriography (Takayasu arteritis, polyarteritis), or clinical criteria and serologic profiles (antiproteinase 3 antibodies in GPA). Biopsies of affected tissue are often necessary to confirm a diagnosis for many of the vasculitides. The most accessible affected tissue is acquired for biopsy first. In many children with vasculitis, this tissue is the skin and consultation with a dermatologist is helpful to determine which lesions and the location within a lesion that will be most likely to yield a diagnosis. If there is no rash, muscle and nerve samples may be taken for biopsy when EMG and nerve conduction studies reveal the presence of myositis or neuropathy. If neither of these sites

gonococcal disease. Likewise, if there has been exposure to tuberculosis, or if a child is immunocompromised, joint fluid aspiration should be strongly considered.

If the child has sustained trauma and it is unclear from the history and physical examination whether a joint effusion is inflammatory or hemorrhagic, joint fluid analysis may be helpful. Similarly, if there is history of a bleeding disorder in the family or in the child, joint aspiration should be considered (see Table 33.7).

Gout and pseudogout are unusual in childhood. Conditions that result in elevated serum uric acid levels predispose a child to gout, and if children with these conditions develop arthritis, the joint fluid

is affected, then the risks and benefits of biopsy of affected organs should be evaluated.

Synovial biopsy is rarely useful in the evaluation of arthritis. Biopsy is necessary to distinguish sarcoid arthropathy from JIA; sarcoid arthropathy is suspected when the young child has erythema nodosum, uveitis, and arthritis, as well as particularly "boggy" synovial effusions. In rare cases, synovial tumors, chronic indolent infections, or foreign bodies are detected by biopsy as well.

JUVENILE IDIOPATHIC ARTHRITIS

To be diagnosed with JIA, a child must have inflammatory arthritis of unknown etiology beginning before age 16 years and persisting for at least 6 weeks. JIA is further classified into different categories (Table 33.10). Specific classification of JIA should be made at 6 months of disease.

Oligoarticular Juvenile Idiopathic Arthritis

This is the most common form of JIA, affecting half of all children with JIA. Oligoarticular JIA can be further classified depending on whether fewer than 4 joints are affected for the entire course of the disease ("persistent") or if more than 4 joints are affected after the 1st 6 months of disease ("extended"). Persistent oligoarticular JIA is the most common form and typically manifests as monoarticular arthritis of the knee. Most affected children have morning stiffness, mild discomfort, swelling, and warmth of the affected joint or joints, but usually remain fairly functional and are systemically well. The arthritis in general has a good prognosis and in some cases may eventually remit on its own. Most such children have a positive ANA test result and are at the highest risk for associated chronic anterior uveitis.

Polyarticular Juvenile Idiopathic Arthritis

There are 2 subtypes of polyarticular JIA: RF-positive and RF-negative. RF-positive disease is most likely identical to adult-onset rheumatoid arthritis, and patients with this tend to have more aggressive, destructive arthritis and associated constitutional symptoms such as fatigue and poor appetite. The arthritis in these subtypes is symmetric and affects both small and large joints. Involvement of the small joints of the hands and feet, as well as the wrists, is very common. Chronic anterior uveitis may occur; it is more common in younger patients, especially if ANA test results are positive.

Enthesitis-Related Arthritis

The older term spondyloarthropathy encompasses a group of diseases that includes ankylosing spondylitis, psoriatic arthritis, inflammatory bowel disease-associated arthritis, and reactive arthritis. These diseases are grouped together because they share common clinical features such as male predominance, enthesitis, dactylitis, peripheral oligoarticular disease, axial arthritis, acute symptomatic anterior uveitis, and association with human leukocyte antigen (HLA)-B27. Psoriatic arthritis is classified separately, and the other spondyloarthropathies were redesignated as *enthesitis-related arthritis* (ERA) because of the recognition that these forms of arthritis do not necessarily affect the spine, especially during childhood. In addition to persistent arthritis, patients with ERA must have 2 of the following criteria: persistent sacroiliac joint tenderness and/or inflammatory lumbosacral pain, positive HLA-B27 antigen, acute symptomatic anterior uveitis, presence of symptoms in a male over 6 years of age, and finally, a 1st-degree relative with a history of ankylosing spondylitis, ERA, sacroiliitis with inflammatory bowel disease, reactive arthritis, or acute anterior uveitis.

TABLE 33.10 Classification Criteria for Juvenile Idiopathic Arthritis (JIA)

General Definition of Juvenile Idiopathic Arthritis
- Arthritis that begins before the 16th birthday and persists for at least 6 wk
- Other known causes of arthritis are excluded

Categories

Systemic Arthritis
- Arthritis in 1 or more joints with or preceded by fever of at least 2-wk duration that is documented to be daily ("quotidian") for at least 3 days, and accompanied by 1 or more of the following:
  - Evanescent (nonfixed) erythematous rash
  - Generalized lymph node enlargement
  - Hepatomegaly and/or splenomegaly
  - Serositis

Oligoarthritis
- Arthritis affecting 1–4 joints during the 1st 6 mo of disease
- Subcategories:
  - Persistent oligoarthritis: affecting not more than 4 joints throughout the disease course
  - Extended oligoarthritis: affecting a total of more than 4 joints after the 1st 6 mo of disease

Polyarthritis (Rheumatoid Factor Negative)
- Arthritis affecting 5 or more joints during the 1st 6 mo of disease
- Negative test for RF

Polyarthritis (Rheumatoid Factor Positive)
- Arthritis affecting 5 or more joints during the 1st 6 mo of disease
- 2 or more positive tests for RF, separated by at least 3 mo during the 1st 6 mo of disease

Psoriatic Arthritis
- Arthritis and psoriasis or suspicion of underlying psoriasis as evidenced by
  - Formal diagnosis of psoriasis, or
  - At least 2 of the following:
    - Dactylitis
    - Nail pitting or onycholysis
    - Psoriasis in a 1st-degree relative

Enthesitis-Related Arthritis
- Arthritis and enthesitis, or
- Arthritis or enthesitis with at least 2 of the following:
  - History of sacroiliac joint tenderness and/or inflammatory lumbosacral pain
  - Positive HLA-B27 antigen
  - Onset of arthritis in a male over 6 yr of age
  - Acute (symptomatic) anterior uveitis
  - History of ankylosing spondylitis, enthesitis-related arthritis, sacroiliitis with inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis in a 1st-degree relative

Undifferentiated Arthritis
- Arthritis that fulfills criteria in no category or in 2 or more of the above categories

HLA, human leukocyte antigen; RF, rheumatoid factor.
Criteria from Petty RE, Southwood TR, Manners P, et al. International League of Associations for Rheumatology classification of juvenile idiopathic arthritis: second revision, Edmonton, 2001. *J Rheumatol.* 2004;31:391-392.

Psoriatic Arthritis

A diagnosis of psoriatic arthritis can be made when a patient has chronic arthritis accompanied either by a personal diagnosis of psoriasis or by a combination of 2 other clinical criteria (dactylitis, nail pitting/onycholysis, or psoriasis in a 1st-degree relative). Psoriatic arthritis in children has a bimodal distribution with an initial peak between ages 2-3 years that appears clinically similar to oligoarticular JIA and a later peak between ages 10-12 years that appears clinically similar to ERA. The early-onset form of psoriatic arthritis is more likely to affect girls than boys, more often has associated dactylitis and a positive ANA, and is less often associated with a positive HLA-B27. In contrast, the later-onset form is more likely to occur in boys, is more often associated with a negative ANA and positive HLA-B27, and is more likely to manifest with enthesitis and axial arthritis. Psoriasis usually precedes the development of arthritis, but in a sizable minority, arthritis can precede the skin disease, sometimes by many years. Up to 30% of patients with psoriasis also have associated arthritis, with patients that have nail involvement being more likely to develop arthritis. The severity of the arthritis does not typically correlate with the severity of the skin disease.

Systemic Juvenile Idiopathic Arthritis

In systemic JIA (SJIA), any number of joints may be affected, but most patients eventually develop polyarticular involvement. Children with SJIA initially have a characteristic quotidian fever pattern, consisting of 1 or 2 high fever spikes each day with rapid return to normal temperature. An evanescent pink macular rash appears with the fever and may resolve completely as the child's fever abates (see Figs. 33.3 and 33.4). Constitutional symptoms such as fatigue, poor appetite, and weight loss are common. Generalized lymphadenopathy and hepatosplenomegaly are also common; pericarditis or pleural effusions may be seen. These children feel and appear ill during the fever spikes, but they may appear much improved once the fever abates. Peripheral leukocytosis of 20,000 WBCs/mm^3 or greater, anemia, and thrombocytosis are characteristic laboratory findings. Tests of ANA and RF are usually negative, and uveitis is very rare. In many patients, the fevers and rashes subside and polyarticular arthritis persists as an isolated manifestation, while in other patients, the fevers and rashes continue to dominate their clinical picture.

Patients with SJIA are at risk for **macrophage activation syndrome.** This can be a life-threatening complication from uncontrolled immune activation that results in disseminated intravascular coagulation (DIC). Clinically, this is manifested by persistent, unremitting fever, petechial/purpuric rashes from DIC, hepatosplenomegaly, and potentially multiorgan dysfunction. Laboratory examination demonstrates elevated CRP and markedly elevated ferritin with a paradoxically falling ESR due to DIC and consumption of fibrinogen. Cytopenias, particularly thrombocytopenia, are observed, as are hypertriglyceridemia and hypoalbuminemia. Hemophagocytosis is observed in various tissues, most commonly in the bone marrow and cerebrospinal fluid.

◆ Diagnosis

The diagnosis of JIA is based on clinical features, and classification is based on clinical and laboratory criteria (see Table 33.10). Although strict adherence to these inclusion and exclusion criteria is necessary for patients in clinical trials, it is not always helpful or practical when diagnosing individual patients. The differential diagnosis is broad (Tables 33.11 and 33.12; see Table 33.1). Lyme disease should always be considered (Table 33.13). Laboratory tests and imaging studies are used when necessary to exclude other illnesses. The ANA and RF tests are used to classify the subtype of JIA and to determine the risk of

uveitis, but they are not diagnostic tests. Ophthalmologic slit-lamp evaluations are necessary at specific intervals to screen for anterior uveitis, because usually the uveitis is asymptomatic and can progress to affect visual acuity before it causes other signs and symptoms. For patients at highest risk—children younger than 7 years of age with a positive ANA test result and oligoarticular or polyarticular JIA—ophthalmologic evaluations should be performed every 3-4 months for at least 4 years after diagnosis, every 6 months for 3 years after that, and then annually. Those with SJIA should have annual examinations since their risk is low. All others should have evaluations at 6-month intervals for the first 4 years after diagnosis, and annually thereafter.

SYSTEMIC LUPUS ERYTHEMATOSUS

In SLE, clinical manifestations are the result of aberrant B cell proliferation and increased production of both specific and nonspecific autoantibodies, with subsequent immune complex formation and deposition throughout the body. The cause of SLE is unknown; it is more common in girls and women, African Americans, and persons with a 1st-degree relative with SLE. In childhood, the peak onset is during the early teen years and rarely occurs in children younger than 5 years. The potential clinical manifestations of SLE are numerous, and the illness demonstrates significant interindividual variability. Children with SLE have more severe disease with a greater incidence of renal involvement and other serious manifestations than adults.

◆ Diagnosis

SLE is suggested by the common manifestations of fever, malar rash (Fig. 33.9), photosensitivity, and arthritis. The arthritis is most often symmetric and polyarticular, and frequently involves the small joints of the hands and feet. In contrast to JIA, the arthritis is typically non-deforming and does not result in erosions or bony remodeling. The Systemic Lupus International Collaborating Clinics (SLICC) criteria were developed for the purpose of research studies and clinical application (Table 33.14). The presence of 4 or more of these criteria is highly sensitive and specific for SLE. Other clinical manifestations of SLE are listed in Table 33.15.

The ANA test is extremely sensitive, positive in more than 95% of children with SLE, and usually in a high titer; however, it is not specific. Testing for anti-dsDNA antibodies, anti-Smith antibodies, anti-RNP antibodies, anti-SSA, and anti-SSB antibodies should be performed in all children suspected of having SLE (see Table 33.4). Anti-dsDNA antibodies and anti-Smith antibodies are highly specific for SLE. Leukopenia, lymphopenia, thrombocytopenia, and autoimmune hemolytic anemia, frequently with a positive direct Coombs test, are common. Urinalysis is mandatory to screen for nephritis; proteinuria indicates disease. The anticardiolipin antibody test identifies antiphospholipid antibodies, a common finding in SLE that results in a hypercoagulable state, placing the patient at risk for thrombotic events. The complement proteins C3 and C4 are low in children with active SLE. Monitoring C3 and C4 levels helps guide therapy; the levels should increase to normal as the illness is better controlled.

DERMATOMYOSITIS

Dermatomyositis is characterized by perivascular inflammation in muscles and skin, occasionally with gut and other organ involvement. Dermatomyositis is more common in girls and can occur at any age; the average age at onset is 8 years. The main manifestations include characteristic skin findings and proximal muscle weakness, specifically involving the neck flexors, deltoids, biceps, triceps, quadriceps, psoas,

(See *Nelson Textbook of Pediatrics,* p. 1176.)

TABLE 33.11	Differential Diagnosis of Juvenile Idiopathic Arthritis: Rheumatic Disease				
	Rheumatic Fever	**Juvenile Idiopathic Arthritis**	**Systemic Lupus Erythematosus**	**Kawasaki Disease**	**Dermatomyositis**
Sex predilection	None	Dependent on subgroup	Girls > boys	None	Girls 3:2
Age at onset	3 yr or older	1 yr or older	Usually > 8 yr	4 yr or younger	2 yr or older
Joint manifestations	Transient migratory arthritis of primarily large joints	Oligoarticular or polyarticular; chronic (≥6 wk)	Arthralgia; transient arthritis; chronic arthritis	Pain and swelling of hands and feet; arthritis occasionally	Joint contractures; arthritis occasionally
Extra-articular manifestations	Fever Cardiac disease Chorea Rash Nodules	Dependent on subgroup: Systemic JIA: fever, rash, lymphadenopathy Oligoarticular JIA: iridocyclitis	Often multisystem disease, including nephritis	Fever Conjunctivitis Oral changes Polymorphous rash Lymphadenopathy Coronary vasculitis	Rash Muscle weakness Myalgia Gut vasculitis Respiratory muscle weakness
Diagnostic studies	Prior streptococcal infection Evidence of carditis on echocardiogram or electrocardiogram	May have ANA, RF	ANA Autoantibodies Low complement Anti-dsDNA antibody	Coronary dilatation or aneurysm on echocardiogram	Elevated muscle enzymes Myopathic electromyography Abnormal muscle biopsy
Pathogenesis	Poststreptococcal	Unknown	Immune complexes	Unknown	Unknown
Diagnosis	Clinical (Jones criteria)	Clinical (JIA criteria)	Clinical plus laboratory (SLICC criteria)	Clinical (Kawasaki criteria)	Clinical: rash plus myositis Muscle biopsy
Natural history	Arthritis–transient. Carditis may cause permanent damage	Chronic: arthritis may be destructive	Chronic or recurrent May be fatal	Self-limited Coronary vasculitis May be fatal	Chronic May be fatal

ANA, antinuclear antibody; Anti-dsDNA, anti–double-stranded DNA; JIA, juvenile idiopathic arthritis; RF, rheumatoid factor; SLICC, Systemic Lupus International Collaborating Clinics.

Modified from Behrman RE, ed. *Nelson Textbook of Pediatrics*. 14th ed. Philadelphia: WB Saunders; 1992:620.

and hamstrings. These symptoms are occasionally accompanied by mild muscle pain, fatigue, or poor endurance. Weakness may be subtle and not recognized for long periods. Frequent early symptoms include difficulties rising from the floor, climbing stairs, climbing in and out of a minivan, and combing the hair.

Skin manifestations include Gottron papules, which are scaly, erythematous plaques or papules that appear over the MCP and PIP joints on the hands (see Fig. 33.6). Similar lesions are seen on the extensor surfaces of the elbows and knees and over the medial malleoli. The distribution of the rash, which may be misdiagnosed as eczema or psoriasis, is an early clue to the diagnosis. The periungual capillaries may become grossly dilated and may develop thromboses that can be visualized either with the naked eye or with mild magnification. Heliotrope rash is a violaceous discoloration of the upper eyelids that is often accompanied by mild edema (see Fig. 33.5) and is pathognomonic for dermatomyositis. Some children develop more extensive erythroderma that may appear over the shoulders, termed the shawl sign, or in a V-neck distribution on the chest. With severe disease, some patients may also develop vasculopathic skin ulcerations.

◆ Diagnosis

The diagnosis is suggested by the rash and proximal muscle weakness detected on physical examination. Muscle enzymes are elevated in most, but not all, children with dermatomyositis. There may be elevations in only 1 or a few enzymes and therefore testing for aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, creatine kinase, and aldolase should be performed. The child with a characteristic rash, definite proximal muscle weakness, and elevated

muscle enzyme levels may not require additional testing for diagnosis. If weakness is questionable, or if the rash is not characteristic, an EMG can confirm the presence of muscle inflammation. MRI is a sensitive test for muscle inflammation and may be a less invasive method of evaluating the muscle. If there is any doubt regarding the diagnosis, a muscle biopsy is performed. The site for biopsy is determined by weakness on physical examination or localization by EMG or MRI. The quadriceps or the deltoids are the most commonly accessed biopsy sites. Involvement of the muscle may be spotty, and a normal finding on muscle biopsy does not exclude dermatomyositis. Typical findings on biopsy include perivascular inflammation and perifascicular atrophy. The biopsy can help exclude other potential myopathies such as muscular dystrophies and metabolic myopathies.

SCLERODERMA

Scleroderma is classified into systemic sclerosis and localized scleroderma (Table 33.16). Localized scleroderma, which includes morphea and linear scleroderma, is limited to the skin and subcutaneous tissues, is much more common in childhood, and rarely progresses to involve internal organs. Systemic sclerosis can be life threatening, as it has the potential to involve internal organs and cause severe and widespread skin disease.

Morphea

Morphea is a patch of hardened skin that appears spontaneously on any part of the body. The skin becomes firm, stiff, atrophic, and discolored. Hair is absent. Initially, the lesion appears violaceous, but then

(See *Nelson Textbook of Pediatrics,* p. 1186.)

TABLE 33.12	Differential Diagnosis of Juvenile Idiopathic Arthritis: Nonrheumatic Disease						
	Septic Arthritis	**Lyme Disease**	**Osteomyelitis**	**Viral Arthritis**	**Childhood Malignancy**	**Structural, Genetic**	**Growing Pains, Psychogenic**
Sex predilection	None	None	None	Girls > boys	None	Dependent on condition	Growing pains: boys > girls; Psychogenic: girls > boys
Age at onset	Any	>2 yr	Any	More common in older children and adults	Any	Any	Growing pains: 2–8 yr; Psychogenic: ≥ 6 yr
Joint manifestations	85% monoarticular; joints swollen, red, hot, painful	Oligoarticular; episodic, recurrent	Sterile joint effusion adjacent to infected bone	Transient arthritis; often polyarticular	Severe bone/ joint pain, night pains	Local bone/joint pain or dysfunction	None or features of complex regional pain syndrome
Extra-articular manifestations	Fever SIRS Other signs dependent on causative organism	Flu-like illness Erythema migrans Meningitis Cranial nerve palsies Heart block	Fever SIRS Bone pain	Dependent on causative organism	Signs of underlying malignancy; no high fever, rash, or morning stiffness	Dependent on underlying condition Dysmorphism Structural abnormalities	Growing pains: none Psychogenic: atypical
Diagnostic studies	Cultures: synovial fluid, blood, genital if *Neisseria gonorrhoeae* suspected	Serologic: antibody to *Borrelia burgdorferi*	Blood and bone culture Bone scan	Viral culture/PCR Rise in antibody titers	Hematologic abnormalities Abnormal radiograph or scan	Demonstration of abnormal structure or metabolic abnormality	Normal
Pathogenesis	Direct synovial infection; immune complex deposition in gonococcal and meningococcal arthritis	Synovial and systemic infection with *B. burgdorferi*	Hematogenous infection of bone	Viral infection of synovium; immune complex deposition in some	Primary bone or periarticular tumor; bony metastasis	Idiopathic or genetic	No organic disease
Diagnosis	Demonstration of organisms in joint fluid	Clinical and serologic	Demonstration of organisms in blood/bone; MRI of bone scan (early); plain radiographs (late)	Clinical; serologic; positive viral culture or PCR from synovial fluid	Bone marrow; tissue biopsy	Recognition of condition or syndrome; positive genetic or biochemical assay	Clinical
Natural history	Joint destruction	Self-resolving	Bone/joint destruction	Self-resolving	Joint manifestations may wax/ wane	Chronic	Growing pains: benign Psychogenic: may become chronic and disabling

MRI, magnetic resonance imaging; PCR, polymerase chain reaction; SIRS, systemic inflammatory response syndrome.

TABLE 33.13 Manifestations of Lyme Disease by Stage

Early Localized Infection (occurs 3–30 days after tick bite)

Erythema migrans (EM) in 80–90% of patients; single lesion, occasionally associated with fever, malaise, neck pain or stiffness, arthralgia, and myalgia

Systemic symptoms noted above in the absence of EM during summer months

Borrelial lymphocytoma (rare, seen primarily in Europe)

Early Disseminated Infection (occurs weeks to months after tick bite)

Profound malaise and fatigue common

Multiple EM lesions with systemic symptoms similar to early localized infection

Migratory polyarthralgia and myalgia

Carditis (<3% of untreated patients)
    Varying degrees of atrioventricular nodal block
    Mild myopericarditis

Neurologic (<10% of untreated patients)
    Cranial neuropathies (especially facial nerve palsy)
    Lymphocytic meningitis
    Radiculoneuropathies
    Encephalomyelitis

Late Disease (occurs months to years after tick bite)

Arthritis (<10% of patients)
    Acute monoarticular or migratory pauciarticular inflammatory arthritis, usually involving the knee
    Chronic antibiotic-refractory arthritis (<10% of patients with arthritis)

Neurologic (rare)
    Peripheral neuropathies
    Mild encephalopathy
    Encephalomyelitis (primarily seen in Europe)

Acrodermatitis chronica atrophicans (primarily seen in Europe)

Modified from Bockenstedt LK. Lyme disease. In: Firestein GS, Budd RC, Gabriel SE, et al., eds. *Kelley's Textbook of Rheumatology.* 9th ed. Philadelphia: Saunders; 2013, Chapter 110, Table 110-1.

TABLE 33.14 Systemic Lupus International Collaborating Clinics (SLICC) Classification Criteria for Systemic Lupus Erythematosus

4 OR MORE CRITERIA (AT LEAST 1 CLINICAL AND 1 LABORATORY)
OR
BIOPSY-PROVEN LUPUS NEPHRITIS WITH A POSITIVE ANA OR ANTI-dsDNA

Clinical Criteria	Laboratory Criteria
Acute cutaneous lupus	ANA
Chronic cutaneous lupus	Anti-dsDNA
Oral or nasal ulcers	Anti-Smith
Nonscarring alopecia	Antiphospholipid antibody
Arthritis	Low complement (C3, C4, CH_{50})
Serositis	Positive direct Coombs (does not count if
Renal	hemolytic anemia already present)
Neurologic	
Hemolytic anemia	
Leukopenia	
Thrombocytopenia	

anti-dsDNA, anti–double-stranded DNA; ANA, antinuclear antibody. From Petri M, Orbai A, Alarcon GS, et al. Derivation and validation of the Systemic Lupus International Collaborating Clinics classification criteria for systemic lupus erythematosus. *Arthritis Rheum.* 2012;64: 2677-2686.

it fades to a yellowish-brown or dusky appearance in most individuals. The patches are nontender, and children are otherwise asymptomatic. The natural history of morphea lesions is to gradually fade and soften after an initial period of expansion. Biopsy reveals excessive amounts of collagen in the dermis with absent hair follicles and diminished vascular structures.

Linear Scleroderma

Linear scleroderma is histologically similar to morphea, though lesions consist not of isolated patches, but rather narrow bands that may extend through an entire limb, part of the limb, or across the scalp and face, a finding termed a coup de sabre lesion. Cosmetically and functionally, linear scleroderma is much more severe than morphea, as the impacted areas may involve the face or limit limb use. Growth of the limb may be affected, and involvement of the digits can cause significant functional difficulty. Coup de sabre lesions, particularly with craniofacial involvement, may be associated with neurologic abnormalities and seizures, and these children should have a careful neurologic examination and brain MRI as part of their evaluation.

Systemic Sclerosis

Systemic sclerosis typically begins with severe Raynaud phenomenon, followed by thickening and tightening of the skin over the digits and hands and then the face, and then by varying degrees of progressive skin changes over the extremities and trunk. Difficulty opening the mouth and decreased facial expression are signs of facial involvement. As the skin over the hands tightens and hardens, pigment changes may occur, and flexion contractures of the small joints may develop. Renal disease, pulmonary fibrosis, pulmonary hypertension, esophageal and gut dysmotility, and cardiac disease may all occur. Anti-Scl-70 antibodies (anti-topoisomerase I) are present in approximately 30-40% of patients with systemic sclerosis and are very specific. There are no other helpful serologic tests. High-resolution CT of the chest, esophagography, and echocardiography should be performed to screen for organ involvement and repeated at periodic intervals. The course of systemic sclerosis is variable; patients with rapid progression tend to have a less favorable outcome. A limited variant of scleroderma is known as CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias). Although less severe than systemic sclerosis, these patients can develop life-threatening pulmonary hypertension. CREST syndrome is associated with anticentromere antibodies.

RHEUMATIC FEVER

Acute rheumatic fever is a poststreptococcal illness, resulting from a cross-reactive immune response to group A streptococcal pharyngitis (see Chapters 1 and 8). It is most common in children older than 5 years and occurs more often after infection with certain serotypes of

(See *Nelson Textbook of Pediatrics,* p. 1186.)

FIGURE 33.9 The malar rash of systemic lupus erythematosus crosses the nasal bridge and spares the nasolabial folds, a distribution that is referred to as a "butterfly rash." (From Cassidy JT, Petty RE, Laxer RM, et al., eds. *Textbook of Pediatric Rheumatology*. 6th ed. Philadelphia: Elsevier; 2011:321.)

group A streptococci. There may also be genetic reasons that predispose some children and adults to the illness. Signs and symptoms of rheumatic fever typically develop 1-3 weeks after streptococcal pharyngitis. Clinical manifestations have been grouped according to the Jones criteria, which separate major from minor criteria (Table 33.17).

The arthritis of rheumatic fever is usually very painful and is disproportionate to the degree of swelling on physical examination. It is usually a migratory arthritis of the large joints; it rarely affects the fingers, spine, or toes. It tends to last in 1 joint for several days and then migrates to a different joint. The duration of joint symptoms is rarely longer than 3-4 weeks in untreated patients. If patients are treated with NSAIDs, the arthritis usually responds dramatically within 1-2 days. When rheumatic fever is a consideration and the diagnosis is unclear, it is helpful to avoid NSAID use early in the course to avoid diagnostic confusion.

In the absence of carditis, rheumatic fever may be difficult to distinguish from early SJIA, Kawasaki disease, and viral-induced fever, rash, and joint pain. The diagnosis is clinical. The Jones criteria were developed as a diagnostic aid and include echocardiographic evidence of valvulitis, and in populations with a higher risk of rheumatic fever, monoarthritis or polyarthralgia as less stringent major criteria (see Table 33.17). The presence of 2 of the major criteria or of 1 major and 2 minor criteria plus evidence of recent streptococcal infection is consistent with acute rheumatic fever, though is not specific. Either a positive throat culture or elevations of the antistreptococcal antibodies (antistreptolysin O, anti-DNase B) are the standard indicators of potential recent streptococcal infection. Fulfilling these criteria is not specific for rheumatic fever, especially when the evidence of recent streptococcal infection is based on mildly elevated serologic test results.

TABLE 33.15 Additional Manifestations of Systemic Lupus Erythematosus

Target Organ	Potential Clinical Manifestations
Constitutional	Fatigue, anorexia, weight loss, fever, lymphadenopathy
Musculoskeletal	Arthritis, myositis, tendonitis, arthralgia, myalgia, avascular necrosis, osteoporosis
Skin	Malar rash, discoid (annular) rash, photosensitive rash, cutaneous vasculitis (petechiae, palpable purpura, digit ulcers, gangrene, urticaria), livedo reticularis, periungual capillary abnormalities, Raynaud phenomenon, alopecia, oral and nasal ulcers, panniculitis, chilblains
Renal	Hypertension, proteinuria, hematuria, edema, nephrotic syndrome, renal failure
Cardiovascular	Pericarditis, myocarditis, conduction system abnormalities, Libman–Sacks endocarditis
Neurologic	Seizures, psychosis, cerebritis, stroke, transverse myelitis, depression, cognitive impairment, headaches, migraines, pseudotumor, peripheral neuropathy (mononeuritis multiplex), chorea, optic neuritis, cranial nerve palsies, acute confusional states, dural sinus thrombosis
Pulmonary	Pleuritis, interstitial lung disease, pulmonary hemorrhage, pulmonary hypertension, pulmonary embolism
Hematologic	Immune-mediated cytopenias (hemolytic anemia, thrombocytopenia, or leukopenia), anemia of chronic inflammation, hypercoagulability, thrombotic thrombocytopenic microangiopathy
Gastroenterology	Hepatosplenomegaly, pancreatitis, vasculitis affecting the bowel, protein-losing enteropathy, peritonitis
Ocular	Retinal vasculitis, scleritis, episcleritis, papilledema, dry eyes, optic neuritis

Modified from Sadun RE, Ardoin SP, Schanberg LE. Systemic lupus erythematosus. In: Kliegman RM, Stanton BF, St Geme JW, Schor NF, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2016:117, Chapter 158, Table 158-1.

TABLE 33.16 Classification of Scleroderma

Systemic Sclerosis
- Diffuse: systemic fibrosis, including widespread skin involvement (face, trunk, and both proximal and distal extremities) and internal organ involvement (lungs, kidneys, gastrointestinal tract, heart)
- Limited (CREST syndrome): skin fibrosis limited to the distal extremities, face, and neck; internal organ involvement occurs late, if at all, with pulmonary hypertension often being the most significant development

Localized Scleroderma
- Morphea: a single, discrete patch of fibrotic skin; no organ involvement
- Generalized morphea: multiple discrete patches of fibrotic skin; no organ involvement
- Linear scleroderma: band of fibrosis on the face (*coup de sabre*) or along an extremity, sometimes extending the entire length; no organ involvement

CREST, calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias.

TABLE 33.17 Jones Criteria for Diagnosis of Rheumatic Fever

All patient populations must demonstrate evidence of a preceding GAS infection

Initial ARF: 2 major manifestations OR 1 major plus 2 minor manifestations

Recurrent ARF: 2 major OR 1 major and 2 minor OR 3 minor manifestations

Major Criteria

Carditis: clinical (audible murmur) or subclinical (echocardiographic evidence of valvulitis)

Subcutaneous nodules

Erythema marginatum

Chorea

Low-risk populations*: polyarthritis

Moderate- and high-risk populations: polyarthritis, monoarthritis, or polyarthralgia[†]

Minor Criteria

Fever (≥38.5°C)

Peak ESR ≥30 mm/hr and/or CRP ≥3.0 mg/dL[‡]

Prolonged P-R interval, after accounting for age variability (unless carditis is a major criterion)

Low-risk populations: polyarthralgia

Moderate- and high-risk populations: monoarthralgia

*Low-risk populations are those with an ARF incidence ≤2/100,000 school-aged children or an all-age rheumatic heart disease prevalence of ≤1/1000 population per yr.

[†]Polyarthralgia should only be considered as a major manifestation in moderate- to high-risk populations after exclusion of other causes. As in past versions of the criteria, erythema marginatum and subcutaneous nodules are rarely "stand-alone" major criteria. Additionally, joint manifestations can only be considered in either the major or minor categories, but not both in the same patient.

[‡]The CRP value must be greater than the upper limit of normal for the laboratory. Because ESR may evolve during the course of ARF, peak ESR values should be used.

ARF, acute rheumatic fever; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; GAS, group A streptococcal.

Modified from Gewitz MH, Baltimore RS, Tani LY, et al. Revision of the Jones criteria for the diagnosis of acute rheumatic fever in the era of Doppler echocardiography. *Circulation.* 2015;131:1806-1818.

Conversely, there are children with isolated chorea or classic rheumatic carditis who have rheumatic fever without necessarily fulfilling the Jones criteria. When a diagnosis of rheumatic fever is considered in a child with joint symptoms, it is important to distinguish arthritis from arthralgia and to evaluate the nature of the arthritis when present. If the arthritis is nonmigratory and is not exquisitely tender, or if it involves unusual joints such as those in the hands, feet, or spine, or lasts longer than 1 week in a single joint, then alternative diagnoses should be strongly considered.

Careful consideration of the diagnosis is especially important because of future implications regarding prognosis and treatment. Children with rheumatic fever may develop carditis with future episodes of streptococcal pharyngitis; each episode of carditis can produce additional heart valve damage. Therefore, prophylactic antibiotic treatment is recommended to minimize streptococcal infections, even for patients who do not have carditis with the initial attack. For those without carditis, most authorities recommend prophylaxis until age 21 years or for 5 years, whichever is longer. For patients with carditis, this recommendation is extended to 10 years or to age 21, whichever is longer. If there is residual valvular damage, prophylaxis is recommended for 10 years or

until age 40, whichever is longer. Prophylaxis is usually either daily oral penicillin or monthly intramuscular injections of long-acting penicillin.

Henoch–Schönlein Purpura

HSP is an acute self-limited systemic vasculitis of children characterized by the classic triad of palpable purpura, arthritis, and nephritis. It occurs most commonly between the ages of 3 and 15 years. The presence of palpable purpura is essential for the diagnosis of HSP. Typically, the rash presents as petechiae that coalesce into larger purpura on dependent areas such as the buttocks and legs. The rash is often edematous and on occasion can become ulcerative. Arthritis occurs in up to 80% of children with HSP, is typically acute with significant pain and limitation of range of motion, and usually resolves within days to a week. Large joints tend to be affected and the arthritis is nonmigratory. In the majority of cases, the rash of HSP precedes the development of arthritis, but occasionally, the arthritis may occur a few days before the rash. Other features that might suggest a diagnosis of HSP are gastrointestinal symptoms, nephritis, or angioedema. Gastrointestinal symptoms result from gut vasculitis causing intestinal edema and potentially ischemia and infarction of the gut. Gastrointestinal disease often presents as episodic abdominal pain from intussusception, or with abdominal angina (postprandial abdominal pain related to intestinal ischemia). Rarely, hematochezia or currant jelly-like stools can result from intestinal necrosis. In up to a third of cases, abdominal pain will precede the rash. Nephritis may occur at any time up to 6 months after the initial presentation, and may manifest with hypertension or with proteinuria, hematuria, or casts on urinalysis. As such, serial urinalysis is recommended until 6 months after the initial presentation to survey for the development of nephritis. Angioedema can occur on the dorsum of the hands or feet, scalp, forehead, eyelids, and scrotum. The acute manifestations of HSP usually resolve in 1-2 weeks, though may recur episodically in less severe form for several weeks after. Nephritis is usually the most concerning complication that requires longer monitoring and prompt referral to a pediatric nephrologist if urinary abnormalities persist.

MYALGIA

In the child with extremity pain, muscle pain needs to be distinguished from joint pain, bone pain, and the less common neuropathic pain. If the complaint is localized to the muscles, the differential diagnosis is narrowed considerably. Intermittent benign bilateral myalgia of the calves or thighs is 1 of the more common muscle pain presentations encountered in young children. These pains occur in an active child who has normal physical examination findings without evidence of weakness or systemic illness. Symptoms typically occur in the evening and resolve with massage or mild analgesics such as acetaminophen or ibuprofen, usually within an hour. The frequency of pain can vary and in some children may escalate periodically. Additional evaluation or treatment is unnecessary in most children, and eventually the pains resolve completely.

As myalgia may accompany polymyositis and dermatomyositis, every child complaining of muscle pain should undergo careful muscle strength testing. Myalgia may also be seen with vasculitis and SJIA. Many children with acute-onset diffuse myalgia have a transient viral illness, and pain usually resolves within several days; however, infection with influenza can cause an exquisitely painful myositis of the gastrocnemius muscles with resultant difficulty ambulating. This condition is usually distinguished easily from a chronic inflammatory muscle disease by the sudden onset and localization to these specific muscles. The creatine kinase level may be very elevated. Myoglobinuria may

ensue and potentially affect renal function; therefore, affected children should undergo urinalysis, in which the presence of myoglobin yields positive results for heme on macroscopic analysis, though no erythrocytes on microscopic examination. The myositis resolves within several days, and treatment is based on symptoms.

Complex Regional Pain Syndrome

CRPS is rare in childhood and is not well understood. After a seemingly minor injury, affected children develop intense pain in an extremity or part of an extremity. Additional symptoms include intermittent autonomic changes such as discoloration, coolness, and localized excessive sweating. The pain leads to progressive disability of the extremity, occasionally resulting in fixed posturing of a hand, foot, or limb. Severely affected children become disabled, are unable to ambulate at times, and are often unable to attend school. Psychosocial comorbidity is common. The treatment is analgesia, intense physical and occupational therapy, education, and psychologic counseling. Some children improve dramatically within a few days of instituting therapy, whereas in others, treatment is difficult and the process lasts indefinitely. In some instances, sympathetic nerve blockade is helpful.

TABLE 33.18	**Potential Pitfalls in Diagnosis**

Do
1. Examine all joints.
2. Order radiographs of both affected and contralateral joints.
3. Ask parents to photograph swelling and rashes.
4. Explore the complete history including the psychosocial history in all patients.
5. Perform a thorough physical examination.

Do Not
1. Indiscriminately order ANA tests, RF tests, or Lyme antibody tests in patients who do not have clinical features consistent with these conditions.
2. Confuse arthralgia (joint pain) with arthritis (inflammation).
3. Treat with prednisone before a diagnosis is clear.
4. Accept laboratory results at odds with your experience; repeat tests if necessary.
5. Be afraid to say, "I don't know."

ANA, antinuclear antibody; RF, rheumatoid factor.

▮ SUMMARY AND RED FLAGS

The differential diagnosis of arthritis is extensive. Thorough history and physical examination, especially repeated over time, are essential in establishing a diagnosis and initiating a treatment plan. Potential diagnostic pitfalls are noted in Table 33.18. Red flags include manifestations suggestive of septic arthritis (fever, single joint involvement, erythema, extreme tenderness, leukocytosis), malignancy (severe polyarthralgia, night pain, nonarticular bone pain, absence of obvious swelling or stiffness, positive radiographic changes, and abnormal CBC), Lyme disease, and Kawasaki disease. Multiple organ system involvement may be primary (as in SLE and rheumatic fever) or secondary to therapy and must be considered in order to avoid ongoing extraarticular involvement, which may be more life-threatening than the articular process.

In addition, the child with a history of injury and the acute onset of extremity pain may have a fracture or traumatic hemarthrosis and requires prompt evaluation. Any child with extremity pain, including children with arthritis, may have leukemia or neuroblastoma. Systemic symptoms, such as fatigue and poor appetite with weight loss, may accompany the pain and increase suspicion of malignancy. Deep bone pain caused by marrow invasion may not be accompanied by any obvious physical findings. A normal or slightly low platelet count with an elevated ESR increases the suspicion of malignancy. If leukemia is suspected, a CBC should be obtained and a bone marrow aspiration should be performed. This is particularly important if treatment with steroids or other immunosuppressive medications is being considered. Steroids may alleviate a rheumatic condition but may also place a child with leukemia at risk for relapse with steroid-resistant disease.

Gait Disturbances

Shayne D. Fehr*

Most gait disturbances are benign and resolve with normal growth and development. Others are pathologic in origin and necessitate treatment (Table 34.1).

GAIT CYCLE

The normal gait cycle is described by foot placement. The gait cycle begins with right heel strike, is followed by left toe-off, left heel strike, right toe-off, and ends with right heel strike. These 5 events describe 1 gait cycle and include 2 phases: stance and swing. The **stance phase** is the period of time during which 1 of the 2 feet is on the ground. The **swing phase** is the period during which a limb is being advanced forward without ground contact.

Measuring the duration of the gait cycle makes it possible to calculate the time required for each of the 5 phases. During normal gait, the duration of each phase is as follows: for weight acceptance, 11%; for single limb stance, 39%; for weight release, 11%; and for swing phase, 39%. Velocity, cadence, step length, stride length, and step width may be calculated from the timed and measured gait cycle.

DEVELOPMENT OF GAIT

Central nervous system maturation is necessary for the development of normal gait and accounts for the normal progression of developmental milestones. The typical milestones for locomotion include independent sitting at 6 months of age, crawling at about 9 months, walking without assistance at 12-15 months, and running at 18 months. A normal 1-year-old child has a wide-based stance and a rapid cadence with short steps; the elbows are flexed and reciprocal arm motion is not present. Foot strike occurs without an initial heel strike. A 2-year-old child shows increased velocity, step length, and diminished cadence in comparison with a 1-year-old child. Most of the adult gait patterns are present in children by 3 years, with changes in velocity, stride, and cadence continuing to 7 years of age. The gait characteristics of a 7-year-old child are similar to those of an adult.

CLINICAL EVALUATION OF GAIT DISTURBANCES

◆ History

The clinician should inquire about the pregnancy and delivery, the age at which developmental milestones occurred, the presence of any systemic illnesses (including chronicity, fever, rash, weight loss, and other organ system involvement), and whether there is a family history of any congenital musculoskeletal abnormalities or syndromes. With

regard to the gait disturbance, it is important to inquire when it was 1st observed, whether it is unilateral or bilateral, whether it is associated with any injuries or intercurrent systemic illnesses, and whether there has been a history of improvement or worsening with time.

◆ Physical Examination
General Musculoskeletal Examination
Although most of the findings in gait disturbances are confined to the lower extremities, the upper extremities and spine may be involved as part of an underlying disease process. A general assessment of all extremities and the spine should be performed to identify any abnormal motion, tenderness, swelling, deformity, or increased warmth.

The lower extremity musculoskeletal examination should begin with the child ambulating in the examination room or adjacent hallway. The child must be adequately undressed and be observed from a distance while walking so that the trunk and lower extremities can be clearly visualized. The positions of the thighs, knees, lower legs, and feet should be observed during ambulation. Combining gait observation with the history typically allows for diagnosing most of the common gait disturbances such as torsional variations (in-toeing and out-toeing), equinus gait (toe-walking), and limping.

Examination of the lower extremities should include measurement of lower extremity lengths and assessment of the hip, knee, ankle, and subtalar joints. The thighs, lower legs, and feet are inspected for evidence of asymmetry, soft tissue swelling, or injury. Palpation for tenderness or areas of increased warmth is performed. The shape of the foot is assessed for possible intrinsic deformity.

Lower extremity length measurements. The most accurate method of measuring lower extremity length is to have the child stand on a firm, level surface with the examiner standing behind the child and placing index fingers over the lateral aspect of each of the child's iliac crests. The presence or absence of pelvic obliquity is observed, and blocks of various heights are placed beneath the child's foot on the short side until the pelvis is level. The height of the block indicates the amount of lower extremity length discrepancy. Measurements obtained by use of a tape measure can also be performed but are less accurate. The most common method is to measure from the anterior-superior iliac spine to the distal aspect of the medial malleolus. These landmarks are sometimes difficult to palpate accurately, and there can be considerable error using this method.

Joint assessment. The ranges of motion of the hips, knees, ankles, and subtalar joints must be assessed. Hip flexion is measured, as are any flexion contractures. With the hip in extension, the degrees of abduction, adduction, internal rotation, and external rotation are measured, preferably with a goniometer, and are recorded. Hip rotation is most accurately measured with the child in the prone position with the knees flexed. Older children and adolescents are typically more comfortable when measured in the supine position with hips and

knees flexed to 90 degrees. Knee flexion and extension, ankle dorsiflexion, and plantar flexion, as well as subtalar motion, must be assessed and recorded.

Spinal evaluation. Spinal mobility should be assessed because abnormalities such as spondylolysis, nerve root impingement, diskitis,

and tumors may manifest as a gait disturbance. The child's ability to flex forward and to reverse lumbar lordosis is a sign of normal mobility (see Chapter 35). Areas of vertebral bone tenderness and muscle spasm are determined by direct palpation.

Neurologic Evaluation
Many gait disturbances have a neurologic cause or association. The neurologic examination should include muscle strength testing, sensory assessment (particularly to establish the specific level of any potential sensory deficits), deep tendon reflexes, and pathologic reflexes, such as the Babinski sign. Abnormal rectal tone or bladder distention is concerning for a spinal lesion.

◆ Radiographic Assessment
The need for radiographic evaluation is based on the differential diagnosis. For many gait disturbances, radiographic assessment is not required. When necessary, plain radiographs of the lower extremities, pelvis, or spine are obtained first, followed by special diagnostic studies, such as a teleoroentgenogram to assess for lower extremity length discrepancy, technetium bone scan to localize occult lesions such as avascular necrosis or stress fracture, and computed tomography (CT) to characterize specific lesions. Magnetic resonance imaging (MRI) is helpful in the diagnosis of occult or soft tissue lesions, such as infection, tumors, or metabolic bone disease, as well as other pathologic structural processes of the spine, such as syrinx, tethered cord, or disk anomaly.

◆ Laboratory Tests
Tests such as complete blood cell count with differential, erythrocyte sedimentation rate, and C-reactive protein level are indicated if an infectious, rheumatic, or otherwise inflammatory condition is suspected. Rheumatoid factor and antinuclear antibody determinations are less helpful in the diagnosis of rheumatic causes of gait disturbances (see Chapter 33). Other tests may be indicated for the diagnosis of specific disorders. Electromyography, nerve conduction studies, muscle biopsies, and nerve biopsies are frequently necessary in the diagnosis of myopathic or neuropathic disorders (see Chapter 29). Determinations of creatine phosphokinase, aldolase, and aspartate aminotransferase levels are important in the evaluation of striated muscle function and should be ordered if an underlying myopathy or myositis is suspected.

GAIT DISTURBANCES
The 3 most common categories of gait disturbances of childhood are torsional variations (in-toeing and out-toeing), toe-walking (equinus gait), and limping.

Torsional Variations
The presence of in-toeing or out-toeing does not necessarily imply an abnormality of the foot; rather, it indicates only the direction in which the foot is pointing during ambulation. Torsional variations can be located from the proximal (i.e., the hip) to the distal (i.e., the foot) region in the involved extremity. Some causes, such as clubfeet, are obvious, whereas others are subtle. Most torsional variations resolve with normal growth and development. The common causes of in-toeing and out-toeing are listed in Table 34.2.

Normal Developmental Alignment
In utero positioning affects the alignment of the lower extremities of infants. In the typical in utero position, the hips are flexed, abducted, and externally rotated; the knees are flexed; and the lower legs are

internally rotated. The feet are in a supinated position against the posterolateral aspect of the opposite thigh. The musculoskeletal examination of an infant characteristically shows 20- to 30-degree hip flexion contractures, 50-60 degrees of abduction, 80-90 degrees of external rotation in extension, and minimal or no internal rotation. The knees have 20- to 30-degree flexion contractures, and internal tibial torsion is present. These are normal findings. The increased external rotation of the hip is caused not by femoral retroversion but rather by a posterior hip capsule contracture, which begins to resolve at the time of independent ambulation.

The combination of external rotation at the hip and internal rotation of the lower leg produces a bowed appearance of the lower extremities in the weight-bearing position. This is not true bowing, but rather reflects this torsional combination. After the child attains independent ambulation, this bowed appearance resolves over a 6- to 12-month period.

Physiologic genu valgum ("knock knees") is seen between 3 and 4 years of age. This is true genu valgum and is not the result of torsional variations. This condition resolves with growth and normal adult knee alignment is obtained between 5 and 8 years of age. Newborns have a mean varus alignment of 15 degrees that corrects to neutral alignment between 18 and 20 months of age. The maximum valgus of 12 degrees occurs by 3-4 years of age. By 7 years of age, the valgus alignment corrects to that of a normal adult (8 degrees in females, 7 degrees in males). Overall, 95% of cases of developmental physiologic genu varum and genu valgum resolve with growth, even in children with more pronounced physiologic genu varus or genu valgus. In some children, the condition may not completely correct until adolescence.

Torsional Profile

The torsional or rotational profile aids in the diagnosis and sequential follow-up of children with torsional variations (Fig. 34.1).

Foot progression angle. The foot progression angle, which is the direction of the long axis of the foot with regard to the direction in which the child is walking (Fig. 34.2), should be measured. Inward

TABLE 34.2 Common Causes of In-Toeing and Out-Toeing

In-Toeing	Out-Toeing
Medial (internal) femoral torsion	Lateral (external) femoral torsion
Medial (internal) tibial torsion	Lateral (external) tibial torsion

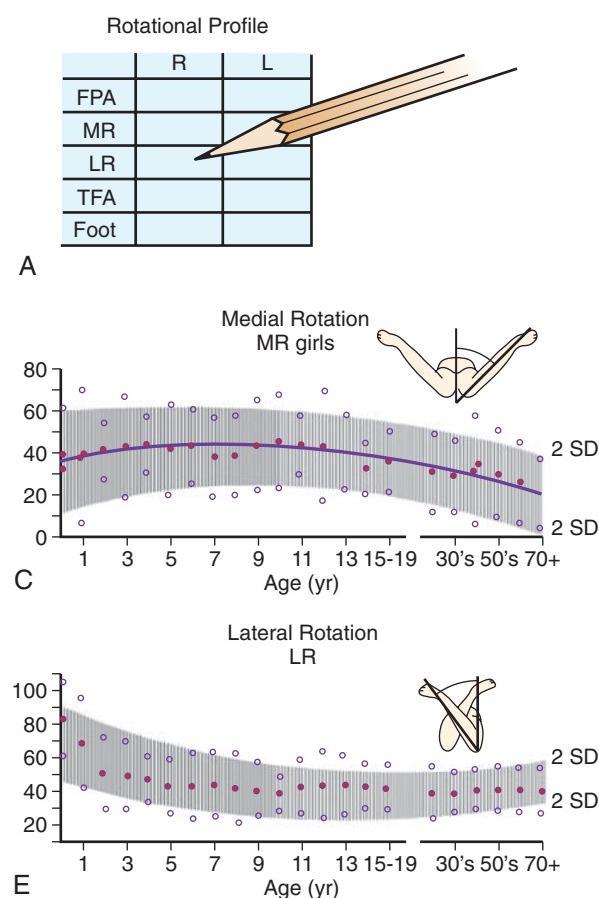
Talipes equinovarus (clubfoot)	Hypermobile pes planus


FIGURE 34.1 The torsional or rotational profile from birth to maturity. *A,* The rotational profile is assessed and tracked at each visit. *B,* Mean foot progression angle (FPA) by age. *C,* Mean femoral medial rotation in girls by age. *D,* Mean femoral medial rotation in boys by age. *E,* Mean lateral rotation by age. *F,* Mean thigh-foot angle. All graphs include 2 standard deviations from the mean. (From Morrissey RT, Weinstein SL, eds. *Lovell and Winter's Pediatric Orthopaedics.* 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 1990.)

rotation is given a negative value and outward rotation a positive value. A normal foot progression angle in children and adolescents is 10 degrees (range, −3 to +20 degrees). The foot progression angle defines whether the gait is normal or if there is an in-toeing or out-toeing gait. The latter is considered abnormal when the foot progression angle exceeds 20 degrees. Recording the angle allows for comparison during follow-up evaluations.

Hip rotation. Measuring hip rotation allows for indirect assessment of femoral version. Typically, the femoral neck creates an anteriorly directed angle with the transcondylar axis of the distal femur (Fig. 34.3). This anterior angulation is known as femoral anteversion and decreases from approximately 40 degrees at birth to 15 degrees by maturity. Increased internal rotation at the hip indicates excessive anteversion, and increased external rotation at the hip indicates retroversion. Hip rotation is assessed with the child in the prone position with the knees together and flexed 90 degrees (Fig. 34.4). In this position, the hip is in neutral alignment. Rotating the lower leg outwardly produces internal rotation of the hip; rotating the lower leg inwardly produces external rotation of the hip. A newborn hip in extension typically rotates externally 80-90 degrees and has a limited internal rotation of 0-10 degrees. By 1 year of age, there is approximately 30-40 degrees of internal rotation. Hip rotation should be bilaterally symmetric. Asymmetric rotation is often indicative of a hip disorder and necessitates radiographs of the pelvis. The mean hip internal rotation in extension in older males is 50 degrees (range, 25-65 degrees), and that in females is 40 degrees (range, 15-60 degrees).

Thigh-foot angle. With the child in the prone position and the knees approximated and flexed 90 degrees, the long axis of the foot in the neutral or simulated weight-bearing position can be compared with the long axis of the thigh (Fig. 34.5). Inward rotation is given a negative value, whereas outward rotation is given a positive value. Inward rotation is indicative of internal tibial torsion, and outward rotation represents external tibial torsion. This angle must be accurately measured and recorded. The mean thigh-foot angle is 10 degrees (range, −5 to +30 degrees) from middle childhood through adult life. Infants have a mean thigh-foot angle of −5 degrees (range, −35 to +40 degrees) as a consequence of the normal in utero position.

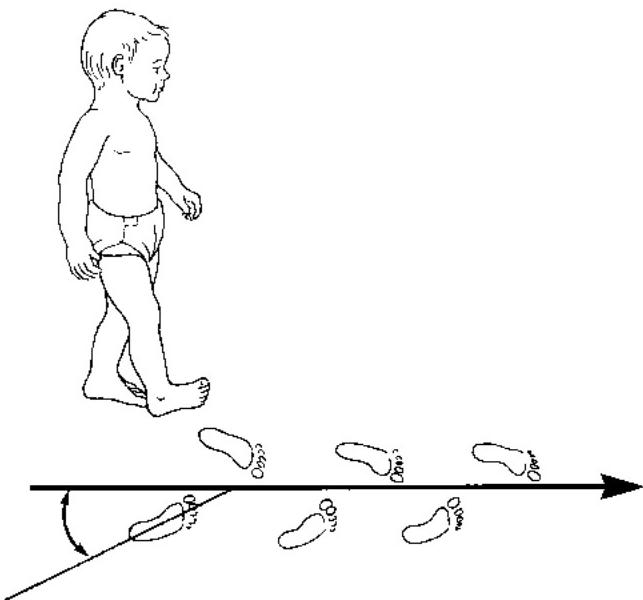
Foot shape. With the child again in the prone position, the shape of the foot is easily appreciated, allowing for assessment of children with metatarsus adductus or a calcaneovalgus foot. The mobility of the


FIGURE 34.2 Foot progression angle. The long axis of the foot is compared with the direction in which the child is walking. If the foot points outward, the angle is positive. If the foot points inward, the angle is negative.
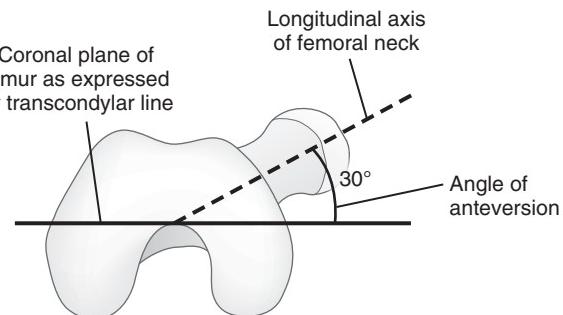

FIGURE 34.3 Femoral version. Typically, the femoral neck creates an anteriorly directed angle with the transcondylar axis of the distal femur.
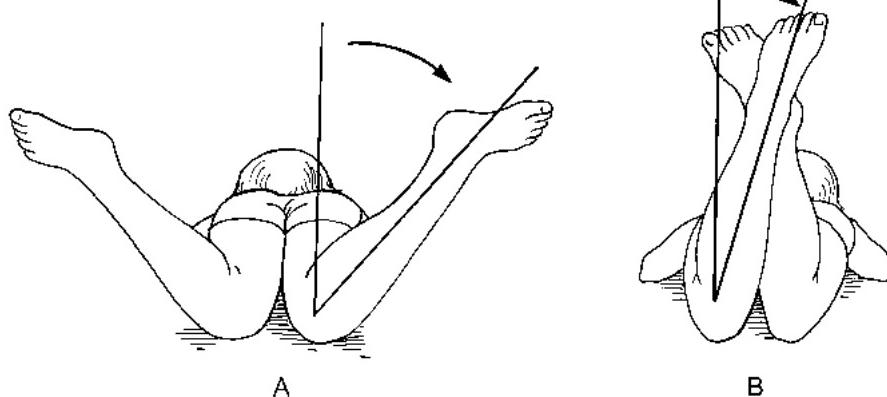

FIGURE 34.4 Hip rotation in extension. The child is in the prone position, with the knees flexed 90 degrees. The lower leg is vertically oriented. This is considered the neutral position. Outward rotation *(A)* of the leg produces internal hip rotation; inward rotation *(B)* produces external hip rotation.
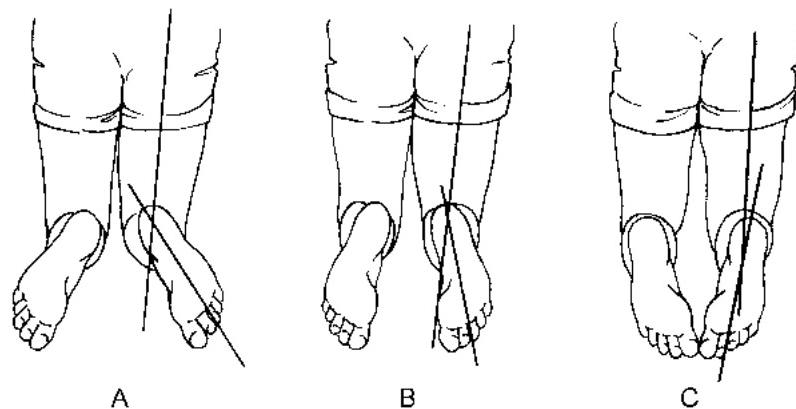

FIGURE 34.5 Thigh-foot angle. With the child in the prone position and the knees flexed and approximated, the long axis of the foot can be compared with the long axis of the thigh. The long axis of the foot bisects the heel and the 3rd or middle toe. External tibial torsion *(A)* produces excessive outward rotation. Normal alignment *(B)* is characterized by slight external rotation. Internal tibial torsion produces inward rotation *(C)*.

FIGURE 34.6 W-sitting is the position of comfort for children with increased femoral anteversion.

ankle and subtalar joint can also be evaluated with the child in this position.

In-Toed Gait

Internal femoral torsion. Increased femoral anteversion, also referred to as internal femoral torsion, is the most common cause of in-toeing in children 3 years of age or older and occurs twice as often in girls as in boys. Many affected children have generalized **ligamentous laxity**. Increased femoral anteversion is secondary to excessive or persistent infantile femoral anteversion and is almost always a benign condition that typically improves by 8-9 years of age. Severe anteversion or lack of progressive improvement by late childhood warrants referral to an orthopedic surgeon.

Children with increased anteversion often run with a circumduction gait secondary to internal rotation at the hip, and the parents may note that the child W-sits rather than sitting cross-legged (Fig. 34.6). W-sitting is of no concern developmentally, is the position of comfort for the child, and does not cause or worsen in-toeing in children. Children will typically stop sitting in this position after sufficient improvement in the internal torsion allows them to sit cross-legged more comfortably. Common femoral anteversion should not be viewed as a reason for decreased athletic ability or as a risk factor for arthritis, bunions, or back pain. A relationship with patellofemoral pain has been reported.

Physical examination. Gait assessment reveals that the entire lower extremity is inwardly rotated during ambulation. Foot progression angle is negative and a circumduction-type gait may be noted. Hip rotation assessment characteristically reveals 80-90 degrees of

FIGURE 34.7 *A,* Clinical photograph of a 5-year-old girl demonstrating internal femoral torsion. She has approximately 80 degrees of internal rotation bilaterally. *B,* External rotation is limited to approximately 15 degrees, for a total arc of rotation of 90-95 degrees.

internal rotation in the prone, extended position (Fig. 34.7). External rotation, as a consequence, is limited to 0-10 degrees. Features of generalized ligamentous laxity are often present, including elbow, wrist, and finger hyperextension, thumb hyperabduction, knee hyperextension, and hypermobile pes planus.

Radiographic evaluation. Radiographic evaluation of internal femoral torsion is not necessary. Anteroposterior radiographs of the pelvis are typically normal, but there may be the appearance of a relatively vertical femoral neck angle, or coxa valga. If coxa valga is noted, repeating the radiograph with the hips in 15 degrees of abduction and

30-40 degrees internal rotation will typically reveal a normal femoral neck angle. In more severe cases, MRI, CT, or ultrasonography of the proximal and distal femur can be used to accurately measure the degree of torsion.

Internal tibial torsion. Internal tibial torsion is the most common cause of in-toeing in children younger than 2 years and is secondary to normal in utero positioning. This condition is commonly seen during the 2nd year of life and may be associated with metatarsus adductus. Significant improvement usually does not occur until the child begins to pull up to standing and walk independently. Spontaneous resolution with normal growth and development can be anticipated typically by 4-5 years of age. Rarely, persistent or severe internal tibial torsion in an older child or adolescent may necessitate surgical derotation.

Physical examination. The degree of tibial torsion can be assessed by measuring the thigh-foot angle (see Fig. 34.5). The measurements should be recorded on each visit to the physician to document improvement.

Radiographic evaluation. Radiographic evaluation of internal tibial torsion is not necessary. MRI and CT can assess the degree of tibial torsion, but these are rarely required.

Metatarsus adductus. Metatarsus adductus is the most common congenital foot deformity, occurs equally in boys and girls, and is bilateral in approximately 50% of cases. Metatarsus adductus has hereditary tendencies and is more common in 1st-born children, most likely as a result of increased molding from the more rigid primigravida uterus and abdominal wall. Up to 10% of children with metatarsus adductus have **developmental dysplasia of the hip**. Significant metatarsus adductus persisting or manifesting after 4 years of age may require surgical correction.

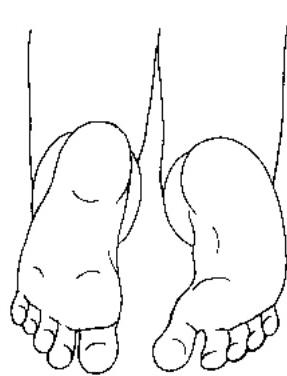
Physical examination. In metatarsus adductus, the forefoot is adducted and occasionally supinated, while the hindfoot and midfoot are normal. A visual line bisecting the heel should normally pass through the 2nd toe or 2nd web space; in metatarsus adductus this line intersects the forefoot more laterally. The lateral border of the foot is convex, the base of the 5th metatarsal is prominent, and the medial border of the foot is concave. There is usually an increased interval between the 1st and 2nd toes, with the great toe being held in an inwardly rotated or varus position (Fig. 34.8). Ankle range of motion is normal. Forefoot mobility, assessed by stabilizing the hindfoot and midfoot in a neutral position and applying pressure over the 1st metatarsal head with the opposite hand, can vary from flexible to rigid. Most cases of flexible metatarsus adductus resolve by several months


FIGURE 34.8 Foot shape. In the same position as for measurement of the thigh-foot angle, the shape of the foot can also be evaluated. In this illustration, the left foot has normal alignment and the right foot demonstrates metatarsus adductus.

of age; rigid deformities may require surgical correction. In the walking child with an uncorrected or partially corrected metatarsus adductus, there is an in-toed gait, abnormal shoe wear, and possible discomfort from shoe pressure.

Radiographic evaluation. Radiographs of the foot are not necessary for routine, flexible metatarsus adductus. When obtained, anteroposterior and lateral weight-bearing radiographs demonstrate adduction of the metatarsals at the tarsometatarsal joint and an increased intermetatarsal angle between the 1st and 2nd metatarsals. The midfoot and hindfoot are usually normal. Radiographs should be obtained if the deformity is rigid or if there are any suspected abnormalities of the midfoot or hindfoot.

Talipes equinovarus (clubfoot). Talipes equinovarus is classified as either positional or congenital. **Positional clubfoot** is a normal foot that has been held in the deformed position in utero, and which is flexible on examination in the newborn nursery. **Congenital clubfoot** represents a deformity not only of the foot but also of the entire lower leg and is categorized as either idiopathic or syndromic. There is a spectrum of severity, but clubfoot associated with neuromuscular diagnoses or syndromes is typically rigid and more difficult to treat. Clubfoot is also extremely common in patients with spinal dysraphism, arthrogryposis, and chromosomal syndromes such as trisomy 18 and chromosome 22q11.2 deletion syndrome.

Congenital clubfoot, when diagnosed and treated in infancy with serial casting, typically does not produce a gait disturbance. However, foot contact pressures may remain high, indicating that gait is not entirely normal following correction. In-toeing secondary to persistent internal tibial torsion is common after appropriate treatment. A mild lower extremity length discrepancy of up to 2 cm may be seen in adolescence, but usually does not produce a limp or necessitate treatment. On occasion, residual muscle imbalance may cause the child to walk on the lateral border of the foot, leading to discomfort and an antalgic gait that may require further surgical correction.

Out-Toed Gait

External femoral torsion. Femoral retroversion, also referred to as external femoral torsion, is a rare disorder that usually causes no significant functional impairment unless it is associated with a **slipped capital femoral epiphysis (SCFE)**. If the femoral retroversion is caused by SCFE, the slip is treated surgically. On occasion, persistent femoral retroversion following surgical treatment of SCFE can lead to ongoing functional impairment, such as a severe out-toed gait and difficulty in approximating the knees in the sitting position, and may require further surgical correction.

Physical examination. Children with external femoral torsion demonstrate limited internal rotation and excessive external rotation when the hip is examined in the extended position. The hip externally rotates 70-90 degrees, whereas internal rotation is only 0-20 degrees. Idiopathic external femoral torsion is usually bilateral. If the deformity is unilateral, especially in an obese older child or a young adolescent, SCFE must be considered and evaluated.

Radiographic evaluation. Anteroposterior and frog-leg lateral radiographs of the pelvis are necessary for any child or adolescent presenting with external femoral torsion, especially one who is obese, has atraumatic or referred anterior thigh or knee pain, or has unilateral deformity. Approximately 20% of children with SCFE have simultaneous bilateral involvement. The typical changes of SCFE include widening of the physis and an abnormal relationship between the capital femoral epiphysis (CFE) and the femoral neck. The femoral head appears to be slipped inferiorly and posteriorly, but in actuality, the femoral neck is rotated anteriorly and superiorly.

External tibial torsion. External tibial torsion is common and is secondary to a normal variation of in utero positioning in which the plantar surface of the foot is against the wall of the uterus, forcing it into a hyperdorsiflexed, everted position. This rotated alignment produces external tibial torsion and typically an associated calcaneovalgus foot (Fig. 34.9). When this alignment of the lower leg and foot is combined with the exaggerated external rotation of the normal newborn hip, the lower extremity appears to have severe out-toeing and external rotation. This condition follows the same clinical course as internal tibial torsion in that significant improvement does not occur during the 1st year of life. With the onset of independent ambulation, spontaneous improvement begins and is typically complete by 2-3 years of age.

Physical examination. External tibial torsion results in a positive thigh-foot angle of 30-50 degrees.

Radiographic evaluation. Radiographic assessment for external tibial torsion is not necessary.

Calcaneovalgus foot. The calcaneovalgus foot is common in newborns and is secondary to in utero positioning (see Fig. 34.9). The foot is hyperdorsiflexed with varying degrees of eversion and forefoot abduction. External tibial torsion is usually present. Calcaneovalgus foot is typically unilateral but may occasionally be bilateral. The hyperdorsiflexion of the foot usually resolves during the 1st 3-6 months of life. On occasion, resistant feet may require passive stretching, taping, or casting into a plantar flexed position. Usually, by the time the child begins to pull to standing and walk independently, the calcaneovalgus condition has resolved. The external tibial torsion, however, persists and follows the same natural history as internal tibial torsion.

Physical examination. The involved extremity demonstrates out-toeing, the dorsum of the foot can easily be brought into contact with the anterior aspect of the lower leg, and the forefoot has an abducted appearance. The increased dorsiflexion should not be confused with the increased joint mobility of premature infants. The deformity is flexible, and plantar flexion of the ankle is normal or almost normal. External tibial torsion of 30-50 degrees is a common associated finding.

Calcaneovalgus foot must be distinguished from the following 3 conditions: (1) congenital vertical talus, (2) posteromedial bowing of the tibia, and (3) neuromuscular abnormalities, such as paralysis of the

FIGURE 34.9 *A,* A clinical photograph of a 2-month-old girl demonstrating excessive external tibial torsion. This reverse or anterior thigh-foot angle shows approximately 50 degrees of external tibial torsion. *B,* A calcaneovalgus foot with forefoot abduction and increased hindfoot valgus in the same infant. There is also hyperdorsiflexibility of the foot in the ankle.

gastrocnemius muscle. Differentiation is typically based on physical examination findings, though radiographs may be required. Congenital vertical talus results in a rocker-bottom appearance to the foot. The deformity is rigid, as opposed to the flexible deformity seen with a calcaneovalgus foot. In posteromedial bowing of the tibia, the apex of the deformity is in the distal tibia, whereas the apex of the deformity in a calcaneovalgus foot is located at the ankle.

Radiographic evaluation. Simulated weight-bearing anteroposterior and lateral radiographs of the foot may be necessary to differentiate between the calcaneovalgus foot and a congenital vertical talus. In a calcaneovalgus foot, the radiographs either are normal or reveal an increase in hindfoot valgus. In the congenital vertical talus, the hindfoot is in equinus, whereas the midfoot and the forefoot are dorsally displaced, producing a rocker-bottom appearance. Anteroposterior and lateral radiographs of the tibia and fibula are necessary if there is bowing of the lower leg.

Hypermobile pes planus. Hypermobile, flexible, or pronated feet are **flatfeet**, a common cause of concern to parents. Children with this deformity are usually asymptomatic and have no limitation of activities. An individual may present for concerns of out-toeing because of the overpronation of the midfoot and hindfoot, which may allow the forefoot to become abducted. Flexible flatfeet are also common in neonates and toddlers as a result of the associated laxity in the bone-ligament complexes of the feet and the abundant fat in the area of the medial longitudinal arch. Most children with flatfeet improve by 6 years of age. In the older child, flexible flatfeet are usually secondary to generalized ligamentous laxity. Most older children and adolescents with flexible flatfeet or hypermobile pes planus are asymptomatic, though feet that are symptomatic with vigorous physical activity usually respond readily to the use of commercially available medial longitudinal arch supports. When the child has excessive heel valgus, pronation, or abnormal shoe wear that is unresponsive to a commercially or custom-made arch support, the use of a UCB (University of California, Berkeley) orthosis may be beneficial. Surgery is rarely indicated.

Physical examination. In the non–weight-bearing position in the older child with a flexible flatfoot, the normal medial longitudinal arch is visible, but in the weight-bearing position, the foot becomes pronated with varying degrees of pes planus and hindfoot valgus. Instead of bearing weight over the lateral column of the foot, the weight is shifted medially, producing pronation. Subtalar motion is examined with the ankle in the neutral position and should be normal or slightly increased. Loss of subtalar motion may indicate a rigid flatfoot. Common causes of rigid flatfeet include Achilles tendon contracture, tarsal coalition, and neuromuscular disorders. Rigid flatfeet may also be a familial trait. Other joints, especially the elbows, hands, and knees, usually demonstrate generalized ligamentous laxity in patients with flexible flatfeet. Children with flexible flatfeet should be evaluated for external tibial torsion.

Radiographic evaluation. Radiographs of asymptomatic flexible flatfeet are usually not indicated. Standing, anteroposterior, and lateral weight-bearing radiographs are obtained, if necessary. The most common indication is the presence of pain (Table 34.3). Anteroposterior radiographs reveal an increase in the talocalcaneal angle (>25 degrees) caused by the excessive hindfoot valgus. The lateral view shows distortion of the normal straight-line relationship between the long axis of the talus and the 1st metatarsal and flattening of the normal medial longitudinal arch.

Equinus Gait (Toe-Walking)

Toe-walking can be a normal finding in children up to 3 years of age. Persistent toe-walking thereafter or acquired toe-walking at a later age

TABLE 34.3	Differential Diagnosis of Foot Pain According to Age

is considered abnormal and necessitates careful evaluation. The differential diagnosis for persistent or acquired toe-walking includes the following:

1. Neuromuscular disorders, such as cerebral palsy, Duchenne muscular dystrophy, or spinal cord abnormality resulting from a tethered spinal cord or diastematomyelia
2. Congenital Achilles tendon contracture (idiopathic toe-walking)
3. Habitual toe-walking
4. Lower extremity length discrepancy

The differentiation of toe-walking can usually be determined from the history and the physical examination. The examiner should establish the time at onset, the amount of time a child spends walking on his or her toes, whether it can be voluntarily corrected, and whether there has been improvement or worsening over time.

Neuromuscular Disorders

The neuromuscular disorder most likely to produce an equinus gait, either unilateral or bilateral, is **cerebral palsy**. The most common type of cerebral palsy is spastic diplegia, a disorder in which the lower extremities are more involved than the upper extremities. Prematurity is a common risk factor for spastic diplegia. It can be symmetric or asymmetric, with 1 side being slightly more involved than the other. Spastic diplegia tends to produce a bilateral equinus gait. Spastic

hemiplegia, in which only 1 side is involved, is usually caused by birth trauma (asphyxia), perinatal stroke, or underlying congenital malformation and results in unilateral toe-walking.

Acquired or late-onset toe-walking is usually a result of a developing neuromuscular disorder, such as Duchenne muscular dystrophy. As fat and fibrous tissues replace muscle, equinus and other contractures occur. There is usually a history of progressive clumsiness and frequent episodes of falling. The diagnosis of muscular dystrophy is usually made when the child is between 3 and 5 years of age. The diagnosis is confirmed by markedly elevated creatine phosphokinase levels, by muscle biopsy, or by genetic testing. In a spastic equinus gait without contracture, physical therapy and orthoses (daytime, nighttime, or both) may be beneficial. If a contracture has developed, serial casting may be performed in young children, whereas surgical lengthening of the Achilles is usually necessary in older children.

Physical examination. The examination of a child with toe-walking secondary to cerebral palsy reveals either an Achilles contracture or a spastic equinus gait without contracture, as well as abnormal neurologic findings. These findings include increased muscle tone, spasticity, hyperactive deep tendon reflexes, and pathologic reflexes, such as a positive Babinski sign. Hamstring tightness, in addition to ankle equinus, may be a subtle sign of underlying mild cerebral palsy.

Children with Duchenne muscular dystrophy typically demonstrate **pseudohypertrophy** of the calves in addition to equinus contracture. They have proximal muscle weakness first, and then generalized weakness, and perhaps decreased or absent upper extremity and patellar tendon reflexes, depending on the stage of progression. Ankle reflexes are usually preserved.

Radiographic evaluation. Radiographic evaluation of a child with toe-walking is rarely necessary. MRI of the brain and spine is occasionally required during the evaluation of a possible neuromuscular disorder.

Other testing. Dynamic electromyography and gait analysis studies can be helpful in distinguishing between toe-walking caused by mild cerebral palsy and that caused by a congenital Achilles contracture. Serum muscle enzyme (creatine phosphokinase, aspartate aminotransferase, and aldolase) levels and muscle biopsies are required for children with suspected Duchenne muscular dystrophy or other myopathies.

Lower Extremity Length Discrepancy

Lower extremity length discrepancy is a common cause for a unilateral equinus gait in older children and adolescents. Usually, mild discrepancies of less than 2 cm can be adequately compensated for during normal gait with minimal, if any, limping or toe-walking. Greater discrepancies may result in toe-walking and may require surgical correction. The differential diagnosis of a lower extremity length discrepancy is extensive (Table 34.4).

Physical examination. Examination of a child with a lower extremity length discrepancy shows shortness of the involved extremity; this can be measured by placing blocks of various heights beneath the foot until the pelvis is level. The range of motion of the joints of the involved extremity, especially of the hips, must be assessed. The neurologic examination is also important. Children with subtle neurologic disorders, such as cerebral palsy, may also have a very mild lower extremity length discrepancy that contributes to an equinus gait.

Radiographic evaluation. Children with a lower extremity length discrepancy require radiographic assessment. Lower extremity lengths are typically measured radiographically by 1 of several methods, including the teleoroentgenogram, orthoroentgenogram, scanogram, and low-dose biplanar radiography. Digital teleoroentgenograms and orthoroentgenograms are currently preferred, but low-dose biplanar

Modified from Moseley C. Leg-length discrepancy. *Pediatr Clin North Am.* 1986;33(6):1385; Tachdjian M. *Pediatric Orthopedics.* 2nd ed. Philadelphia: WB Saunders; 1990; reprinted and modified from Behrman RE, ed. *Nelson Textbook of Pediatrics.* 14th ed. Philadelphia: WB Saunders; 1992:1702.

radiography is becoming more commonplace at large centers. The teleoroentgenogram is a single radiographic exposure of both lower extremities in the standing position. This can be measured using measurement tools within the digital radiography software. Advantages include single exposure and detection of angular deformities. The orthoroentgenogram consists of overlapping exposures centered on the hips, knees, and ankles on a long cassette. Like the teleoroentgenogram, an advantage of this type of radiograph is that it shows associated angular deformities. A scanogram consists of 3 strip exposures of the hips, knees, and ankles on a standard-sized cassette with a radiographic ruler adjacent to the extremity. This is an accurate method of assessing limb length but does not demonstrate angular deformities. Low-dose biplanar radiography is a 3-dimensional imaging method with superior accuracy and decreased radiation exposure but requires a sophisticated radiologist to correctly align the limbs for computer measurement. CT measurement is accurate but is not commonly used secondary to the amount of radiation exposure required. Radiographs of the left hand and wrist for bone age are also obtained to assess when skeletal maturity will occur.

Habitual Toe-Walking

Habitual toe-walking occurs in a child who is walking on his or her toes voluntarily. Toe-walking occurs relatively commonly in young walkers. Their history and physical examination findings are entirely normal. This is a diagnosis of exclusion. The treatment of habitual toe-walkers is observation. As the child becomes heavier and the central nervous system matures, the toe-walking should resolve.

Physical examination. The findings in the examination of the child with habitual toe-walking are normal. The ankle has a full range of motion, and there is no evidence of an underlying neuromuscular disorder.

Radiographic evaluation. Radiographic evaluation is not indicated.

Idiopathic Toe-Walking

Idiopathic toe-walking is defined as the presence of an equinus gait in a child over 2 years of age with or without Achilles tendon contracture in the absence of other etiologies, including habitual toe-walking. The birth and developmental history and the neurologic findings are usually normal. However, mild developmental delays, especially in speech and in fine and gross motor skills, are seen in some children. Some have suggested possible deficits in sensory processing. A family history positive for Achilles contracture, male predominance, and learning disabilities are common findings. Muscle biopsy samples have shown an increase in type I fibers, suggesting a neuropathic process. Serial casting typically leads to resolution, though in some children, surgical lengthening of the Achilles tendon may be required.

Physical examination. If present, Achilles tendon contracture leads to an inability to dorsiflex the foot to the neutral or plantigrade position. Examination of the ankle shows a 10- to 15-degree fixed equinus contracture. The assessment of an Achilles contracture should be performed with the hindfoot held in a slightly supinated position to bring the calcaneus beneath the talus. If this position is not used, dorsiflexion of the foot produces hindfoot valgus with the appearance of more dorsiflexion than is actually present. In congenital Achilles contractures, no other musculoskeletal or neurologic abnormalities are present.

Radiographic evaluation. Radiographs are not necessary unless an associated abnormality within the foot is thought to be present. Should this occur, anteroposterior and lateral weight-bearing radiographs of the foot should be obtained.

Limping

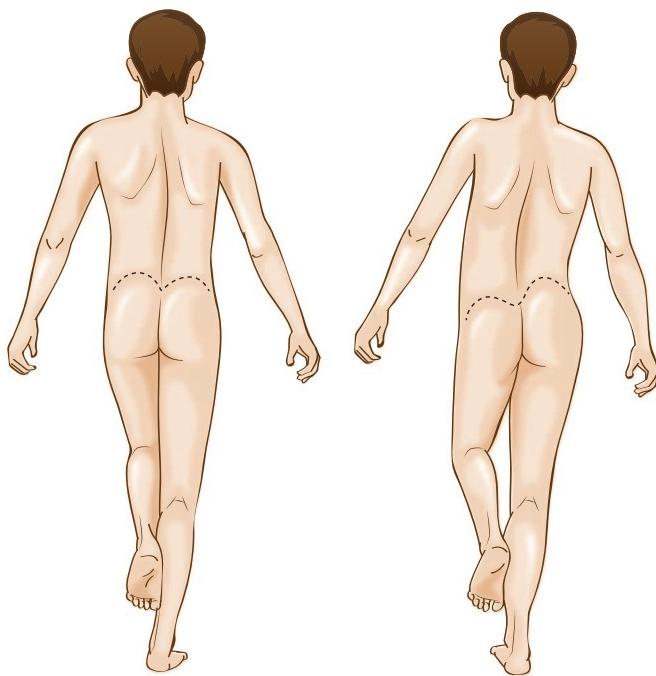
Limping is categorized as either painful (antalgic gait) or nonpainful (Trendelenburg gait), depending on the length of the stance phase. With an **antalgic gait**, the stance phase is shortened because the child decreases the time spent on the painful extremity. In a **Trendelenburg**


FIGURE 34.10 Trendelenburg gait. With functional weakness of the hip abductor muscles, it is difficult to support the body's weight on the affected side; the pelvis tilts down and away from the weak side, the patient leans toward the affected side.

gait (Fig. 34.10), which indicates underlying proximal muscle weakness (e.g., muscular dystrophy) or hip instability (e.g., developmental hip dysplasia), the stance phase is the same for the involved and uninvolved sides, but the child leans over the involved side to shift the center of gravity for balance. If the disorder is bilateral, it produces a **waddling gait**. The differential diagnosis is extensive (Table 34.5). Most causes involve the lower extremity, but spinal disorders can also produce limping or difficulty walking, especially if there is spinal cord or peripheral nerve involvement. Painful (antalgic) gaits are predominantly caused by trauma, infection, neoplasia, and rheumatic disorders. Trendelenburg gaits are generally caused by congenital, developmental, or neuromuscular disorders. Thus, antalgic gaits result from *acute* disorders, whereas Trendelenburg gaits usually result from *chronic* disorders. The type of gait, the presence or absence of systemic symptoms, and the anatomic location of the symptoms can usually be determined from the history and physical examination findings.

Antalgic Gait

Congenital origin: Tarsal coalition. Tarsal coalition, also called **peroneal spastic flatfoot**, is characterized by a painful, rigid valgus or pronation deformity of the midfoot and hindfoot, in association with peroneal muscle spasm but without true spasticity. This condition represents a congenital fusion or failure of segmentation between 2 or more tarsal bones. However, any condition that alters the normal motion of the subtalar joint may produce the clinical appearance of a tarsal coalition. Thus, congenital malformation, inflammatory disorders, infection, neoplasms, and trauma involving the subtalar joint can manifest with pain, limping, or other symptoms similar to those of a tarsal coalition.

The most common coalitions occur between the calcaneus and navicular (calcaneonavicular) and the middle or medial facet between the talus and calcaneus (talocalcaneal). Coalitions can be fibrous, cartilaginous, or osseous. The incidence of tarsal coalition is

TABLE 34.5 **Differential Diagnosis of Limping in Children**

From Marcdante K, Kliegman R, eds. *Nelson Essentials of Pediatrics.* 7th ed. Philadelphia: Saunders; 2015.

approximately 1%, and it appears to be inherited as an autosomal dominant trait. Approximately 60% of calcaneonavicular and 50% of talocalcaneal coalitions are bilateral. Casting and orthotics may provide some relief of symptoms, though surgical repair is typically required.

Physical examination. The onset of symptoms is insidious and usually occurs during late childhood or early adolescence. Although mild limitation of subtalar motion and a valgus or pronated hindfoot may have been present since early childhood, the onset of symptoms varies with the age at which the fibrous or cartilaginous coalition begins to ossify and further decrease motion. The talonavicular coalition ossifies between the ages of 3 and 5 years; the calcaneonavicular coalition, between 8 and 12 years; and the middle facet talocalcaneal coalition, between 12 and 16 years of age. The pain is typically felt laterally in the hindfoot and radiates proximally along the lateral malleolus and distal fibula into the peroneal muscle region. Symptoms are usually

aggravated by sports or other vigorous activities and are relieved by rest. The foot is pronated in both the weight-bearing and the non–weight-bearing positions. Subtalar joint motion is diminished or absent, and attempts at motion produce pain.

Radiographic evaluation. The diagnosis of tarsal coalition is made radiographically. The initial radiographs should include anteroposterior and lateral weight-bearing radiographs of the foot and an oblique radiograph. The latter is necessary in making the diagnosis of a calcaneonavicular coalition. Beaking of the anterior aspect of the talus in the lateral view suggests a talocalcaneal coalition. Axial views of the hindfoot can be useful in the diagnosis of a middle facet talocalcaneal coalition. CT has traditionally been the diagnostic procedure of choice for coalition, but MRI is useful for detecting fibrous coalitions. CT or MRI should be performed on all coalitions for surgical planning because more than 1 coalition can be present.

Developmental origin

Legg–Calvé–Perthes disease. Legg–Calvé–Perthes disease (LCPD) is idiopathic avascular necrosis of the CFE and its associated complications in an immature, growing child. This disorder is caused by an interruption of the blood supply to the CFE, occurs predominantly in males (up to 5:1), and is bilateral in approximately 20% of affected children. Children with LCPD have delayed skeletal or bone age, disproportionate growth, and mildly short stature. Secondary osteonecrosis is seen in patients with sickle cell anemia. LCPD is a local, self-healing disorder. Prevention of femoral head deformity and secondary degenerative osteoarthritis in adulthood is the only indication for treatment.

Physical examination. The symptomatic onset of LCPD typically occurs between 2 and 12 years of age, at a mean age of 7 years. Most of these children present to care with a limp and mild or intermittent pain in the anterior thigh or knee, such that this condition is often referred to as a "painless limp." Pertinent early physical findings include antalgic gait; muscle spasm with mild restriction of hip motion, especially abduction and internal rotation; proximal thigh atrophy; and mild short stature.

Radiographic evaluation. The diagnosis is typically made from anteroposterior and frog-leg lateral radiographs of the pelvis (Fig. 34.11). The radiographic characteristics can be divided into 5 distinct stages, depending on the interval from the onset of symptoms: (1) cessation of CFE growth, (2) subchondral fracture, (3) resorption or fragmentation, (4) reossification, and (5) healed, or residual. The symptoms are usually most pronounced during the phase of the subchondral fracture and fragmentation. A child with LCPD has the potential for collapse and extrusion of the femoral head, which results in a permanent deformity. If plain radiographs do not demonstrate LCPD in suspected cases, a bone scan or MRI is helpful.

Slipped capital femoral epiphysis. SCFE is the most common adolescent hip disorder. It generally occurs in obese adolescents with delayed skeletal maturation, or in tall and thin adolescents who have had a recent growth spurt. SCFE can also occur as a complication of an underlying endocrine disorder, such as hypothyroidism and pituitary disorders. When SCFE occurs before puberty, a hormonal abnormality or systemic disorder should be suspected. The histopathologic features of SCFE indicate that mechanical factors are the ultimate cause of slippage. The initial abnormality is most likely secondary to endocrine changes during early adolescence. Obesity produces high shear forces across a weakened and obliquely oriented CFE, resulting in slippage. Surgical stabilization is required.

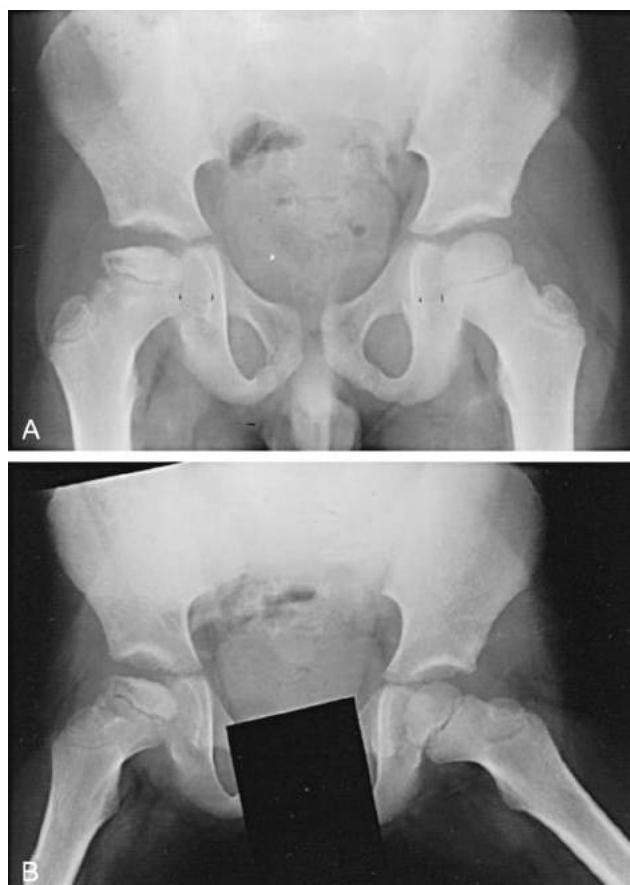
Physical examination. The physical findings depend on the degree of slippage and the classification. The disorder is classified as either stable or unstable. In an unstable or acute SCFE, the CFE is separated from the femoral neck. This is extremely painful, and the adolescent is


FIGURE 34.11 *A,* An anteroposterior radiograph of the pelvis demonstrating Legg–Calvé–Perthes disease (LCPD) of the right hip. The capital femoral epiphysis (CFE) is collapsing, and there is mild widening of the medial joint space. The left CFE is normal. *B,* A frog-leg lateral radiograph of the pelvis demonstrating limited hip abduction caused by LCPD.

unable to stand or bear weight. In a stable or chronic SCFE, the most common type, the CFE and femoral neck are in continuity, and the slippage is occurring slowly by plastic deformation. The adolescent has an antalgic, out-toed gait. The hip range of motion demonstrates a lack of internal rotation and an increase in external rotation; as the hip is flexed, it becomes progressively more externally rotated. Limitation of flexion and abduction in extension may also be present as a result of the deformity of the proximal femur.

Radiographic evaluation. The diagnosis of SCFE is confirmed radiographically. Anteroposterior and frog-leg lateral radiographs of the pelvis must be obtained (Fig. 34.12). Both hips should be visualized on each radiograph for simultaneous comparison. The earliest sign of SCFE is widening of the physeal plate without slippage, which is considered a pre-slip condition. If slippage occurs, the CFE remains in the acetabulum, whereas the femoral neck rotates anteriorly and superiorly, resulting in varus orientation and retroversion of the femoral head and neck. The severity of slippage can be classified by the degree of displacement of the CFE on the femoral neck.

Trauma

Sprains, strains, and contusions. **Sprains** are ligamentous injuries, whereas **strains** are muscle injuries. **Contusions** are the result of a direct injury and involve the skin and the subcutaneous tissues as well as underlying muscle.

FIGURE 34.12 *A,* An anteroposterior radiograph of the right hip in a 13-year-old obese boy who had been limping and complaining of anterior thigh and knee pain for approximately 2 months. There is a mild stable or chronic slipped capital femoral epiphysis (SCFE). Klein line, a line drawn along the superior aspect of the femoral neck, does not intersect the lateral portion of the capital femoral epiphysis (CFE) and thereby indicates slippage. Also, the physis is wide and irregular. *B,* A frog-leg lateral radiograph clearly demonstrates the slippage of the CFE with respect to the femoral neck. *C,* An anteroposterior radiograph of the pelvis demonstrates an asymptomatic mild stable or chronic left SCFE. It is always important to order radiographs of the pelvis rather than individual views of the right or left hip. *D,* A frog-leg lateral radiograph confirms bilateral SCFE.

Sprains are divided into 3 grades:
1. Grade I: mild with only slight stretching of the ligament
2. Grade II: a moderate injury with partial tearing of the ligament but normal stability
3. Grade III: a severe injury with ligamentous disruption and instability

Sprains, strains, and contusions of the lower extremities are among the most common injuries that produce limping. There is usually a history of trauma, and the location is readily apparent because of soft tissue swelling, ecchymoses, and pain. Most of these injuries occur during athletic activities, but they can also be the result of falls or other minor injuries. In the absence of an associated physeal injury or other fracture, treatment is typically immobilization with a gradual return to activity.

Physical examination. In sprains, the physical examination typically reveals that the involved ligament is tender to direct palpation. There may be soft tissue swelling as well as ecchymoses. The range of motion of the involved joint is typically decreased because of pain. On occasion, a mild joint effusion or hemarthrosis may be present.

Strains involve the muscles, and there is usually tenderness to palpation, soft tissue swelling, and pain with joint motion as a result of stretching of the involved muscle. A palpable defect within the muscle is uncommon except in the most severe injuries. These injuries usually limit the excursion of the muscle and its associated joints.

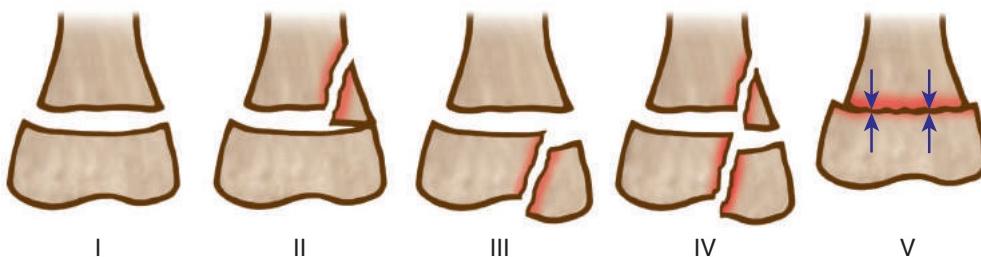
Radiographic evaluation. In children who sustain sprains, strains, or significant contusions, anteroposterior and lateral radiographs should be obtained. A word of caution regarding sprains is necessary. In children, ligaments are usually stronger than the adjacent physes. Therefore, a **physeal injury** may be present and may have the same clinical features as a sprain (Fig. 34.13; see also Table 34.6). This is especially true with lateral ankle injuries. It is more likely that a Salter–Harris type I separation of the distal fibular epiphysis has occurred, rather than a true ligament injury. This condition should be suspected when there is more tenderness to palpation over the lateral malleolus than over the ligaments. If plain radiographs are normal, stress radiographs may be necessary to establish the diagnosis. This concept also applies to the knee.


FIGURE 34.13 Salter-Harris classification of physeal fractures, types I-V.

TABLE 34.6	Salter–Harris Classification
Salter–Harris Type	**Characteristics**
I	Separation through the physis, usually through the zones of hypertrophic and degenerating cartilage cell columns
II	Fracture through a portion of the physis but extending through the metaphysis
III	Fracture through a portion of the physis extending through the epiphysis and into the joint
IV	Fracture across the metaphysis, physis, and epiphysis
V	Crush injury to the physis

From Baldwin KD, Wells L, Dormans JP. Common fractures. In: *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Saunders; 2016:3317, Chapter 683, Table 683-1.

Occult fractures. Occult fractures of the tibia are a relatively common cause of limping or refusal to bear weight in very young children. They can also occur in the femur and fibula. These fractures can be the result of very innocuous trauma, such as tripping while walking, stepping on a toy, or falling from a height. Frequently, the injury may not have been observed, and the child cannot convey to the parents what happened, confounding diagnosis.

The most common occult fracture in early childhood is the **"toddler's fracture"** of the tibia. This is an oblique fracture of the distal third of the tibia without an associated fibula fracture. It most commonly occurs in children younger than 4 years of age. Occult tibia fractures can also occur in the metaphyseal regions, usually distally, but only rarely in the diaphysis. Diaphyseal fractures are more commonly the result of child abuse.

Physical examination. Physical findings in a child with an occult fracture can be subtle. There is usually minimal, if any, soft tissue swelling. There is mild tenderness and perhaps increased warmth on palpation over the fracture. On occasion, the increased warmth may be indicative of osteomyelitis. Stress examination of the involved bone increases discomfort.

Radiographic evaluation. Anteroposterior and lateral radiographs should be obtained (Fig. 34.14). The characteristic finding of a toddler's fracture is a faint oblique fracture line crossing the distal third of the tibia. On occasion, oblique radiographs may be helpful in revealing the fracture. Frequently, initial radiographs reveal no abnormality. If plain radiographs are normal, the child has no systemic symptoms, and an occult fracture of the tibia is suspected, simple immobilization in a long-leg cast is indicated. Another set of radiographs in 1-2 weeks usually reveals the fracture and evidence of healing. If, however, the child has systemic symptoms, such as low-grade fever, and if

FIGURE 34.14 *A,* An anteroposterior radiograph of the lower leg of a 2-year-old girl who had been limping on the left lower leg for approximately 1 week. There was no observed trauma. No obvious abnormality is visible in this view. *B,* A lateral radiograph showing a faint oblique fracture line *(arrows)*. This is characteristic of the "toddler's fracture." There is already early subperiosteal new bone or callus formation posteriorly.

osteomyelitis is thought to be present, evaluation including a complete blood count with differential, blood culture, C-reactive protein level, erythrocyte sedimentation rate, and an MRI should be obtained.

Neoplasia. Benign and malignant neoplastic lesions that involve bone, cartilage, or soft tissue of the spine, pelvis, and lower extremities can manifest as a mass, can cause pain, and can produce an antalgic gait. Leukemia or metastatic neuroblastoma of the bone marrow may produce deep bone pain and limp without objective findings of swelling or tenderness on physical examination. Night pain is a common characteristic of both benign and malignant primary or metastatic tumors. Osseous lesions can usually be diagnosed on plain radiographs, whereas for those of cartilage or soft tissue, MRI or other special imaging studies may be required for diagnosis.

Benign neoplasms. The most common benign lesions that produce limping include a unicameral (simple) bone cyst and osteoid osteoma (Table 34.7). Other less common benign lesions that can produce pain and limping include eosinophilic granuloma of the bone, osteochondroma, and chondroblastoma. Chondroblastoma typically involves the epiphysis, especially of the proximal humerus.

In **unicameral bone cysts**, the symptoms are usually caused by a nondisplaced pathologic fracture. On occasion, a displaced fracture may occur. The most common location for a unicameral bone cyst is the proximal humerus, followed by the proximal femur. These can occur in any of the bones of the lower extremities, including the foot.

Osteoid osteomas have a highly vascularized nidus, which incites an intense, painful, inflammatory reaction that produces sclerosis of the surrounding bone. The pain is typically worse at night and is characteristically relieved by nonsteroidal antiinflammatory drugs (NSAIDs) and aspirin.

Radiographic evaluation. Most benign neoplasms are visible on anteroposterior and lateral radiographs of the symptomatic area. Characteristics of benign lesions include well-circumscribed lesions without periosteal new bone formation or soft tissue mass. If a lesion is suspected but not visible on plain radiographs, such as may occur in an osteoid osteoma, a technetium bone scan may be helpful. Further

evaluation can be achieved with CT or MRI. Diagnosis is further aided by surgical biopsy, which may also allow for surgical treatment.

Malignant neoplasms. Leukemia is the most common childhood malignancy and is frequently accompanied by musculoskeletal complaints, such as limping, fever, bone pain, pallor, bruising, and weight loss (Fig. 34.15). Common malignancies involving the musculoskeletal system include osteogenic sarcoma, Ewing sarcoma, and intraspinal tumors, such as astrocytomas (Table 34.8). Intraspinal tumors tend to produce neurologic symptoms, such as muscle weakness, as the cause of limping. The other lesions may produce a mass, bone weakness, and possible pathologic fractures. Weight loss, fever, and pain are common associated complaints.

Physical examination. A careful musculoskeletal and neurologic examination is necessary for any child with a suspected neoplasm. In many cases, a mass, either in the involved bone or in adjacent soft tissues, may be palpable. These are typically tender and warm. These lesions are frequently adjacent to joints and may result in decreased range of motion. Neurologic evaluation may show evidence of muscle weakness or abnormal reflexes, suggestive of spinal cord or peripheral nerve involvement.

Radiographic evaluation. Anteroposterior and lateral radiographs of the involved area usually reveal the presence of a neoplasm.

TABLE 34.7	**Benign Bone Tumors and Cysts**			
Disease	**Characteristics**	**Radiographic Findings**	**Treatment**	**Prognosis**
Osteochondroma (osteocartilaginous exostosis)	Common; distal metaphysis of the femur, proximal humerus, proximal tibia; painless, hard, nontender mass	Bony outgrowth; sessile or pedunculated	Excision, if symptomatic	Excellent; malignant transformation rare
Multiple hereditary osteochondromas	Osteochondroma of long bones; bone growth disturbances	As above	As above	Multiple lesions develop until skeletal maturity, after which no new lesions develop; malignant transformation rare
Osteoid osteoma	Pain relieved by aspirin; femur and tibia; found predominantly in boys	Dense sclerosis surrounds small radiolucent nidus <1 cm	As above	Excellent
Osteoblastoma (giant osteoid osteoma)	As above, but more destructive	Osteolytic component; size >1 cm	As above	Excellent
Enchondroma	Tubular bones of hands and feet; pathologic fractures, swollen bone; Ollier disease if multiple lesions are present	Radiolucent diaphyseal or metaphyseal lesion; may calcify	Excision or curettage	Excellent; malignant transformation rare
Nonossifying fibroma	Silent; rare pathologic fracture; late childhood, adolescence	Incidental radiographic finding; thin sclerotic border, radiolucent lesion	None or curettage with fractures	Excellent; heals spontaneously
Eosinophilic granuloma	Age 5–10 yr; skull, jaw, long bones; pathologic fracture; pain	Small, radiolucent without reactive bone; punched-out lytic lesion	Biopsy, excision rare; irradiation	Excellent; may heal spontaneously
Brodie abscess	Insidious local pain; limp; suspected as malignancy	Circumscribed metaphyseal osteomyelitis; lytic lesions with sclerotic rim	Biopsy; antibiotics	Excellent
Unicameral bone cyst (simple bone cyst)	Metaphysis of a long bone (femur, humerus); pain, pathologic fracture	Cyst in medullary canal, expands cortex; fluid-filled unilocular or multilocular cavity	Curettage; steroid injection into lesion	Excellent; some heal spontaneously
Aneurysmal bone cyst	As above; contains blood, fibrous tissue	Expands beyond metaphyseal cartilage	Curettage, bone graft	Excellent

Modified from Marcdante K, Kliegman R, eds. *Nelson Essentials of Pediatrics.* 7th ed. Philadelphia: Saunders; 2015.

FIGURE 34.15 *A,* Anteroposterior pelvic radiograph of a 2-year-old girl who had been limping for 4 months. There is an extensive destructive lesion on the right proximal femur. *B,* A large soft tissue mass is demonstrated on magnetic resonance imaging scan. The preoperative diagnosis was Ewing sarcoma, but at biopsy the diagnosis was acute lymphoblastic leukemia.

TABLE 34.8	**Comparison of Osteogenic and Ewing Sarcoma**	
	Osteogenic Sarcoma	**Ewing Sarcoma**
Age	Adolescence	Childhood and adolescence
Racial predilection	All races	Predominantly non-Hispanic white
Sex (M:F ratio)	1.5:1	1.5:1
Cell	Spindle cell, osteoid	Nonosseous, small round cell
Predisposing risk factors	Retinoblastoma Radiotherapy Alkylating agents	None
Site	Metaphysis, epiphysis; distal femur > proximal tibia > proximal humerus	Diaphysis, medullary cavity, cortical bone, soft tissue; femur > pelvis > tibia > humerus
Presentation	Local pain	Pain, fever, increased ESR, FUO, weight loss
Roentgenogram	Lytic, sclerotic Sunburst pattern	Mottled, lytic Onion-skin pattern
Differential diagnosis	Ewing sarcoma, osteomyelitis	Osteomyelitis, eosinophilic granuloma, lymphoma, neuroblastoma, rhabdomyosarcoma
Metastasis	Lung, bones Skip lesions in the same bone	Lung, bones
Treatment	Surgery, chemotherapy Limb salvage if tumor is resectable and the patient is near adult height	Surgery, radiotherapy Chemotherapy
Outcome	50–60% survival	60% survival without metastasis; 5–15% with metastasis, primary site dependent
Poor prognosis	Onset at age <10 yr, large tumor size (>15 cm), symptoms <2 mo, metastasis	Pelvis, soft tissue tumor, increased LDH, metastasis, increased circulating PMNs, decreased circulating lymphocytes

ESR, erythrocyte sedimentation rate; F, female; FUO, fever of unknown origin; LDH, lactate dehydrogenase; M, male; PMN, polymorphonuclear neutrophil.
Modified from Behrman RE, ed. *Nelson Textbook of Pediatrics.* 14th ed. Philadelphia: WB Saunders; 1992:1312.

Characteristics of a malignant osseous lesion include bone destruction, permeative or infiltrative appearance, periosteal new bone formation (Codman triangle), and an associated soft tissue mass (see Table 34.8). Radiographic abnormalities associated with acute leukemia include diffuse osteopenia, metaphyseal bands, periosteal new bone formation, geographic lytic lesions, sclerosis, and permeative distraction. Additional studies, such as a bone scan or MRI, may be helpful in localizing the lesion.

Infection

Septic arthritis and osteomyelitis. Bone and joint infections are common causes of limping in toddlers and children. When the infection is confined to the synovium of a joint, the condition is termed septic arthritis. If the primary focus of the infection is within bone, even if the joint is secondarily involved, the condition is termed osteomyelitis. Bacterial pathogens are the most frequent cause of osteoarticular infections in children, with *Staphylococcus aureus* being the most frequent etiology. In neonates, group B streptococcus and gram-negative bacteria are common. Beyond the neonatal period, *Kingella kingae* is the second most frequent cause in children under 5 years of age. In older children and adolescents with puncture wounds of the foot, *Pseudomonas aeruginosa, S. aureus,* and streptococci are commonly implicated. Sexually active adolescents may develop septic arthritis as a result of gonococcal infections. Patients with sickle cell anemia may develop osteomyelitis as a result of *Salmonella* species or pneumococcal infection.

Acute hematogenous osteomyelitis most commonly involves the femoral neck, the distal femoral metaphysis, and the proximal tibial metaphysis. Acute septic arthritis usually involves the hip, knee, or ankle. Children with these infections may be acutely ill; many may just have fever, limp, and localized pain. Treatment is with surgical drainage as needed and with prolonged antibiotics.

Subacute osteomyelitis, which has very distinct manifestations, occurs most commonly in the knee (Fig. 34.16). These children are usually afebrile and have night pain. Their hematologic studies yield normal findings. Radiographs show sclerotic metaphyseal lesions that occasionally cross the growth plate into the epiphysis. Culture specimens are positive only occasionally, and they typically show *S. aureus.*

Physical examination. Children with acute bone and joint infections may exhibit the clinical signs of bacteremia and infection, including elevations in temperature, white blood cell count, erythrocyte sedimentation rate, and C-reactive protein level. Some infants present only with **pseudoparalysis** of the affected limb. When the hip joint is involved, the child holds the hip in a position of flexion, abduction, and external rotation. This position unwinds the hip capsule and allows it to hold the greatest volume of intracapsular fluid. This initially decreases pressure, but as the pus continues to accumulate, even this position fails to relieve symptoms. A hip joint effusion is usually not palpable, but there may be overlying soft tissue swelling and tenderness.

Infections of peripheral joints, such as the knee, are more easily diagnosed. There is typically a joint effusion and perhaps soft tissue swelling, erythema, and increased warmth over the metaphysis if osteomyelitis is present. Osteomyelitis typically manifests with point tenderness over the involved site; with continued bone destruction and rupture of pus into the periosteum, tenderness becomes more diffuse. Infections can also occur about the ankle and foot. Infection of the foot is less common except as a sequela to puncture wounds through a tennis shoe, producing the classic *P. aeruginosa* or staphylococcal osteomyelitis-osteochondritis.

Radiographic evaluation. Plain radiographs are not helpful in the first 7-10 days of osteomyelitis, inasmuch as they are usually normal, but must be obtained in the assessment of the child. After 10-14 days

FIGURE 34.16 *A,* Anteroposterior radiograph of the distal femur in a 12-year-old girl with limping and nighttime knee pain for 6 months. There is a lucent lesion with surrounding sclerosis in the metaphysis. The lesion crosses the epiphysis; this is characteristic of a subacute osteomyelitis. *B,* Anteroposterior tomography clearly demonstrates the lucent nature of the lesion and its surrounding sclerosis.

of active infection, bone destruction or periosteal bone elevation is seen. MRI, or alternately bone scan, is both sensitive and specific for osteomyelitis and septic arthritis, even early in the course of the disease (Figs. 34.17 and 34.18).

If a septic process about the hip is suspected, an ultrasound study may be beneficial in demonstrating an effusion. If this is present, arthrocentesis or hip aspiration is necessary. The synovial fluid analysis should include a cell count, measurement of protein and glucose levels, Gram stain, cultures, and sensitivity studies. *K. kingae* polymerase chain reaction (PCR) testing should be performed, particularly in younger children. Infections of peripheral joints, such as the knee, are more readily diagnosed by arthrocentesis.

If an osteomyelitis of a metaphyseal region is suspected based on imaging studies, the subperiosteal space and bone may be directly aspirated with a large-bore needle. The material should be sampled for culture and sensitivity, as well as for *K. kingae* PCR testing in younger children. Despite these interventions, microbiologic studies may frequently fail to yield results.

Diskitis. Diskitis, inflammation of the vertebral disk that is often related to infection, may produce refusal to walk and/or limping either, via disk or bone inflammation, referred pain or intraspinal extension (see Chapter 35) (Fig. 34.19).

Rheumatic causes

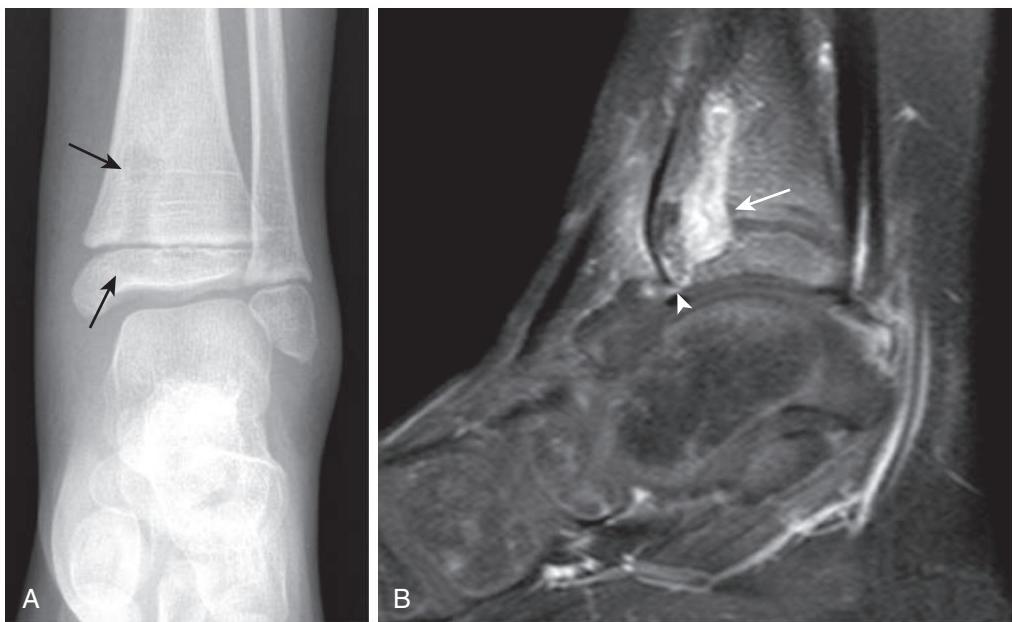
Transient synovitis. Transient synovitis (also known as toxic synovitis) of the hip is the most common cause of limping in children. It can occur in all age groups, but the mean age at onset is 6 years; most patients are between 3 and 8 years of age. Hip transient synovitis is characterized by acute onset of monoarthritic hip pain, an associated limp, and mild restriction of hip motion, especially abduction and internal rotation. The pain is felt in the groin, anterior thigh, or knee. Any child with atraumatic anterior thigh or knee pain must be


FIGURE 34.17 *A,* A frontal radiograph demonstrates a lytic lesion in the distal tibial metaphysis extending into the epiphysis *(arrows). B,* A T1 weighted fat-saturated postgadolinium sagittal view demonstrates a thick, rim-enhancing lesion with a small amount of nonenhancing fluid consistent with early abscess formation with epiphyseal extension *(arrow)* and a small cloaca *(arrowhead)* extending to the tibiotalar joint. (From Kan JH, Azouz EM. Musculoskeletal infections. In: Coley BD, ed. *Caffey's Pediatric Diagnostic Imaging.* 12th ed. Vol II. Philadelphia: Elsevier; 2013:1472.)
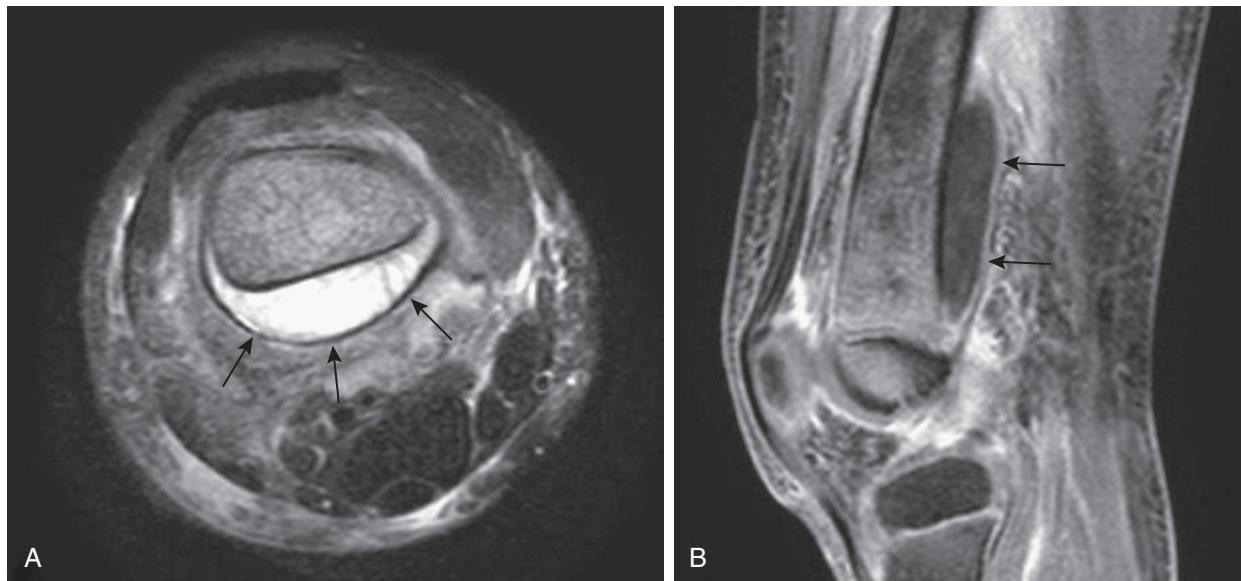

FIGURE 34.18 Acute osteomyelitis of the distal femur in a 5-year-old boy. *A,* T2 weighted fat-saturated axial magnetic resonance imaging (MRI) shows a large subperiosteal abscess *(arrows)* at the posterior aspect of the femur. Increased signal is seen within the bone, and there is adjacent soft tissue edema. *B,* T1 weighted fat-saturated postgadolinium sagittal MRI shows the longitudinal extent of the subperiosteal abscess with an enhancing wall *(arrows).* (From Kan JH, Azouz EM. Musculoskeletal infections. In: Coley BD, ed. *Caffey's Pediatric Diagnostic Imaging.* 12th ed. Vol II. Philadelphia: Elsevier; 2013:1476.)

carefully evaluated for hip disease because these are the sites of referred pain. Septic arthritis and osteomyelitis must be excluded.

The cause of this disorder remains uncertain. Suspected causes include active or recent systemic viral infection, trauma, and allergic hypersensitivity. Approximately 70% of affected children have had a nonspecific viral upper respiratory infection 7-14 days before the onset of symptoms.

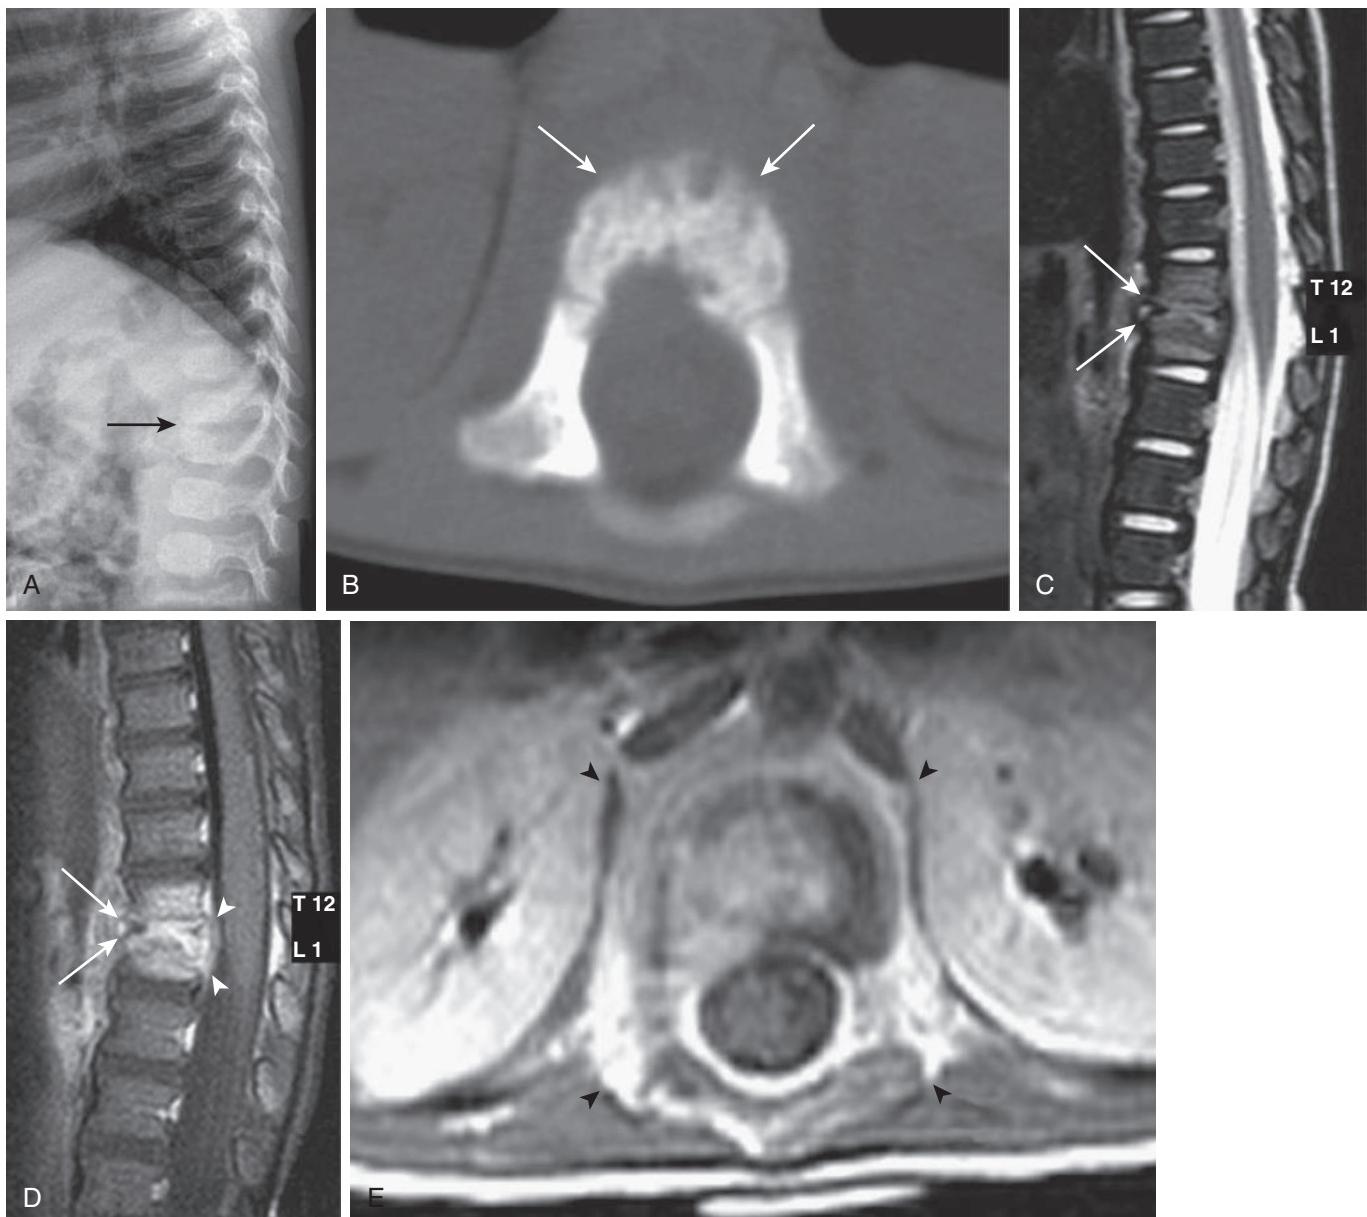
Physical examination. The patient is usually ambulatory, and the hip is not held in a position of flexion, abduction, or external rotation unless a significant effusion has developed. The child walks with an


FIGURE 34.19 A 15-month-old girl with an abnormal gait and concern for an intraspinal mass had diskitis/ osteomyelitis. Lateral spine radiographs demonstrate narrowing of the T12-L1 intervertebral disk space *(arrow in A)*. An axial bone window from a noncontrast computed tomography scan of the spine demonstrates irregularity to the vertebral end plates *(arrows in B)*. A sagittal T2 weighted image *(C)*, a sagittal fat-saturated T1 weighted postcontrast image *(D)*, and an axial T1 weighted postcontrast image *(E)* of the thoracolumbar junction demonstrate loss of height of the T12-L1 intervertebral disk space with adjacent T2 prolongation of the adjacent end plates *(arrows in C)*, with corresponding abnormal enhancement in the same regions *(arrows in D)*, and surrounding masslike soft tissue enhancement *(arrowheads in E)*. Note the thickening/elevation and enhancement of the posterior longitudinal ligament *(arrowheads in D)*. (From Pollock AN, Henesch SM. Infections of the spine and spinal cord. In: Coley BD, ed. *Caffey's Pediatric Diagnostic Imaging*. 12th ed. Vol I. Philadelphia: Elsevier; 2013:465.)

antalgic gait on the involved side and is usually afebrile. Laboratory findings are usually within normal limits, but occasionally a minimal elevation of the white blood cell count or erythrocyte sedimentation rate may be seen.

Radiographic evaluation. Anteroposterior and frog-leg lateral radiographs of the pelvis are obtained to rule out the presence of other lesions. The radiographs in transient synovitis are normal. On occasion, ultrasonography of the hip may be useful in demonstrating a small joint effusion. MRI is helpful in identifying septic joints or other causes of pain when there is doubt regarding the diagnosis. Bone scans as well may be helpful in difficult or unusual cases; in synovitis, these results are always normal. When the diagnosis of transient synovitis is in doubt, hip arthrocentesis may be necessary. The fluid that is aspirated shows a low white blood cell count (typically well under 25,000 cells/μL), and the cultures are negative.

Trendelenburg Gait

Developmental anomalies

Developmental dysplasia of the hip. Developmental dysplasia of the hip (DDH) refers to the condition of increased laxity of the hip joint and encompasses the following classifications: (1) acetabular dysplasia, (2) hip subluxation, and (3) hip dislocation. Developmental dysplasia of the hip is considered either typical, in which no underlying genetic or syndromic association is identified, or teratologic. Early identification and management improve the functional outcome of surgical repairs. If not identified and appropriately treated, DDH will present with limping, toe-walking, or both. When the problem occurs unilaterally, the child walks with a mild Trendelenburg gait or demonstrates toe-walking. With bilateral involvement, the child stands with an increased lumbar lordosis and has a waddling gait. There is functional impairment resulting from a lack of stability and associated muscle weakness, particularly in the hip abductors.

Physical examination. The most common physical finding in the older child with a developmentally dislocated hip is limited hip abduction on the involved side. There may be a mild hip flexion contracture and apparent shortening of the extremity. The greater trochanter lies above a line between the anterior superior iliac spine and the ischial tuberosity (Nélaton line). In bilateral dislocations, the physical findings are more symmetric but there is still limitation of hip abduction. Positive Trendelenburg signs are present on the involved sides. The normal response to a Trendelenburg test occurs when the patient stands on the uninvolved leg and the abductor muscles are able to maintain balance by elevating the contralateral pelvis. A positive Trendelenburg sign, resulting from weakness, is demonstrated when the abductor muscles are unable to maintain pelvic balance and the patient compensates by leaning to the affected side (see Fig. 34.10).

Radiographic evaluation. The diagnosis can be made from routine anteroposterior and frog-leg lateral radiographs of the pelvis (Fig. 34.20). Specialized studies, such as MRI and CT, are usually not necessary. Ultrasound study is not usually necessary in the older child because the CFE is ossified.

FIGURE 34.20 An anteroposterior radiograph of the pelvis of an 18-month-old girl demonstrating a developmental dislocation of the left hip. The acetabulum is severely dysplastic, there is delayed ossification in the capital femoral epiphysis compared to the normal right hip, and the femoral head is displaced laterally and superiorly.

Lower extremity length discrepancy. Lower extremity length discrepancy in older children and adolescents has been discussed earlier in this chapter.

Neuromuscular Origin

Cerebral palsy. Children with spastic hemiplegia or diplegia may have an associated painless limp caused by muscle spasticity and concomitant weakness of the antagonist muscles. The history should focus on risk factors for cerebral palsy, prematurity, and other congenital anomalies external to the central nervous system, followed by a physical examination, with particular attention to the neurologic system. The neurologic examination reveals evidence of increased muscle tone, spasticity, hyperactive deep tendon reflexes, and pathologic reflexes, such as Babinski signs.

■ SUMMARY AND RED FLAGS

Conditions associated with limp must be divided into acute, painful lesions and chronic, painless lesions; on occasion, presentations may be mixed. Infection and trauma must be considered emergencies, as should conditions that are joint or limb threatening, such as septic arthritis and osteomyelitis of the hip, avascular necrosis, or SCFE. In addition, signs of spinal cord involvement (see Chapter 35) suggest acute processes that warrant immediate attention to prevent permanent paralysis.

Red flags include acute hip pain, fever with limp, neurologic manifestations (including bowel and bladder dysfunction), point tenderness, the presence of a mass, night pain, and signs of weight loss or hematologic abnormalities such as pallor or bruising.

Back Pain in Children and Adolescents

John G. Thometz

Persistant back pain in children necessitates a thorough evaluation to rule out disorders that can result in significant morbidity, such as infection or tumor. Back pain in younger children is unusual and suggests significant diseases. The prevalence of complaints of low back pain increases with age, and is as prevalent as 30% by the teenage years. Back pain is frequently mild and often resolves spontaneously in adolescents. The complaints are often related to overactivity in sports, work, or a specific traumatic event. Back pain is not a disease but a symptom and is often associated in adolescents with headaches, emotional problems, daytime tiredness, and behavioral disorders. Activity modification and rehabilitation or exercises for the spine are sufficient to prevent recurrent episodes of back pain. *Severe or persistent back pain necessitates a thorough history, physical examination, and appropriate imaging studies to evaluate the child for potentially serious pathologic processes.*

EVALUATION OF THE PEDIATRIC SPINE

Examination of the spine should be part of the routine physical examination in the healthy child and adolescent. Even in patients who present with back pain as a chief complaint, the most important diagnostic steps are a detailed history and a thorough and systematic examination (Table 35.1).

When findings on screening examinations are abnormal or when a patient presents with complaints of back pain, a more detailed examination is required. The spinal vertebral column, spinal cord, and spinal nerves are intimately related, and disorders affecting any 1 of these elements produce symptoms and signs in the others. Detailed examination of strength in the muscles of the spine and lower extremities (Fig. 35.1), sensation (Fig. 35.2), abdominal and lower extremity reflexes, anal sphincter tone, and perianal sensation should be performed when the primary examination suggests involvement of the neural structures that pass through the spinal column. Persistent or severe back pain is uncommon in young children and may be associated with serious underlying disease.

NORMAL GROWTH AND DEVELOPMENT OF THE SPINE

Vertebral growth occurs in an orderly manner throughout childhood and adolescence. About 50% of vertebral column height is present by the age of 2 years. Acceleration of vertebral growth occurs during the adolescent growth spurt but contributes less to total height than does lower limb growth; the sitting heights of siblings in early and late adolescence are often remarkably similar. Spinal growth slows at menarche in girls and at the time of voice change in boys and is usually complete 2-3 years later. Developmental abnormalities of the column, such as idiopathic scoliosis, most commonly first appear just before the growth spurt. Alterations in spinal configuration caused by congenital deformities of vertebral segments change most rapidly during periods of rapid spinal growth: before the age of 2 and at the time of the adolescent growth spurt.

There is a strong association of genitourinary tract, cardiac, and neural abnormalities in patients with congenital abnormalities of the spine. Warning signs in patients with congenital spine deformities include leg length inequality, foot size asymmetry, high foot arches, hairy patches or hemangiomas or a mass over the spine, sacral dimpling, enuresis, toe-walking, asymmetry or abnormality in the lower extremity deep tendon reflexes, and lower extremity weakness.

NORMAL SPINAL ALIGNMENT

The normal trunk is symmetric when viewed from the front or the back (Fig. 35.3). The shoulders and pelvis are parallel to each other and to the ground. The distance between the right and left elbows and the sides of the trunk is equal. When the trunk is viewed from the side, a series of curves is present (see Fig. 35.3). A convex anterior lordotic curve is present in the cervical region. The spine is concave anteriorly in a kyphotic pattern in the thoracic region. The normal lumbar spine is lordotic, and the sacrum and coccygeal regions are kyphotic. Normal adult sagittal alignment develops gradually; children younger than 10 years typically have less cervical lordosis and more lumbar lordosis than adults. Healthy children are often quite swaybacked. Injuries, infections, tumors, inflammation, and developmental abnormalities of the spine often produce alterations in these expected contours. Range of motion is demonstrated in Fig. 35.4.

BACK PAIN OF BRIEF DURATION

Few children younger than 10 years sustain significant injuries of the spinal column or associated musculature in routine play and organized sports activities; extremity injuries are far more common. When the trunk is involved, contusions and abrasions are much more common than ligament sprains and muscle strains.

When a child presents with back pain of brief duration after a play- or sports-related injury, a careful examination should be performed. If there are no other associated injuries and the screening examination shows no alterations in trunk configuration or lower extremity strength or sensation (see Figs. 35.1 and 35.2), no further work-up is necessary. A brief period of rest for 1-2 days, followed by gradual resumption of activities, is appropriate treatment. Routine imaging is not necessary when the duration of symptoms is short and the physical examination findings are normal. Signs of systemic illness (fever, weight loss) or neurologic deficits warrant an immediate evaluation.

Acute back injuries occur more frequently in adolescence, as the sizes of participants and potential forces generated in recreational

(See *Nelson Textbook of Pediatrics,* p. 3245.)

TABLE 35.1 Guidelines for Primary Examination of the Back

History

Is there a history of back pain? If so, what is the:
   Frequency?
   Duration?
   Relationship to activity?
Antecedent trauma?
Is there associated pain in the legs?
Is there incontinence or enuresis?
Is walking painful?
Have there been systemic signs of chronic illness?
Is there a family history of deformity?
Is there a family history of disk disease?

Physical Examination

General Appearance

Are the right and left sides of the trunk symmetric?
Are there hairy patches, nevi, sinuses, or dimpling over the midline of the
   spine?
Are the pelvis and shoulders level?
Is there normal kyphosis and lordosis?
On forward bending, is a rib hump present?
Is there localized tenderness?
Is there muscle atrophy?

Motion

Can the patient easily bend forward and touch his or her toes?
Is normal hamstring flexibility present?
Is the gait normal?

Lower Extremities

Are leg lengths equal?
Is strength normal in the major motor groups of the lower limbs?
Is sensation normal in the lower limbs?
Are reflexes normal at the knees and ankles?
Are pathologic reflexes present?
What is the response to straight leg *and* cross straight leg raising maneuvers?

activities increase. If there are no other associated injuries and the screening examination findings are normal, no further imaging work-up is necessary. A period of rest followed by gradual resumption of activities is appropriate treatment. The importance of a comprehensive and balanced conditioning exercise program should be stressed to young athletes. Most sports-related injuries can be prevented by preparticipation conditioning, appropriate warm-up, careful supervision, and resting when fatigued.

Trauma sufficient to cause spine fractures may occur as a result of motor vehicle or bicycle crashes, falls, and diving and gymnastic injuries. The frequency and severity of spine trauma rises in later adolescence as exposure to potentially violent forces in sports and motor vehicles increases. In such cases, there is a clear relationship between the crash and the onset of symptoms. Injury to the spinal column should be suspected in all individuals whose level of consciousness is impaired after an accident, regardless of the presence or absence of symptoms.

Children with suspected acute spinal injury should be immobilized on backboards designed for children until definitive imaging studies can be performed and interpreted. Immobilization of the child's cervical spine on a solid backboard should be avoided. The child's occiput projects farther posteriorly than that of the adult, and flexion of the neck occurs if the child's neck is immobilized on a standard backboard. Spinal immobilization boards for children are readily available and have a cut-out section to accommodate the occiput. When such boards are not available, a blanket or firm mattress should be interposed between the trunk and the backboard to prevent neck flexion.

PERSISTENT BACK PAIN

Persistent or severe back pain is uncommon in young children but is more common in adolescents. Mechanical low back pain is said to be present in the patient with no definable pathology on physical exam or imaging studies. This is the case in over 50% of patients presenting with low back pain. The implications of severe or persistent back pain are more serious in younger patients than in adolescents. Persistent back pain in young children is usually not the result of a congenital spinal deformity or developmental disorders of the spine. As a child enters and passes through the adolescent growth spurt, back pain may

arise from a small number of congenital and developmental disorders of the spinal column. Degenerative disorders of the spine such as intervertebral disk herniation are uncommon causes of back pain in childhood. In evaluating a patient, it is important to try to distinguish musculoskeletal-mechanical disorders from those with more generalized systemic signs or those suggestive of a neoplasia (Fig. 35.5). If the MRI shows no definitive pathology, patients are considered to have mechanical low back pain and have continued conservative treatment. Pediatric multidisciplinary pain clinics also help those who have persistent pain, have no defined pathology, and have failed conservative treatment.

The differential diagnosis of persistent back pain in children younger than 10 years includes intervertebral diskitis and vertebral body osteomyelitis, neoplasia of the vertebrae, primary neoplasia of the spinal cord, and metastatic neoplasia (Table 35.2). In older children and adolescents, congenital variations in the formation of the lower lumbar spine are sometimes responsible for chronic back pain (see Table 35.1). Developmental round back (kyphosis) is occasionally associated with midthoracic back pain in middle and late adolescence. Diskitis, skeletal neoplasia, and tumors of the spinal cord and nerves

also occur in adolescence. In documenting the history, special attention must be given to the nature of the onset of symptoms, the presence of radiating pain in the legs, bowel and bladder function, associated abdominal pain, and the presence or absence of fever.

Although this issue is controversial, some authorities believe that school-aged children who carry an excessively heavy backpack are at risk for back pain and alterations of gait or posture. To alleviate this, it is recommended that the backpack be of appropriate size with wide padded straps and back padding. In addition, the weight limit of the pack should not exceed 10-15% of the child's body weight. The pack should be lifted with bending of the knees, and the straps should be adjusted so that the pack fits on the back and not below the waist.

SPECIFIC DIAGNOSIS

Intervertebral Diskitis

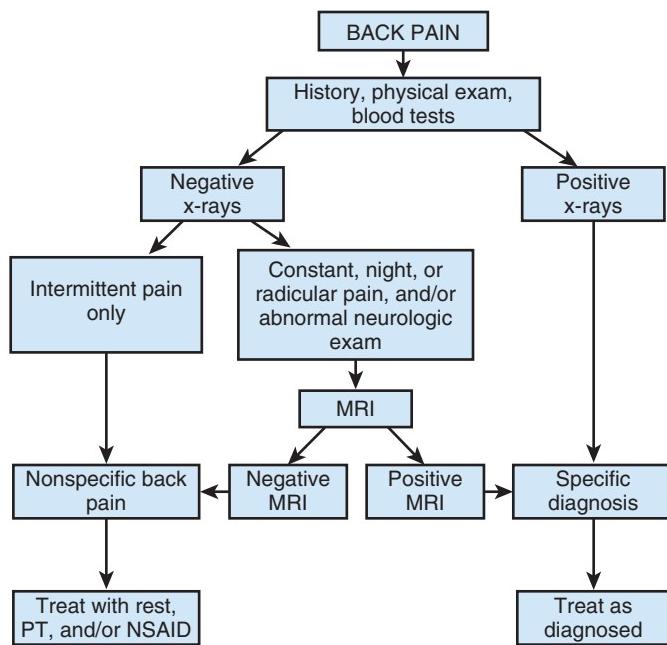
Intervertebral diskitis is the term applied to a number of processes that are characterized by back or leg pain and identified radiographically by narrowing of the intervertebral joint space between 2 adjacent vertebral segments (Figs. 35.6 and 35.7). Magnetic resonance imaging


FIGURE 35.5 Pediatric back pain algorithm for children ≥4 years of age. MRI, magnetic resonance imaging; NSAID, nonsteroidal antiinflammatory drug; PT, physical therapy. (From Feldman D, Straight J, Badra M, et al. Evaluation of an algorithmic approach to pediatric back pain. *J Pediatr Orthop.* 2006;26:353-357.)

(MRI) studies suggest that diskitis may begin as a micro abscess within the vertebral body adjacent to the vertebral end plate. The disk becomes infected from perforating vascular channels across the end plate. Vascular channels may also perforate the end plate on the opposite side of the disk, leading to involvement of the opposite vertebral body. In some patients, the symptoms resolve spontaneously without treatment.

Most authorities believe that diskitis is a bacterial infection, usually caused by *Staphylococcus aureus*. Tuberculosis infection of the spine must also be considered in patients who have spent significant time outside the United States or in high-risk patients such as those who are immunocompromised. Surgical drainage, a critical component of effective treatment of other closed space infections of the musculoskeletal system, is not usually required in most patients with intervertebral diskitis.

Clinical Findings

Three age-dependent patterns of presentation have been noted for intervertebral diskitis. Children younger than 3 years (the most common age) often present with irritability and refusal to walk and sit or have apparent dysfunction (limp, antalgic gait) of the lower extremities. Patients may have very tight hamstrings, loss of lumbar lordosis (the lumbar spine is the most common site), and refusal to allow passive motion of the lumbar spine. Patients between the ages of 3 and 8 years often have pain referred to the abdomen, particularly when the disk involves the lower thoracic spine. Adolescents with diskitis often have back pain; the discomfort often radiates into both legs. Additional features at all ages include low-grade fever; refusal to bear weight (sitting or standing); hyperlordosis; and, if intraspinal inflammation is present, decreased lower extremity muscle strength, decreased tone, and alterations of deep tendon reflexes. The erythrocyte sedimentation rate is usually elevated; the white blood cell count is usually normal but may be elevated in late cases. Early in the process, plain radiographs

of the spine are often normal. Over a certain period of time, the disk space narrowing develops with subsequent erosion of the vertebral end plates (see Fig. 35.6). Traditionally, a bone scan has been recommended for assessment of diskitis. However, MRI is more sensitive than the bone scan. The MRI reveals the extent of the inflammatory process better and can delineate the degree of bone destruction (if any), the presence of abscess formation, or intraspinal inflammation (see Fig. 35.7).

Treatment

The diagnosis of intervertebral diskitis should be suspected in young children with fever and unexplained back or leg pain and in previously healthy toddlers who become irritable and refuse to walk. Vertebral body osteomyelitis is a major consideration in the differential diagnosis and can usually be diagnosed with radiographs and MRI. After appropriate laboratory studies, including blood cultures, have been performed, treatment should be started. A bacterial cause is likely if fever, leukocytosis, and elevation of the sedimentation rate are present. Antibiotic therapy should be started in such cases, because *S. aureus* is the most commonly responsible organism. Knowing the antibacterial sensitivity patterns of community-acquired *S. aureus* helps the clinician choose the appropriate antibiotic (clindamycin, vancomycin, or methicillin). In immunocompromised hosts, broader spectrum antibiotic coverage is essential. If an organism is recovered, antibiotic coverage can be adjusted appropriately. Initial therapy should be intravenous; oral antibiotics can be considered as pain decreases and laboratory studies return to normal. A total of 4-6 weeks of therapy is recommended for patients with infectious intervertebral diskitis.

Immobilization of the spine is used for persistent symptoms. Patients without systemic signs of infection and in whom laboratory studies show no leukocytosis and only moderate elevation of the sedimentation rate may be occasionally managed by antiinflammatory agents and rest.

Patients who remain ill or worsen after the initiation of rest and antibiotic treatment should undergo surgical biopsy and drainage. Biopsy should also be performed in patients in whom tuberculous intervertebral disk space infection is suspected (positive exposure history, positive purified protein derivative findings; see Chapter 2).

The evolution of plain radiographic findings lags behind clinical findings in intervertebral diskitis. Although patients with intervertebral diskitis may experience disk space narrowing and end plate erosion during the course of treatment, normal radiographs and bone scans at the time of initial evaluation do not preclude the diagnosis. Radiographic changes continue long after the inflammatory process has resolved. Progressive disk space narrowing, intervertebral disk space calcification, and spontaneous intervertebral arthrodesis are potential late findings.

Lack of focal changes on plain films obtained 2-3 weeks after the onset of symptoms significantly lessens the likelihood of intervertebral diskitis. In such patients, careful study for other potential diagnoses is essential. Tumors of the spinal cord may manifest in a similar manner without causing the changes in the vertebral segments necessary to produce alterations on bone scanning. In such patients, MRI is invaluable.

Spondylolysis and Spondylolisthesis

The most common abnormalities of the lower lumbar and lumbosacral spine—spina bifida occulta, at L5 or S1, and spondylolysis, usually at L5 to S1—are often noted as incidental radiologic findings in entirely asymptomatic individuals. A few individuals with spondylolysis (defect in the pars interarticularis without slippage) experience back pain and progressive slippage deformity, known as spondylolisthesis.

(See *Nelson Textbook of Pediatrics,* p. 3293.)

TABLE 35.2 Differential Diagnosis of Back Pain

Inflammatory Diseases
Diskitis*

FIGURE 35.6 Intervertebral diskitis. There is loss of intervertebral disk space height between vertebral segments L3 and L4, with early end plate erosion on the anteroinferior surface of L3 and anterosuperior surface of L4.

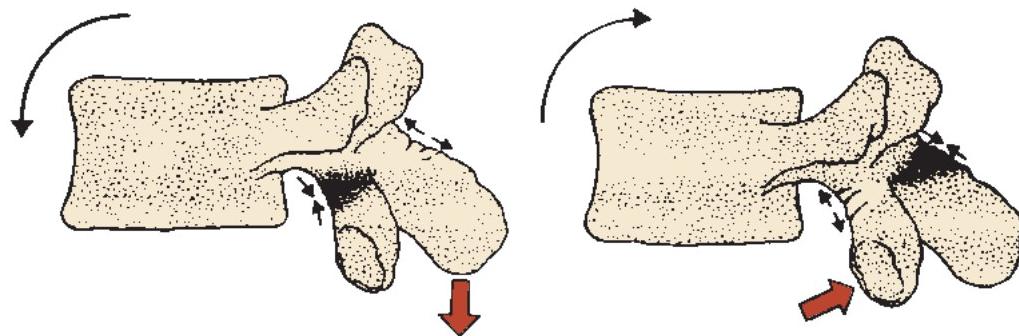
FIGURE 35.7 Intervertebral diskitis, magnetic resonance image. Note the increased marrow signal from the vertebral bodies adjacent to the narrowed L4 intervertebral disk. The normal bright signal is missing from the involved disk itself, and there is evidence of soft tissue abscess formation anterior to the involved disk space.


FIGURE 35.8 Stress leading to fracture of the pars interarticularis.
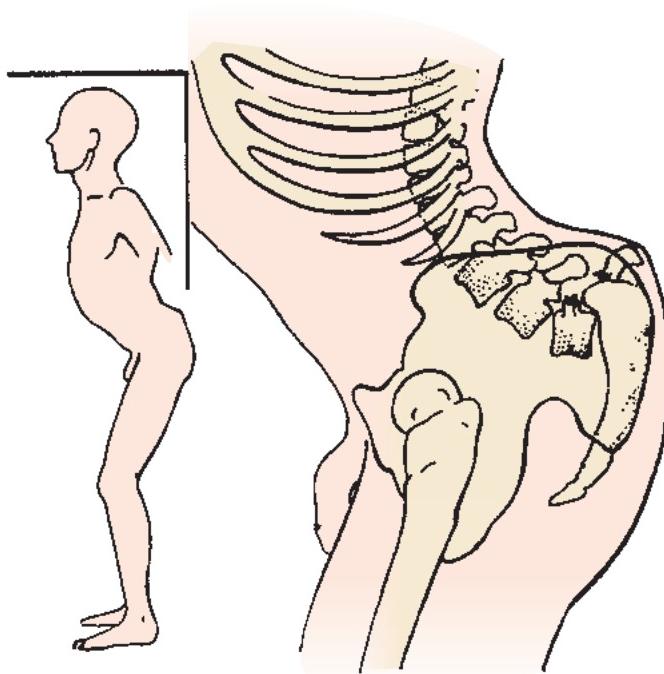

FIGURE 35.9 Clinical picture of severe spondylolisthesis.

As a consequence of the normal lordotic tilt of the lumbar spine, shear forces are generated between the L5 and S1 vertebral segments. Forward displacement of L5 on S1 is normally prevented by the stable articulation of the superior facets of S1 and the inferior facets of L5. Defective formation of the posterior elements of the lumbosacral joint or defects in the bone connection between the body and the arch of the 5th lumbar vertebra render the anterior junction of L5 and S1 unstable and may lead to relative displacement.

Cause

Spondylolysis and spondylolisthesis in children and adolescents usually involve the 5th lumbar and 1st sacral units. Spondylolysis is not present at birth, but with growth and activity, it is seen by age 6 years in about 4% of children and 6% of adults. Spondylolysis appears to be less common in black persons and much more common in some North American Eskimo groups; the lowest incidence has been reported in black females, and the highest in white males. The male to female ratio is $2:1$. The disorder appears to be multifactorial; both hereditary and mechanical factors have been implicated. Relatives of patients with spondylolysis are much more likely to be affected than are individuals in the general population, although the degree of slippage is not as well correlated.

Fatigue fracture of the posterior elements of L5 may be responsible for acutely painful spondylolysis in some preadolescent and adolescent athletes (Figs. 35.8, 35.9, and 35.10). Activities that involve repeated trunk flexion and extension have been implicated; adolescent divers and gymnasts are reported to be susceptible to spondylolysis and spondylolisthesis. A high rate of spondylolysis has been reported in Scheuermann disease (thoracic kyphosis), which may be related to compensatory excessive lumbar lordosis. In addition, an increased incidence of spondylolisthesis has been noted among both patients with myelodysplasia and those with cerebral palsy.

Acute fracture-dislocation of vertebral units resulting from violent trauma in a strict sense is 1 form of spondylolisthesis, but because it differs so greatly from other types of spondylolisthesis in cause, presentation, and treatment, it is usually considered as a separate entity.

Presentation

Symptoms in patients with spondylolysis and spondylolisthesis are quite variable; many patients are asymptomatic. Some patients with minimal slips have extreme pain, while others with moderate to severe slips have little or no discomfort. Symptomatic patients complain of aching in the lumbar and lumbosacral regions. Buttock and posterior thigh pain may be present, but radicular symptoms of nerve root compression are usually absent unless the spondylolisthesis is severe. In severe cases, bowel and bladder dysfunction may also be present. Discomfort is usually increased by exercise and relieved by rest.

Signs vary with the severity of spondylolisthesis. Asymptomatic patients with slips of mild severity may have no outward manifestations of vertebral abnormality. Patients with moderate to severe slips usually have tenderness on palpation of the lumbar spine and increased lumbar lordosis. Spasm of the hamstring muscles may extend the sacral spine, causing the buttocks to seem flattened or heart-shaped in appearance. In severe slips, a step-off of L5 on S1 can be palpated. A flexible scoliotic deformity caused by paraspinal muscle spasm may be present.

Neurologic examination findings are usually normal in children with spondylolysis. Symptoms and signs of nerve root compression and mechanical instability are much more common in adult patients with progressive or severe untreated adolescent spondylolisthesis.

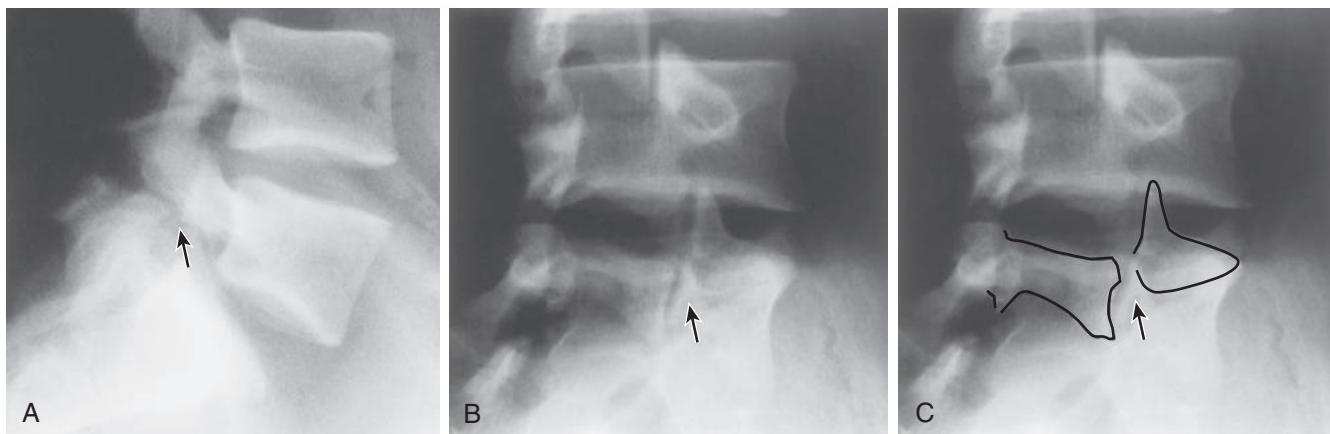
Hamstring muscle spasm is a common finding in patients with symptomatic spondylolisthesis and at times may be the chief presenting problem. Affected patients are unable to flex far enough forward to touch their toes without bending their knees. When severe, hamstring spasm results in a loss of normal lumbar lordosis and produces a flattened appearance of the low back. Hamstring muscle spasm also


FIGURE 35.10 *A,* Radiograph features of spondylolysis showing lytic defect *(arrow)* in the pars interarticularis. *B,* In isthmic defects, this appears as the collar *(arrow)* of the "Scotty dog" sign. *C,* Collar of the Scotty dog sign outlined on film. (From Rathjen KE. Back pain. In: Herring JA, ed. *Tachdjian's Pediatric Orthopaedics.* 5th ed. Philadelphia: Elsevier; 2014:95.)

interferes with gait; stride length is shortened, and patients run with a peculiar stiff-legged posture. The cause of hamstring spasm in spondylolisthesis is unclear; it does not appear to be caused by compression of spinal nerves, and it is rarely accompanied by other signs of nerve root compromise. Most authorities believe it is a result of abnormal strain on the hamstring muscles caused by mechanical instability of the lumbosacral junction.

Radiographic Assessment

If spondylolysis is suspected, radiographic assessment includes anterior-posterior lateral views of the lumbar spine (Fig. 35.11; see also Fig. 35.10). In cases of unilateral spondylolysis, there may be hypertrophy of the opposite pars or pedicle. A computed tomographic (CT) scan is helpful in determining the anatomy of the defect and can help assess the status of healing during treatment. CT scans also may identify sites of nerve root compression. The bone scan (single photon emission computed tomography scan) is sensitive in identifying the stress fracture before disruption is evident on radiographs. Immobilization at this point may heal the lesion. MRI has been increasingly utilized for assessing spondylolysis due to increasing concern over radiation exposure with CT and bone scan; improved techniques for obtaining MRI images are leading MRI to be the procedure of choice in assessing spondylolysis.

If the clinician suspects an associated herniated disk, MRI is indicated. The plain radiographs illustrate the degree of slippage. This must be documented to see whether progression is occurring over time. The most common classification system notes the position of the posterior border of the L5 vertebral body with regard to the S1 body. When the slip is less than 25% of the width of the 1st sacral body, the slip is considered mild. Slips exceeding 50% are considered severe. These cases are of concern in that the progression may proceed to the point at which L5 dislocates in front of the S1 vertebral body, which is called spondyloptosis.

Treatment

In asymptomatic patients with a mild slip, no treatment is required; likelihood of progression is low. However, if significant progression occurs (even if a patient is asymptomatic), a posterolateral fusion is recommended. When a slip exceeds 50%, the likelihood of continued progression is high, and surgical stabilization should be performed. Both symptomatic and asymptomatic patients with this severe condition should undergo surgical stabilization.

FIGURE 35.11 Spondylolisthesis. Slippage of L5 on the underlying body of S1 has occurred as a consequence of the defective formation of the posterior elements of L5. In this case, slippage is moderate, measuring slightly more than 25% of the width of the S1 vertebral segment.

Initial treatment of patients with symptomatic spondylolysis should be conservative. The examiner must also rule out other causes of back discomfort. Activity restriction with antiinflammatory medication is the initial treatment. When the pain is severe, a brace or corset is helpful. Then abdominal and paraspinal strengthening exercises are instituted to help relieve symptoms. Most patients with symptomatic spondylolysis or mild spondylolisthesis respond to conservative therapy and are able to return to sports. However, a small percentage of patients do not respond to conservative therapy; for these patients, surgical stabilization may be necessary. Patients with a severe slip who have a neurologic deficit that does not respond to conservative management also require surgical intervention. A fusion in situ (L5 to S1) is the most commonly performed surgical procedure for patients with

a slip of less than 50%. Extension of the fusion to L4 is necessary to create a satisfactory fusion in patients with a more significant slip.

Idiopathic Kyphosis

Abnormal increases in expected thoracic kyphosis in children and adolescents produce round back deformities (Fig. 35.12). These may be congenital, neuromuscular, or idiopathic in origin. Mild to moderate increases in kyphosis cause little deformity and few symptoms. Severe kyphosis is disfiguring, often causes back pain, and may lead to spinal cord compromise.

Round back posture is often encountered in otherwise healthy adolescents at school screening examinations. Affected patients are usually asymptomatic, although their parents often report poor posture. A history should be obtained and physical examination performed. Complaints of severe back pain or leg pain, enuresis, and findings of lower extremity weakness or increased reflex tone in patients with round back are ominous findings and warrant referral.

If accentuated kyphosis is present, radiographic follow-up is indicated. Two radiologic patterns are common. The majority of

individuals, especially younger adolescents, have thoracic kyphotic curves of 20 to 45 degrees, with no underlying structural vertebral changes. Usually such curves correct easily on passive or active hyperextension. For such children, no treatment except for a thoracic hyperextension exercise program and periodic follow-up examination is necessary.

More severe kyphosis with accompanying structural changes in vertebral bodies at the apex of the deformity is present in a small subset of adolescents with kyphosis. Affected individuals often have kyphotic curves greater than 60 degrees and show little correction with hyperextension. Radiographs show vertebral wedging, end plate irregularity, and kyphosis (Fig. 35.13). **Scheuermann kyphosis** (an osteochondrosis) occurs in approximately 5-8% of the population, affecting males 5-10 times more often than females. The cause remains unclear but may be the result of disruption of growth of the anterior portion of the vertebral body and consequent wedging of multiple vertebral bodies. Back pain is usually mild; many affected patients have no pain at all. The deformity in most affected patients is minimal and only rarely is cosmetically unacceptable. Late neurologic complications are extremely rare.

Treatment depends on the degree of deformity and the age of the patient. Skeletally immature individuals with significant deformity may improve with a program of exercise and use of a Milwaukee or modified Boston brace. Bracing does not reverse a deformity, but it may prevent progression. Older patients with back pain usually respond to a back-strengthening exercise program. Patients with unacceptable deformity who are too old for brace treatment require surgical correction. Often this requires a combination of anterior release and posterior spinal instrumentation and fusion.

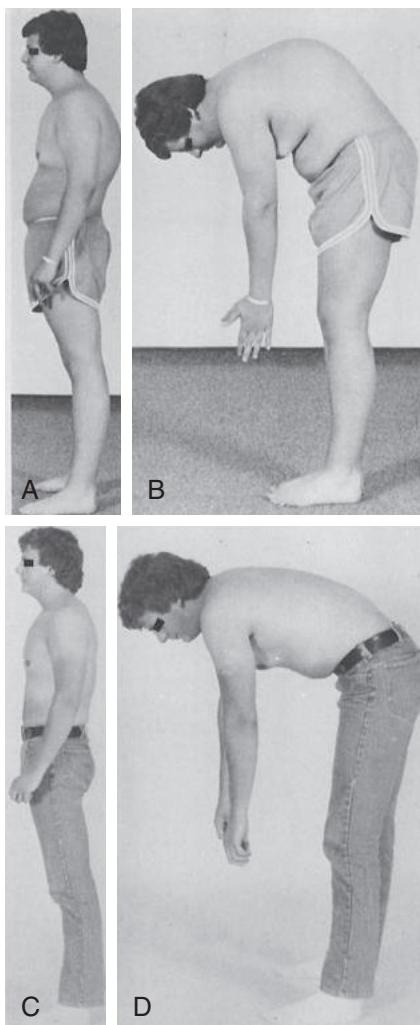
Congenital vertebral malformations that produce kyphotic deformities develop during the 1st trimester of gestation and, like other


FIGURE 35.12 Preoperative *(A and B)* and postoperative *(C and D)* views of an adolescent boy with severe kyphosis secondary to Scheuermann disease. He required both anterior and posterior spinal fusion. He now has a markedly improved appearance and no further progression of the kyphosis. (From Renshaw TS. *Pediatric Orthopedics.* Philadelphia: WB Saunders; 1986:53.)

FIGURE 35.13 Scheuermann kyphosis. Lateral radiographs of the midthoracic spine in an asymptomatic 16-year-old male with moderately severe kyphosis. There is severe wedging, loss of vertebral height, and end plate irregularity present on these films. His radiographic findings appear far worse than his symptoms and signs. If further collapse was to develop and the kyphosis became more severe, surgical intervention would be necessary.

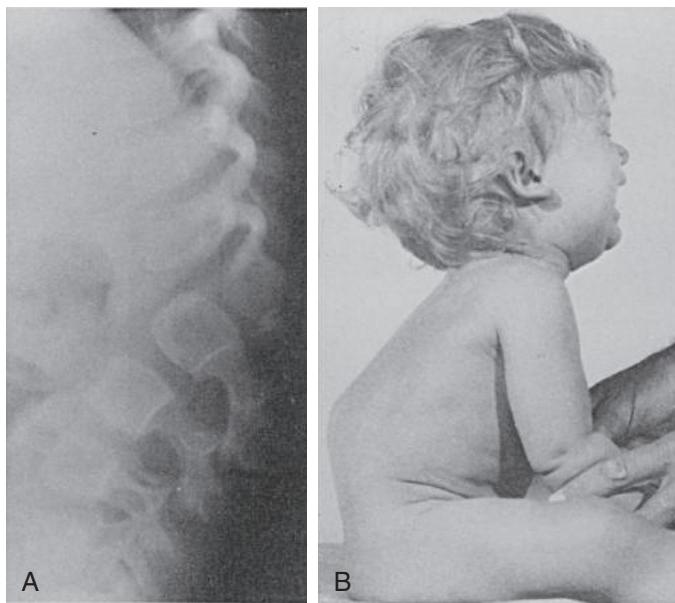
(See *Nelson Textbook of Pediatrics,* p. 3291.)


FIGURE 35.14 *A,* Congenital kyphosis secondary to failure of vertebral bodies to form at T12 and L1. *B,* The clinical appearance of the child. Thoracolumbar kyphosis is obvious. (From Renshaw TS. *Pediatric Orthopedics.* Philadelphia: WB Saunders; 1986:44.)

congenital abnormalities of the spine, are often associated with abnormalities of the genitourinary tract or the spinal cord. Kyphosis that results from congenital vertebral deformities is often obvious early in life and may be rapidly progressive (Fig. 35.14). The spinal cord may become tented over the apex of the deformity, producing symptoms and signs of spasticity in the lower extremity and bladder. Progression of deformity is dangerous; congenital kyphosis is the spinal deformity most often associated with paraplegia. Patients should be promptly referred for orthopedic evaluation.

Intervertebral Disk Herniation

Intervertebral disk rupture is much less common in children than in adults. Because most such patients are treated nonoperatively, the absolute incidence of the disorder is not known. In the United States, fewer than 1% of patients undergoing diskectomy are younger than 16 years. The frequency of symptomatic intervertebral disk herniation may be more common in Asian persons than in white persons, perhaps because of the smaller size of the spinal canal.

Some patients have a significant history of trauma. In other patients, congenital anomalies of the lumbar spine, such as transitional vertebra or spina bifida occulta, are noted. There may be a family history of low back pain or herniated disks. An autosomal dominant trait has been linked to the *COL9A2* collagen IX gene.

The symptoms of a herniated lumbar disk in adolescents differ somewhat from those in adults; this may delay recognition. The initial complaint in adolescents is significant low back discomfort; it is only months later that the symptoms of leg discomfort become more noticeable or prominent. Pain is typically aggravated by activity and relieved with rest. Symptoms may be intermittent. The affected adolescent has poor back mobility, often with paravertebral muscle spasm. Lumbar lordosis may diminish, and there is a tendency to walk bent forward. Hamstring tightness with limited straight-leg raising is almost universal. Neurologic signs are less likely to be prominent in the adolescent with herniated disk than in the affected adult. Clues to suggest a lumbosacral radiculopathy include abnormal straight leg or cross

straight leg raising responses, weak ankle dorsiflexion, calf wasting, diminished ankle reflex, and decreased sensation. Plain radiographs are needed as an initial study. These are usually normal other than for the loss of lumbar lordosis. The MRI is the procedure of choice for diagnosing a disk herniation. In rare cases, adolescents may develop a lesion that is a fracture of the posterior vertebral apophysis, which displaces posteriorly into the spinal canal and acts like a herniated disk. This is an avulsion fracture that is identified with either a CT scan or MRI. When a patient has severe symptoms, treatment should begin with bed rest, analgesics, and antiinflammatory agents. When the symptoms have begun to abate, physical therapy for lumbar and paraspinal strengthening is helpful. A lumbar corset may be helpful for patients who also have significant symptoms. Patients who present with progressive neurologic deficits require early surgical excision. Similarly, patients who fail to respond to a significant period of nonoperative management also require disk surgery.

The long-term results of a disk excision are good in 70-80% of the patients. Spinal fusion is not required unless the patient shows evidence of instability, which is quite rare.

Scoliosis

Idiopathic scoliosis, a combination of lateral deviation and rotation of vertebral bodies, does not always produce back pain. When painful scoliosis is present, a careful search for the cause of the symptoms must be undertaken. Infection, tumor, a spinal cord syringomyelia or diastematomyelia (more common with left thoracic curves), and occult fractures may produce clinical findings that resemble idiopathic scoliosis but, in contrast to idiopathic scoliosis, cause significant chronic pain as well. Any patient with painful scoliosis should have a careful evaluation for other spinal anomalies causing the pain.

Etiology

Idiopathic scoliosis begins in the immature spine, although progression of preexisting curvatures may occur in adult life. The cause of idiopathic scoliosis remains unknown. Hormonal factors appear to play a role in curve progression, inasmuch as severe curves occur much more often in girls. Some studies have demonstrated abnormalities of proprioception and vibratory sensation in affected patients, which suggests that abnormalities of posterior column function may contribute to the development of curvature. Other investigators have implicated cerebellar or muscular (myopathy) dysfunction as a possible cause of spinal imbalance.

No clear genetic pattern has been established. Curves occur more frequently in individuals with affected 1st-degree relatives, but transmission is not Mendelian. Although curvature is more likely to develop in the daughters of affected mothers than in other children, the magnitude of curvature in an affected individual is not related to the magnitude of curvature in relatives. It appears likely that a combination of genetic predisposition and other undefined factors is responsible for development and progression of idiopathic scoliosis.

Classification

Idiopathic curves are grouped into infantile (birth-3 years), juvenile (4-10 years), and adolescent categories on the basis of age at onset of curvature. The infantile form differs enough from the other varieties to be considered a distinct entity. The distinction between juvenile and adolescent scoliosis is not as sharp.

Infantile idiopathic scoliosis. Infantile idiopathic scoliosis is rare in the United States, probably accounting for fewer than 1% of new cases of idiopathic scoliosis. It is more common in Europe. The majority of patients are males, and most curves are convex toward the left rather than the right, as in the other varieties of idiopathic scoliosis.

Some infants suspected of having idiopathic deformity actually have subtle congenital vertebral abnormalities. The diagnosis of idiopathic deformity is appropriate only when radiographic studies show no evidence of congenital vertebral anomalies (e.g., hemivertebra) and there are no signs of spinal dysraphism or of neuropathic or myopathic disorders.

Although many infantile curves resolve spontaneously, others progress relentlessly and are very difficult to treat effectively. Observation is appropriate until 6 months of age in infants with mild idiopathic scoliosis, but prompt referral should be made if curves persist or increase during the period of observation.

Juvenile idiopathic scoliosis. Juvenile idiopathic scoliosis begins before the adolescent growth spurt. Some curves are probably undetected cases of infantile scoliosis. Others, particularly those that occur in older children, may be early manifestations of adolescent idiopathic scoliosis. Some curves remain small and, in fact, may resolve spontaneously. Others remain stable until the onset of the growth spurt and then progress unless treated. Still others progress steadily throughout childhood and adolescence. Some are associated with intraspinal anomalies (syrinx). There is no reliable method of predicting the behavior of juvenile curves at the time of diagnosis, but, in general, high-magnitude curves in young patients are more likely to increase with growth than are smaller curves in older children.

The majority of patients with juvenile curves greater than 25 degrees at the time of diagnosis require some form of active treatment. Treatment must begin at the time progression is first documented if severe deformity is to be prevented.

Adolescent idiopathic scoliosis. Most cases of idiopathic scoliosis in North America develop around the time of the adolescent growth spurt (Figs. 35.15 and 35.16). Often parents and children are unaware of the presence of curvature at the outset. Nerve root impingement, intervertebral disk disease, and spinal cord compression are uncommon in young patients with idiopathic scoliosis. Large curves are more common in females than in males (7:1 ratio). Pain is so rare that children and adolescents with painful curves must be carefully studied in order to exclude neoplastic and inflammatory processes of the spinal column or neural canal. Idiopathic scoliosis is usually a painless disorder during childhood and adolescence. Severe structural curves may cause no pain until degenerative changes develop in adulthood.

School Screening Programs

School screening for spinal deformity is common in North America. Most programs concentrate on children in the late juvenile and early adolescent periods. The most common screening method employed is the forward-bend test, based anatomically on the vertebral rotation that accompanies lateral spinal deviation (see Fig. 35.15). Associated clinical findings include shoulder asymmetry, unequal distances between the medial borders of the elbows and the flanks, and apparent leg length inequality or pelvic tilt. Breast asymmetry, caused by forward rotation of the chest wall on the side of the curve concavity and backward displacement of the chest wall on the convex side of the curve, is often present in affected girls.

The threshold for "identification" on screening examination is subjective, and it is not surprising that the incidence of spine asymmetry detected by school screening programs varies with the method of screening and the experience of the examiner. A range of 3-20% has been reported. Follow-up radiographic studies of children thought to have abnormal curvatures on school screening examinations indicate an incidence of scoliosis in screened children of less than 15% (range, 0.4-14%). The incidence of curves greater than 20 degrees at the time of primary screening is probably less than 0.5%. Simple devices such as the scoliometer determine spine asymmetry by measuring the angle

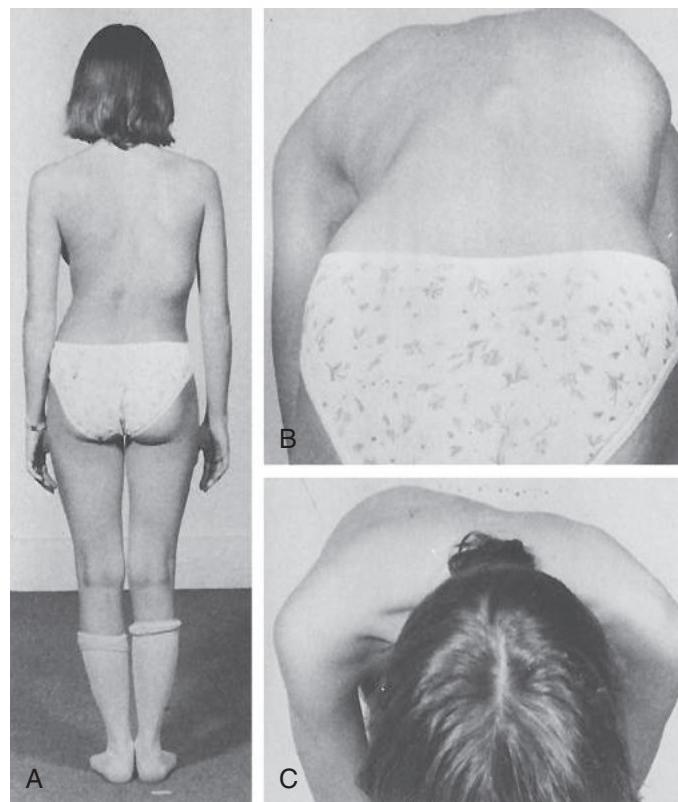

FIGURE 35.15 *A,* Adolescent idiopathic scoliosis, viewed from the back. Note the right-sided thoracic prominence. When the patient bends forward *(B),* the rib prominence is even more apparent. This is secondary to rotation of the ribs and spine. The rib prominence is also quite evident when viewed from the front *(C).* (From Renshaw TS. *Pediatric Orthopedics.* Philadelphia: WB Saunders; 1986:47.)

of trunk rotation at the apex of the rib hump. An angle of more than 7 degrees is an appropriate criterion for referral.

The 1st response to a positive school screening examination should be a repeated physical examination. If asymmetry is confirmed, a single standing posteroanterior spine film, including vertebral levels T1 to S1, should be obtained. Lateral films, bending films, and oblique views are not necessary. Referral is appropriate for skeletally immature children or adolescents with curves greater than 20 degrees.

Natural History

The natural history of curvature in patients with spine asymmetry is highly variable. Factors that appear to be associated with risk of progression include the magnitude of curvature at the time of detection, the chronological and skeletal age of the patient, the pattern of curvature, and the menarcheal status. Immature patients with large-magnitude curves are far more likely to experience progression than are more mature patients with small curves. Progression of curves after skeletal growth is uncommon in idiopathic thoracic curves of less than 30 degrees at the end of growth but is likely to occur in patients with curves greater than 50 degrees at maturity.

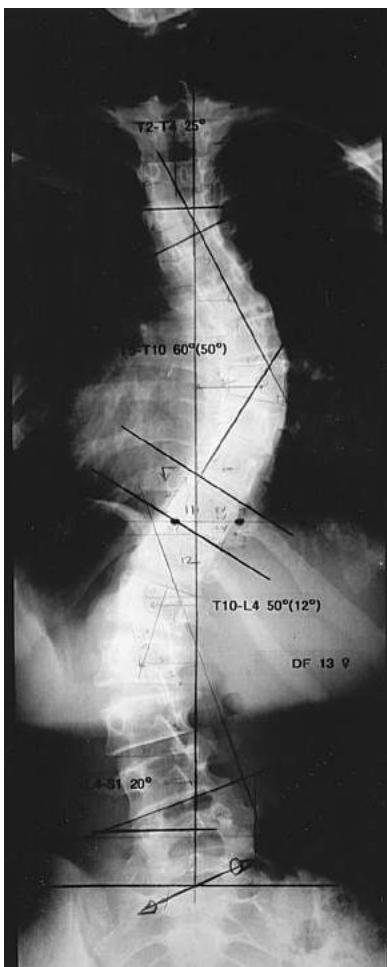
Uncontrolled curve progression causes significant problems in adult life. Unacceptable deformity, back pain, chronic fatigue, and decreased work capacity are common. Premature degenerative arthritis and nerve root impingement caused by deformity and osteophytic spurring occur in patients with lumbar curves or double thoracic-lumbar curves. Asymptomatic decreased vital capacity is common in patients with thoracic curves; symptomatic cardiopulmonary


FIGURE 35.16 Adolescent idiopathic scoliosis. The patient, a 13-year-old girl, had a severe double-curve pattern with significant accompanying deformity but no pain. Surgical treatment was warranted to halt progression and restore spinal alignment.

FIGURE 35.17 Osteoid osteoma of the spine. Technetium bone scanning shows increased uptake in the T10 vertebral body in a 15-year-old boy. Note the scoliosis that accompanies this painful lesion. The condition did not respond to antiinflammatory medications, and surgical excision was necessary.

compromise (cor pulmonale) may develop in patients with curves greater than 80 degrees.

Treatment

The goal of treatment in idiopathic scoliosis is to bring a patient to skeletal maturity with a cosmetically acceptable, balanced, and stable curve that is unlikely to progress in adult life. Mature adolescents with curves less than 30 degrees need no treatment beyond initial evaluation. Further progression of curvature is unlikely to occur in these individuals. Patients with juvenile scoliosis and less mature adolescents with curves between 10 and 20 degrees should be monitored at 6-month intervals with single standing posteroanterior spine radiographs. If progression occurs, they should be referred for orthopedic care.

Active treatment is indicated for growing patients with curves greater than 30 degrees. Brace treatment remains the standard method of nonoperative treatment of idiopathic curvature. Surgical treatment is appropriate for patients with curves too severe for brace treatment. Documented progression in spite of nonoperative treatment is another indication for surgical intervention.

Improved instrumentation and internal fixation devices, intraoperative monitoring of spinal cord function, and autologous transfusion have improved the safety and efficacy of surgical correction. In most cases, patients can be out of bed the day after surgery and are discharged within 5 days of surgery. Return to school is usually possible within 3 weeks; most activities of normal life, including sports, can be resumed within 6 months. In many instances, no postoperative immobilization is required; in other cases, a removable lightweight plastic orthosis can be employed. Prolonged periods of immobilization in a plaster cast are uncommon.

Tumors of the Spinal Column

Persistent back pain, muscle spasm, and abnormal trunk posture are ominous findings in children. Neoplastic disease must be considered in patients with no other obvious source of pain (see Table 35.2).

Primary Lesions of Bone

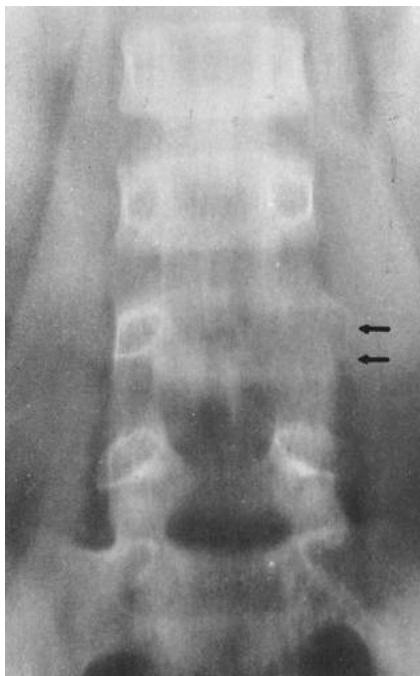
The most common primary bone tumors affecting the spinal column in children are osteoid osteomas (Fig. 35.17), osteoblastomas (Fig. 35.18), eosinophilic granulomas, and aneurysmal bone cysts. Although benign, these lesions may cause considerable back pain and local bone destruction. Osteogenic sarcoma, a malignant lesion of bone, occurs less commonly in the spine than in the long bones of children. Unexplained pain is the hallmark of spinal neoplasia and is usually the presenting complaint. At times, pain may be severe and unresponsive to nonnarcotic analgesics. In other instances, as in osteoid osteoma, the relief of symptoms that occurs with nonsteroidal antiinflammatory agents is so characteristic that it is considered a diagnostic finding. Paraspinal muscle spasm, tenderness in the soft tissues on the side of the spinal column, and alterations in spinal configuration are common. Scoliosis, loss of lumbar lordosis, or accentuations of thoracic kyphosis may be present.


FIGURE 35.18 The patient presented with left-sided lumbar back pain. Note the destruction of the vertebral pedicle at L4 *(arrows)*. This proved to be an osteoblastoma. Children with back pain should be suspected of having a tumor of the spine or spinal cord until it is proven otherwise. (From Renshaw TS. *Pediatric Orthopedics*. Philadelphia: WB Saunders; 1986:57.)

FIGURE 35.19 Osteomyelitis at T11 and T12. Note the destruction of the disk space and vertebral bodies with the beginning of anterior ossification. In this patient, fusion occurred spontaneously, and the patient is now asymptomatic. (From Renshaw TS. *Pediatric Orthopedics*. Philadelphia: WB Saunders; 1986:59.)

Initial evaluation of patients with suspected spinal tumors should include standard anteroposterior and lateral radiographs of the spine (see Fig. 35.18). These may not show small lesions hidden in vertebral pedicles or posterior elements; other studies are often necessary. Technetium bone scanning is particularly useful (see Fig. 35.17). *MRI and CT scans are usually necessary to localize lesions for surgical treatment.* Prompt referral is essential when spinal neoplasia is suspected. The success of treatment depends in large part on early discovery and intervention.

Tumors of Neural Elements

Back pain, lower extremity weakness, and sphincter disturbances are common manifestations of neoplasms of the spinal cord. Although such lesions are rare, they must be suspected in children with unexplained back or leg pain, weakness, sensory or reflex abnormalities, bowel or bladder incontinence, or unexplained gait abnormalities. Neuroblastoma is the most common lesion, but sarcomas (including Ewing sarcoma, rhabdomyosarcoma, and hemangiosarcoma) and astrocytomas or ependymomas also occur in the neural contents of the spinal canal.

In such patients, standard radiography often shows only loss of lordosis or scoliosis secondary to muscle spasm. MRI demonstrates the abnormality, but definitive diagnosis usually requires biopsy. The success of treatment is often related to promptness of diagnosis. Early referral of patients with unexplained back pain is essential for appropriate treatment.

Leukemia

Skeletal involvement is common in patients with leukemia; back pain or limb pain may be the presenting symptom in some children. Proliferation of abnormal hematopoietic tissue in the marrow of long bones or vertebral bodies causes pain and weakens their structure.

Clinical symptoms and signs in children with leukemic skeletal involvement may be confusing. Fever, localized pain and swelling, and elevations of the white blood cell count and erythrocyte sedimentation rate may be mistaken as signs of septic arthritis, osteomyelitis, or intervertebral disk space infection. The presence of abnormal white blood cells on the peripheral blood cell count or of thrombocytopenia increases the likelihood of bone marrow tumor rather than infection.

Osteopenia, periosteal elevation, and metaphyseal lucencies are common radiographic findings in leukemic involvement of long bones. These may be difficult to detect in patients with spinal involvement. Vertebral compression and wedging are sometimes present and may mimic acute fracture or, on occasion, osteomyelitis (Fig. 35.19). The absence of a history of trauma should alert the examiner to search for other causes of the radiographic abnormality. Preservation of intervertebral disk space height with collapse of adjacent vertebral segments is an indication that the vertebral bodies rather than the intervertebral disk are the sites of the abnormality. Technetium bone scanning is useful for detecting other areas of involvement, although it is not as reliable in leukemia as in other spinal lesions. MRI is useful for detecting areas of spinal involvement not visible on plain radiographs and for assessing the extent of intraspinal infiltrate or spinal cord compression present.

The diagnosis of leukemia can be established by bone marrow aspiration. Biopsy of involved vertebral segments is rarely necessary. Support of the spine in a custom-fabricated orthosis is useful for relieving pain and preventing further vertebral collapse during the initial phases of treatment. Prolonged brace treatment may be necessary to prevent vertebral compression fractures that may accompany the osteopenia resulting from steroid therapy. Surgical decompression and fusion may be required in rare cases of acute vertebral compression and spinal cord compromise.

TABLE 35.3   Red Flags: Most Common Indications From History and Examination for Pathologic Findings Needing Special Attention and Sometimes Immediate Action

• Children <18 yr old with considerable pain • History of violent trauma • Nonmechanical nature of pain (i.e., constant pain not affected by movement, pain at night) • History of cancer • Systemic steroid use • Drug abuse • HIV infection or other immunocompromised patients • Unintentional weight loss • Systemically ill, particularly signs of infections such as fever or night sweats	• Persisting severe restriction of motion or intense pain with minimal motion • Structural deformity • Difficulty with micturition • Loss of anal sphincter tone or fecal incontinence, saddle anesthesia • Progressive motor weakness or gait disturbance • Marked morning stiffness • Peripheral joint involvement • Iritis, skin rashes, colitis, urethral discharge, or other symptoms of rheumatologic disease • Inflammatory disorder such as ankylosing spondylitis suspected • Family history of rheumatologic disease or structiral abnormality

HIV, human immunodeficiency virus.
Modified from Nachemson A, Vingard E. Assessment of patients with neck and back pain: a best-evidence synthesis. In: Nachemson AL, Johnsson B, eds. *Neck and Back Pain: The Scientific Evidence of Causes, Diagnosis, and Treatment.* Philadelphia: Lippincott Williams & Wilkins; 2001.

SUMMARY AND RED FLAGS

Back pain in children may be referred pain from intraabdominal or retroperitoneal disease (see Table 35.2) or may represent direct involvement of the spinal cord, vertebral bodies, or paraspinal musculature. In most children with normal examination findings, back pain is benign, short-lived, and responsive to rest or nonsteroidal antiinflammatory agents.

Chronic persistent back pain, pain associated with lower extremity or bowel and bladder neurologic deficits, cutaneous lesions over the lumbar spine, systemic signs (as in inflammatory bowel disease, leukemia, osteomyelitis), acute pain, and tenderness with neurologic dysfunction after trauma are red flags (Table 35.3). Signs of cord involvement are particularly ominous and are emergencies. Spinal cord involvement above T10 produces symmetric weakness, increased deep tendon reflexes, up-going toes, and an appropriate sensory loss; conus medullaris involvement (T10 to L2) produces symmetric weakness, increased knee and decreased ankle deep tendon reflexes, a saddle-type anesthesia, and up- or down-going toes on Babinski testing; and cauda equina involvement (below L2) produces asymmetric weakness, loss of deep tendon reflexes, and down-going toes. Such findings represent an acute emergency that warrants immediate imaging (MRI) and therapy, which may include high-dose corticosteroids, radiation therapy, or laminectomy to prevent permanent paralysis.

Lymphadenopathy and Neck Masses

Brett J. Bordini

Given the role of the lymphatic system in developing adaptive responses to numerous antigenic challenges and the rate at which the immune system is exposed to novel antigens early in life, enlarged lymph nodes are regularly encountered both incidentally and within the context of many childhood illnesses. The challenge for the clinician is determining when a change in the size or quality of a lymph node is physiologic and when such a change represents pathology. A thorough history, physical examination, and recognition of the anatomic drainage patterns of the lymphatic system will oftentimes sufficiently narrow the differential diagnosis of lymphadenopathy such that complicated or invasive diagnostic evaluations are unnecessary.

MECHANISM OF LYMPHADENOPATHY

The lymphatic system is a network of vessels and tissues that collects excess fluid from the cellular interstitium and returns it to the peripheral circulation. This interstitial fluid is similar in composition to plasma, though it may contain additional proteins, pathogens, other antigens, and antigen-presenting cells. The collected fluid, termed **lymph**, enters the lymphatic system via specialized lymphatic capillaries and passes into nearby lymph nodes via afferent lymphatic vessels. The lymph nodes contain both B and T lymphocytes lying in a supportive framework within a connective tissue capsule (Fig. 36.1). Additional lymphocytes may enter lymph nodes from the peripheral venous circulation via postcapillary high endothelial venules. Antigens, antigen-presenting cells, and pathogens present within the lymph interact with the lymphocytes, allowing for the production of B- and/or T-cell immune responses in an effort to clear the antigen or pathogen. Efferent lymphatic vessels then carry lymph and antigen-sensitized lymphocytes from the nodes back to the peripheral circulation via the thoracic duct.

Enlargement of lymph nodes can come about via several mechanisms. First, **physiologic hyperplasia** can occur as nodal and circulating lymphocytes proliferate within nodes in response to antigenic stimulation. Second, bacteria that have been transported to the nodes may stimulate the recruitment of polymorphonuclear cells and the elaboration of inflammatory mediators that can lead to the edema, erythema, and tenderness characteristic of **bacterial lymphadenitis** or to suppuration and abscess formation. Third, **malignant cells** may arise within the node itself and proliferate, causing enlargement, or arrive from distant cancerous sites and infiltrate the nodal tissue. Fourth, certain **medications** can cause lymphadenopathy either

directly or as part of a serum sickness-like reaction. Finally, in rare **genetic storage diseases** (Niemann–Pick, Gaucher diseases), macrophages laden with abnormally metabolized lipids may lodge within lymph nodes, causing enlargement.

The regional drainage pattern of each lymph node group is important in determining the cause of lymphadenopathy, particularly when localized to an individual node or contiguous group of nodes (Fig. 36.2 and Tables 36.1 and 36.2). The cervical lymph nodes drain lymph from distinct areas of the head, neck, and throat and may enlarge if a local infection is present. Consequently, because otitis media and pharyngitis are common infections in children, head and neck lymphadenopathy is one of the more frequently encountered regional lymphadenopathy patterns in small children. The axillary nodes drain lymph from the arms, lateral breasts, and superficial chest and upper abdomen, and isolated enlargement of these nodes may suggest pathology in these areas. The inguinal nodes drain the lower extremities, genitourinary system, and perineum, which may indicate lower extremity pathology or the presence of a sexually transmitted infection in patients with an exposure history. Supraclavicular lymphadenopathy is a concerning finding and should prompt concern for an underlying neoplasm, fungal infection, tuberculosis, or sarcoidosis. **Generalized lymphadenopathy**, defined as the presence of enlarged or abnormal lymph nodes in 2 or more noncontiguous lymph node groups (with or without hepatosplenomegaly), is often indicative of a systemic response to an infectious or otherwise inflammatory process but may also indicate malignant proliferation of lymphocytes (Table 36.3).

◆ History

History should be aimed at establishing the time course of the development of lymphadenopathy, whether the lymphadenopathy is restricted to a particular anatomic region or is generalized, and if there are any associated signs, symptoms, or exposures that may suggest an etiology.

Lymphadenopathy that develops rapidly over several days is more suggestive of an acutely inflammatory, often infectious process, whereas more indolently developing lymphadenopathy may suggest malignancy, chronic disease, or an atypical infection. The sudden onset of unilateral inguinal adenopathy shortly following lower extremity trauma suggests an infection in the traumatized extremity. In contrast, progressive enlargement of multiple noncontiguous nodal groups over the course of weeks or months that is accompanied by

(See *Nelson Textbook of Pediatrics,* p. 2413.)

weight loss, fevers, or night sweats, suggests a systemic illness such as lymphoma or tuberculosis. When establishing the time period over which the lymphadenopathy developed, the clinician should clarify both when the node was first noted to be abnormal, as well as the last time the node was felt to be normal. This information is particularly essential if associated symptoms, overlying skin changes, and tenderness are absent, since more slowly developing lymphadenopathy may not be noticed until the node or nodes are quite enlarged, or

if lymphadenopathy was noted only incidentally when dressing, grooming, or bathing.

The age of the child with lymphadenopathy is similarly important in the consideration of the cause (see Table 36.3). Neonatal lymphadenopathy is typically indicative of exposure to an infectious agent in utero, such as cytomegalovirus (CMV), syphilis, human immunodeficiency virus (HIV), rubella, or toxoplasmosis, though may less frequently be associated with congenital malignancy or storage diseases. In contrast, toddlers and children with adenopathy tend to have either focal infections that drain into the affected nodal chain, or systemic viral infections, resulting in diffusely enlarged nodes. Adolescents may acquire exposures that place them at risk for sexually transmitted infections and inguinal adenopathy. Just as exposure to certain infectious agents may vary with age, the risk of hematologic malignancy varies as well: acute leukemias are more common in toddlers and young children; non-Hodgkin lymphoma is more common is school-aged children, and Hodgkin lymphoma is more common in adolescents.

The past medical history and review of systems should be explored for conditions that may either cause lymphadenopathy directly or place the patient at increased risk for opportunistic infections, such as congenital or acquired immunodeficiency. The clinician should inquire about any signs or symptoms that would suggest an acute infectious process or more slowly progressive constitutional symptoms that may suggest malignancy or indolent infection. The quality of oral hygiene practices and dentition should be assessed as **odontogenic infections** may not readily be appreciated as a source of cervical lymphadenopathy. The use of any prescription medications, over-the-counter medicines, or traditional remedies should be ascertained. In addition to medications that may directly cause lymphadenopathy, other substances may provoke lymphadenopathy as a component of a serum sickness-like reaction or be associated with autoimmune or rheuma-

tologic conditions that cause generalized lymphadenopathy (see Table 36.3).

After determining the timing and distribution of the lymphadenopathy and placing these findings within the context of the child's age and past medical history, the clinician should inquire about any exposures that may have led to the development of lymphadenopathy, focusing in particular on diet, travel history, and contact with individuals, animals, or environments that may pose a risk for disease transmission. Contact with or consumption of raw or undercooked meats, particularly pork, lamb, and venison, may transmit *Toxoplasma gondii*, leading to toxoplasmosis. Similarly, contact with agricultural animals or ingestion of unpasteurized dairy products may place patients at risk for acquiring certain pathogens, such as *Brucella* species or *Mycobacterium bovis*; infection with either of which may lead to generalized lymphadenopathy. Potential exposures in the home environment should be assessed, including the risk of contaminated drinking water and whether there are concerns for mold exposure, particularly in immunocompromised patients. The presence of pets, either within the home or in the area, should be determined. Cats or kittens that may scratch the child and transmit *Bartonella henselae*, the etiologic agent of **cat-scratch disease**, are often omitted from the history unless such questions are specifically asked. Furthermore, some families may deny the presence of household pets but forget to mention that the child plays with a pet present in a barn or around the neighborhood. Travel history should determine whether the child is from or has been exposed to geographic areas associated with a higher risk for acquiring certain infections, such as tuberculosis in developing nations or histoplasmosis in the Ohio River valley. The clinician should inquire whether any family members or close contacts are ill or taking medications, whether any have recently traveled to or immigrated from other countries, and whether any have recently been incarcerated. Adolescents should be questioned about risk factors for HIV and sexually transmitted infections, such as syphilis or lymphogranuloma venereum, which may cause generalized or inguinal lymphadenopathy, respectively.

The family history should also focus on potentially heritable conditions, such as autoimmune or rheumatologic disorders, certain

TABLE 36.3   Differential Diagnosis of Generalized Lymphadenopathy

Neonate	Child	Adolescent
Common Causes

hematologic and soft tissue malignancies as well as storage diseases that may be associated with noninfectious forms of lymphadenopathy.

◆ Physical Examination

Physical examination should assess general appearance and look for signs or symptoms that may reveal the underlying cause of lymphadenopathy. Examination of the lymphatic system should establish the size, quality, and distribution of any abnormal lymph nodes and should assess for the presence of tenderness or changes in the overlying skin or surrounding tissues.

Size

The threshold beyond which a particular node is considered enlarged varies by nodal group. In general, nodes over 1 cm in diameter are considered enlarged; exceptions include epitrochlear nodes greater than 0.5 cm in diameter and inguinal nodes greater than 1.5 cm in diameter.

Quality

The quality of the nodes often yields some clues as to the cause of the adenopathy. The clinician should assess consistency, mobility, shape, tenderness, and whether any changes to the overlying skin or soft tissues are present. The following general patterns are worth noting:
- Erythematous, tender, and warm: acute bacterial infection with suppurative adenitis
- Tender, nonerythematous, and soft: viral infection or other systemic infection
- Firm, hard, rubbery, and nontender: lymphoma or other infiltrating tumor
- Hard, matted, immobile, and nontender: tumor, metastatic or local; fibrosis that follows acute infection

Distribution

All areas in which lymphadenopathy is commonly present should be palpated, including the cervical, auricular, axillary, epitrochlear, inguinal, and supraclavicular areas, because lymphadenopathy in certain regions is linked to systemic or local illness. If more than 2 noncontiguous nodal groups are abnormal, without evidence of distinct focal infections inciting the lymphadenopathy within each group, the lymphadenopathy is generalized.

Regional lymphadenopathy usually reflects pathologic processes within the lymphatic drainage distribution of that particular nodal chain (see Table 36.2). Several patterns of regional lymphadenopathy should prompt further evaluation. The presence of palpable supraclavicular nodes is often a red flag for a serious illness such as malignancy. **Supraclavicular nodes** that are palpated on the right side often reflect a mediastinal tumor or invasive mediastinal infection, such as histoplasmosis. Supraclavicular nodes on the left side are often the result of metastatic spread of an abdominal tumor. The presence of either type of node mandates an urgent evaluation, including computed tomography (CT) or magnetic resonance imaging. **Epitrochlear nodes**, if unilateral, commonly indicate the hand or arm as a source of distal infection; however, palpable bilateral epitrochlear lymph nodes usually reflect systemic illness, such as syphilis, sarcoidosis, or lymphoma. **Inguinal** node enlargement is common and is usually caused by the frequent occurrence of minor trauma and infections in a child's legs and feet. Significantly enlarged inguinal nodes may also be present with sexually transmitted infections, such as syphilis, chlamydial urethritis, lymphogranuloma venereum, or with urinary tract infection, lymphoma, or abdominal tumors.

Mediastinal adenopathy (or mass) may be detected incidentally, or secondary to chest symptoms, or during the evaluation of peripheral but generalized lymphadenopathy. The differential diagnosis is noted in Table 36.4.

◆ Differential Diagnosis

The differential diagnosis of lymphadenopathy is developed in a stepwise fashion, first by determining whether the lymphadenopathy is regional or generalized. Next, the time course of the lymphadenopathy should be defined as acute or as chronic, defined as being present for a period of more than 4 weeks. Finally, the quality of the nodes and

From Alexander S, Ferrando AA. Pediatric lymphoma. In: Orkin SH, et al, eds. *Nathan and Oski's Hematology and Oncology of Infancy and Childhood.* 8th ed. Philadelphia: Elsevier; 2015;2:1627; Box 53-2.

the presence of any associated signs or symptoms should be ascertained. Using this approach, a comprehensive differential diagnosis and evaluation plan can then be developed (Figs. 36.3 and 36.4).

Differential Diagnosis of Head and Neck Lymphadenopathy: Head and Neck Masses

Several congenital and acquired lesions of other head and neck structures, many of which are benign, may mimic lymphadenopathy and deserve consideration. History and physical examination should provide sufficient information to arrive at an appropriate differential diagnosis and evaluation strategy of these mimics. Important factors in distinguishing lymphadenopathy from nonnodal congenital or acquired lesions of the head and neck include the age of the child, anatomic position, presence of signs of inflammation, associated symptoms, and the time course of the development of symptoms (Figs. 36.5 and 36.6).

◆ Evaluation and Management Strategies

Many previously healthy children with acute lymphadenopathy require few, if any, laboratory or imaging studies. No laboratory testing may be required for well-appearing children whose acute, localized adenopathy can be attributed to an infection in the vicinity of the node. Patients with localized cutaneous bacterial infections causing adenopathy also may not need laboratory investigations before the initiation of empiric antimicrobial therapy unless there is suspicion of bacteremia or invasive spread of the infection to underlying tissues.

Acute cervical adenopathy accompanying pharyngitis in children older than 18 months may necessitate a throat culture for group A *Streptococcus*. The additional presence of hepatomegaly or splenomegaly should raise suspicion of Epstein-Barr virus (EBV)–related infectious mononucleosis. The clinician could obtain a complete blood cell count with white blood cell differential (to identify lymphocytosis and atypical lymphocytes) and EBV titers (or a monospot heterophile antibody test in older children).

Supraclavicular adenopathy, acute cervical adenopathy accompanied by respiratory distress, or prolonged cervical adenopathy warrants anteroposterior and lateral radiographs of the neck and/or chest, a complete blood cell count with white blood cell differential, and interferon gamma release assay or placement of a purified protein derivative (PPD) tuberculin skin test. CT with contrast is necessary in certain situations to fully delineate cervical adenopathy that is excessively large or that impinges on the airway, or to determine whether mediastinal adenopathy is also present.

Children presenting with prolonged diffuse lymphadenopathy, hepatomegaly or splenomegaly, weight loss, night sweats, fevers, recurrent infections, or failure to thrive must be more thoroughly studied. Only after the complete blood cell count and differential and chest radiograph are analyzed should other diagnostic studies be considered. HIV, EBV, and CMV studies (culture, polymerase chain reaction [PCR], and serologic profiles) may be obtained for some children. Because the diagnoses of leukemia (through bone marrow aspiration, biopsy), lymphoma (through bone marrow aspiration, biopsy), systemic lupus erythematosus (through antinuclear antibody, double-stranded DNA antibodies), and cat-scratch disease (through biopsy and/or *B. henselae* serologic profile) require more invasive and expensive tests, the physician should first consider all aspects of the history and physical examination before ordering laboratory studies.

Regional Lymphadenopathy

The typical child with acute regional lymphadenopathy presents with enlarged nodes, commonly in the cervical region. A thorough history and careful physical examination should reveal whether nodes are definitively involved, as opposed to other nonnodal structures, such as the parotid gland. In many cases, no other abnormalities are found on examination, and systemic signs are minimal. Laboratory tests should include a complete blood cell count and differential as well as measurement of the erythrocyte sedimentation rate and the C-reactive protein. In the child with fever and a tender cervical lymph node, oral antibiotics (with activity against mouth flora, streptococci, and staphylococci) should be started; if the lymphadenopathy persists or worsens, intravenous antibiotics are indicated. A PPD or interferon gamma release assay should be undertaken, and if the results are negative and symptoms resolve, it is reasonable to complete the antimicrobial course orally.

In contrast, if the lymphadenopathy continues or becomes frank lymphadenitis with erythema and tenderness despite antimicrobial therapy, further work-up is indicated. Imaging the involved area is helpful but not always necessary. Although ultrasonography can reveal enlarged nodes or a fluid-filled abscess or cyst, contrast-enhanced computed tomography of the area is the best method for defining the extent of inflamed nodes and whether an abscess is present (Fig. 36.7). If an abscess is found, incision and drainage, followed by appropriate bacterial and mycobacterial cultures and stains, are appropriate. If atypical mycobacteria are suspected on the basis of a borderline positive PPD result or clinical presentation, fine-needle aspiration or excisional biopsy is preferred because incision and drainage often leads to draining sinus tracts that are difficult to heal. Enlarged nodes that do not recede in several weeks with appropriate antimicrobial therapy and without explanation (such as acute EBV infection) should also raise the suspicion of malignancy.

Generalized Lymphadenopathy

In the child with generalized lymphadenopathy, the cause may be infectious, immunologic, or malignant. Infectious causes, such as HIV, EBV, toxoplasmosis, secondary syphilis, and CMV infections, can generally be determined quickly through serologic testing. Noninfectious causes, such as systemic lupus erythematosus and serum sickness, can

also generally be excluded by a thorough history and serologic studies when indicated. Drugs may cause serum sickness but may also produce hypersensitivity reactions with resulting generalized lymphadenopathy. Medications associated with drug-induced lymphadenopathy include allopurinol, atenolol, captopril, carbamazepine, gold, hydralazine, penicillins, phenytoin, primidone, procainamide, pyrimethamine, quinidine, sulfonamides, sulindac, and tetracyclines. If the generalized lymphadenopathy cannot be attributed to an infectious or other cause, if the nodes fail to recede within several weeks, and especially if there are systemic symptoms, malignancy must be considered. An abnormal complete blood cell count demonstrating anemia, leukopenia, or thrombocytopenia, or radiologic evidence of mediastinal adenopathy or pleural disease is highly suggestive of malignancy. Because serious disseminated infections, such as tuberculosis and histoplasmosis, can

manifest in a similar manner, fine-needle aspiration or biopsy of an involved node or bone marrow aspiration is crucial. Excision of a node is preferred in some cases in order to obtain adequate tissue for pathologic study, stains, or cultures.

Lymphadenopathy Patterns

Several patterns of lymphadenopathy and their underlying causes deserve special mention, due either to the frequency with which they are encountered in pediatric practice, or to the potential severity of the underlying cause.

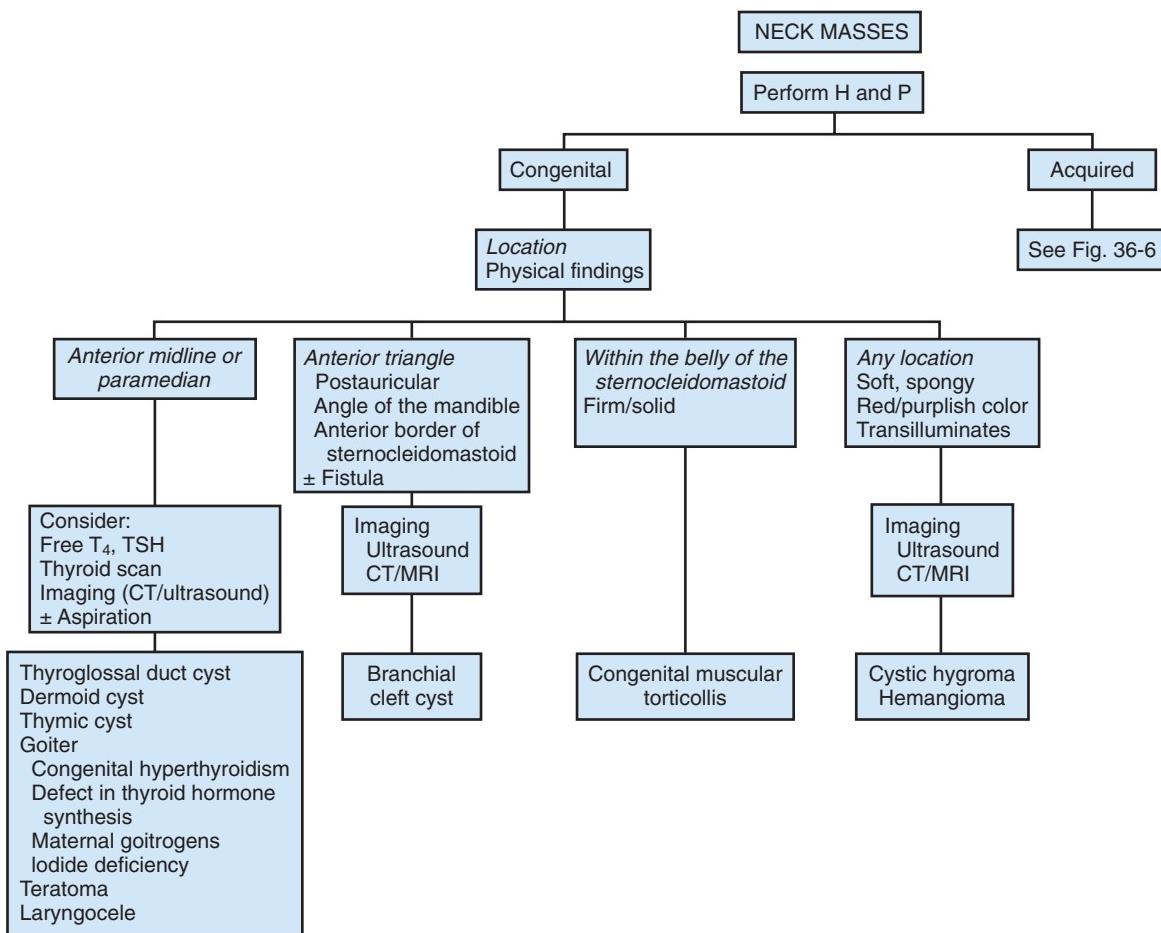
Infections of the oropharynx. Pharyngeal infection is the most common cause of regional lymphadenopathy in children (see Chapter 1). Many of these pharyngeal infections are associated with cervical lymphadenopathy and are viral in origin. Frequent viral causes include adenovirus, parainfluenza, influenza, rhinovirus, and enterovirus. EBV and CMV also commonly cause exudative pharyngitis and cervical


FIGURE 36.5 Diagnostic algorithm for congenital neck masses. CT, computed tomography; H and P, history and physical examination; MRI, magnetic resonance imaging; T_4, thyroxine; TSH, thyroid-stimulating hormone. (Modified from Pomeranz AJ, Sabnis S, Busey SL, Kliegman RM. *Pediatric Decision-Making Strategies*. 2nd ed. Philadelphia: Elsevier; 2016:9.)

lymphadenopathy. The chief complaint usually includes pain with swallowing and with talking, as well as tender, enlarged lymph nodes in the neck. Systemic manifestations, such as fever, myalgia, chills, and rhinorrhea may also be present. An examination of the throat typically reveals a symmetrically erythematous posterior oropharynx with enlarged tonsils that often contain exudates. Exudates can be seen with both viral and bacterial causes of pharyngitis and adenopathy, and thus do not reliably enable the examiner to discriminate between the 2 causes. Herpes stomatitis with mucocutaneous involvement and herpes pharyngitis with oropharyngeal vesicles are also associated with bilaterally enlarged, tender, non-erythematous cervical nodes.

Bacterial infection of the pharynx is also commonly associated with enlarged, tender cervical lymph nodes. Strains of group A β-hemolytic streptococci are the most common causes of such infections and are difficult to differentiate clinically from viral causes of pharyngitis and lymphadenopathy; thus, throat culture, PCR, or rapid antigen detection is necessary. An associated sandpapery rash and beefy-red tonsils with palatal petechiae are not usually seen with viral pathogens and should make the examiner consider group A streptococci and toxin-mediated scarlet fever as a likely cause. Other bacteria can cause pharyngitis and cervical adenopathy, including non–group A streptococci and anaerobic organisms, such as *Fusobacterium* species. Anaerobic organisms can lead to painful oral gingivitis or stomatitis and pharyngitis (Vincent angina) that may progress to peritonsillar abscess.

Asymmetry in the tonsils and surrounding tissues, as well as deviation of the uvula away from the affected side may be seen with peritonsillar abscesses, along with unilateral tender, enlarged cervical lymph nodes ipsilateral to the abscess. Complications of acute bacterial pharyngitis may also include **Lemierre syndrome**, the findings of which include high fever and unilateral, lateral neck swelling that may be confused with adenopathy. Lemierre syndrome is due to septic thrombosis of the internal jugular vein (and pulmonary septic emboli), usually caused by invasion of the bloodstream by *Fusobacterium* organisms, and should lead to prompt hospitalization, blood cultures, treatment with intravenous antibiotics, and imaging of the internal jugular vein via Doppler flow ultrasonography or contrast-enhanced computed tomography.

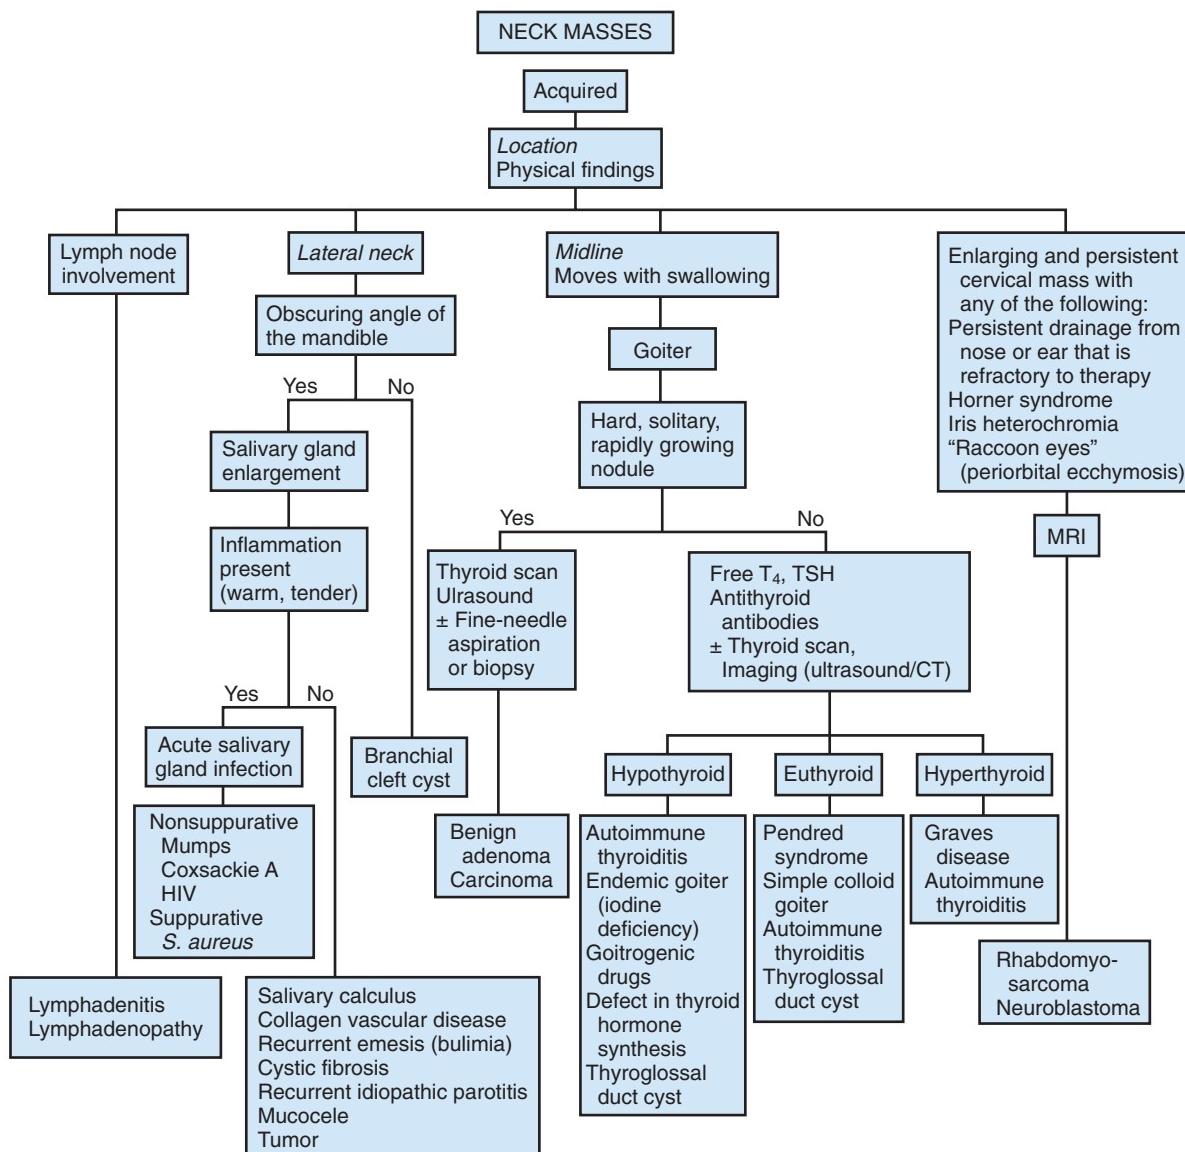
Acute cervical lymphadenitis—inflammation of the cervical lymph nodes with tender enlargement—is most likely to occur with group A streptococcal or *Staphylococcus aureus* infection. There may or may not be a history of sore throat or pharyngeal inflammation on examination. Infection with other oral bacteria, including non–group A streptococci and anaerobes such as *Fusobacterium* or *Arcanobacterium* species may also occur, presumably with the pharynx as the portal of entry. Other common sites for acute lymphadenitis are the submandibular nodes. Usually, these nodes quickly diminish in size after institution of appropriate antibiotic therapy, providing some degree of retrospective diagnosis while simultaneously being therapeutic.


FIGURE 36.6 Diagnostic algorithm for acquired neck masses. CT, computed tomography; MRI, magnetic resonance imaging; T$_4$, thyroxine; TSH, thyroid-stimulating hormone. (Modified from Pomeranz AJ, Sabnis S, Busey SL, Kliegman RM. *Pediatric Decision-Making Strategies*. 2nd ed. Philadelphia: Elsevier; 2016:11.)

Suppuration and spontaneous drainage of the nodes is less common than adenitis and is not typically seen in the setting of viral infections. Acute suppurative cervical adenitis can be seen in infections of the face and scalp and is usually caused by infection with group A streptococci or *S. aureus*. Management of suppuration includes incision and drainage or excision of the suppurative node. Gram stain and bacterial, fungal, and mycobacterial cultures of the drainage should be obtained. If there is concern for mycobacterial disease, a tuberculin skin test should be placed and/or interferon-gamma release assay should be performed. Total excision should be performed if atypical mycobacterial infection is suspected, because draining fistulas may form if a needle biopsy or partial resection is performed. Fine-needle aspiration may reduce the risk of sinus formation.

Infections of the extremities. Bacterial infections of the skin and soft tissues are common causes of localized lymphadenopathy and adenitis, and can lead to axillary or inguinal adenopathy if these infections originate in the extremities. These infections, primarily caused by group A β-hemolytic streptococci or *S. aureus*, may drain into and inflame single or multiple regional lymph nodes. Any laceration or insect bite that becomes infected may yield adenopathy upstream in the nodal drainage basin of the infected site. Occasionally, penetrating injuries to the feet occurring through damp shoes or in wet areas may yield infections with other bacteria, such as *Pseudomonas aeruginosa*. These penetrating infections usually manifest with cellulitis or osteomyelitis; lymphadenopathy is noted during the physical examination. The most common sites of infection include the foot or leg, leading to unilateral inguinal lymphadenitis, and the hand or arm, causing axillary lymphadenitis or unilateral inflammation of the epitrochlear nodes.

Epstein–barr virus infection. Infection with EBV is a common cause of both regional (bilateral cervical) and diffuse lymphadenopathy. This virus classically causes a mononucleosis syndrome in adolescents (Fig. 36.8), consisting of acute pharyngitis that may have a prolonged course, with tender and firm cervical adenopathy, malaise, fever, weight loss, and anorexia. Nearly half of patients will have generalized lymphadenopathy as well. More than 80% of patients have

mild hepatitis that is clinically silent but can be documented with liver enzyme studies; approximately 10% become jaundiced. Splenomegaly is present in more than 50% of patients and, in rare cases, progresses to splenic rupture. A small number of patients also have parapharyngeal and tonsillar lymphoid hyperplasia, which causes difficulty swallowing or breathing and can produce significant problems, leading to dehydration or airway obstruction. Small children with EBV infection often present with atypical symptoms or may be completely asymptomatic. In these children, fever and mild cervical adenopathy may be the major symptoms on presentation, or the child may be significantly ill with high fever and pharyngitis. In some, a nonspecific rash, appearing often after beginning empiric antibiotic therapy with penicillins, will suggest the diagnosis. Young children with acute EBV infection are more likely to have hepatosplenomegaly, rash, and eyelid edema than are young adults.

The diagnosis of EBV infection in older children focuses on the characteristic clinical syndrome and a relative lymphocytosis of 40-50% seen in the differential white blood cell count, with up to 10-20% atypical lymphocytes. Heterophile immunoglobulin M (IgM) antibodies, which are non-EBV directed and agglutinate sheep and horse red blood cells, are found in more than 80% of young adults with EBV and are at maximal titer 3-4 weeks after infection. Heterophile antibodies are rarely found in children younger than 5 years with EBV infections. In young children, antibody titers directed to specific EBV antigens are necessary to confirm the diagnosis (Table 36.5). IgM antibodies against viral capsid antigen (VCA) followed by immunoglobulin G (IgG) directed to VCA and early antigens (EAs) are the most common antibody profile. Antibodies to nuclear antigens develop

FIGURE 36.7 Suppurative lymphadenitis in a 5-year-old female with neck swelling and redness. Contrast-enhanced computed tomography image reveals a group of enlarged nodes in the right posterior triangle with central hypoattenuating necrosis *(arrow)*. Also, note the enlarged tonsils (T) in this child with recurrent tonsillitis. (From Lowe LH, Smith CJ. Infection and inflammation. In: Coley BD, ed. *Caffey's Pediatric Diagnostic Imaging*. 12th ed. Philadelphia: Elsevier; 2013;1:139.)

FIGURE 36.8 The clinical course of acute Epstein-Barr mononucleosis. Adenopathy occurs early in the infection and can persist for weeks. (Modified from Rapp CE, Hewston JF. Infectious mononucleosis and the Epstein-Barr virus. *Am J Dis Child*. 1978;132:78.)

TABLE 36.5	Frequently Determined EBV-Specific Antibodies			
Antibody Specificity	**Positive in IM (%)**	**Time of Appearance in IM**	**Persistence**	**Comments**
Viral Capsid Antigen				
VCA-IgM	100	At clinical presentation	4–8 wk	Highly sensitive and specific; of major diagnostic utility
VCA-IgG	100	At clinical presentation	Lifelong	Useful for documentation of past EBV infection
Early Antigen				
Anti-Diffuse	70	Peaks 3–4 wk after onset	3–6 mo	Correlates with disease severity; seen in NPC patients
Anti-Restricted	Low	2 wk to several months after onset	2 mo to >3 yr	Occasionally seen with unusually severe cases; seen in African Burkitt lymphoma patients
EBNA	100	3–4 wk after onset	Lifelong	Presence excludes primary EBV infection

EBNA, EBV nuclear antigen; EBV, Epstein–Barr virus; IM, infectious mononucleosis; NPC, nasopharyngeal carcinoma; VCA, viral capsid antigen.
Modified from Schooley RT. Epstein-Barr virus (infectious mononucleosis). In: Mandell GL, et al., eds. *Principles and Practice of Infectious Diseases*. Philadelphia: Churchill Livingstone; 2010.

weeks later and, if present with EA IgG, are indicative of infection in the recent past. Approximately 20% of children present after the VCA IgM has already declined. In these children, VCA and EA IgG are present.

Organ transplant and other immunosuppressed patients may develop a **lymphoproliferative syndrome** due to EBV that presents with generalized lymphadenopathy, hepatosplenomegaly, and fever. Diagnosis is based on the EBV viral load determined by PCR on blood.

Because group A streptococcal infection can present in a similar manner, or be present simultaneously with EBV infection, and because other viruses can cause pharyngitis and tender, enlarged cervical lymph nodes, differentiating these various causes of pharyngitis and lymphadenopathy is important. Acute streptococcal pharyngitis improves after institution of penicillin therapy; EBV infections do not, and they also have a more prolonged clinical course. In addition, severe malaise and splenomegaly do not occur with most bacterial or viral causes of pharyngitis and cervical lymphadenopathy. These findings prompt the clinician to consider EBV infection. Similarly, most viral causes of cervical adenopathy and pharyngitis, with the exception of CMV, are not associated with the brisk atypical lymphocytosis commonly seen with EBV infections, and they are not usually associated with abnormal liver function results.

Cytomegalovirus infection. Infection with CMV in children can be associated with a mononucleosis-like syndrome and lymphadenopathy. CMV mononucleosis is associated with fever and malaise similar to that seen in EBV; however, in contrast to EBV, CMV mononucleosis does not usually cause severe, exudative tonsillopharyngitis or the production of heterophile-specific or EBV-specific antibodies. CMV mononucleosis can be associated with an atypical lymphocytosis and diffuse lymphadenopathy in the immunocompetent host. Women who are pregnant when they have primary CMV infections are at risk of delivering a child with congenital CMV infection through transplacental infection; approximately 10% of these neonates will have severe systemic findings. Lymphadenopathy may be present in congenital CMV but is not a common finding. Intrapartum transmission via cervical secretions or postpartum transmission via breast milk typically does not result in clinically apparent infection. Identifying CMV in the urine of the neonate in the 1st week of life confirms congenital infection.

The diagnosis in older children is usually made serologically, in tests measuring both IgM and IgG antibodies directed to CMV. Viral culture and nucleic acid amplification assays can also identify CMV from blood, throat swab, and urine specimens. Although CMV culture (especially from the urine) is frequently positive in children with CMV infection, many children, especially those in daycare, are silently infected and excrete CMV in absence of clinical signs and symptoms. Therefore, CMV culture is less useful in the toddler age group.

Cat-scratch disease. Cat-scratch disease is caused by a small gram-negative bacillus, *B. henselae*, which can also cause bacillary angiomatosis in patients with HIV infection. Cat-scratch disease occurs several days after the scratch or bite of an infected cat or kitten. A papule at the site of the trauma usually develops, followed 1-3 weeks later by regional lymphadenopathy; there is no lymphangitis. Most patients with cat-scratch disease have a single enlarged, usually non-suppurative lymph node. Nodes may be tender, particularly in the 10-30% that suppurate. Axillary nodes are the most common to be enlarged, likely secondary to the upper extremities being the part of the body most frequently scratched or bitten. The next most common sites for adenopathy are the neck and jaw, followed by the inguinal region. Although single nodes are most commonly affected, regional adenopathy may also occur. Generalized lymphadenopathy is unusual in the immunocompetent host.

Approximately half the patients have low-grade fever and malaise, but a small number have high fevers (>39.5°C) and more severe systemic symptoms. In most patients, the swollen, inflamed nodes regress spontaneously within several weeks; approximately 10-30% progress to have purulent fluid drainage that is culture-negative by standard techniques. Uncommon complications include a spontaneously resolving encephalopathy, erythema nodosum, oculoglandular syndrome of Parinaud (in which *B. henselae* is inoculated into the eye and causes conjunctivitis and preauricular adenopathy), thrombocytopenia, hepatitis or splenitis with granulomas, transverse myelitis, and in rare cases osteolytic bone lesions. Other causes of **oculoglandular syndrome** include tularemia, adenoviruses, and enteroviruses.

The diagnosis is based on the history of contact with kittens or cats and the classic clinical manifestations, including a careful search for an entrance site papule. Confirmatory testing is difficult, as *B. henselae* is a fastidious organism and is difficult to isolate via conventional culture techniques. Acute and convalescent antibody titers are typically employed, though the clinician should exercise caution in interpretation given the high rate of seroprevalence in the general population and the potential for cross-reactivity with other infections. Pathologic samples of tissue from the involved node may provide further evidence if they demonstrate granulomas, central necrosis, and organisms on Warthin–Starry silver stain. The decision to perform a biopsy is usually reached when there is no clear history of a preceding contact with a cat or kitten, or when the presentation is atypical and cannot be differentiated from other, more serious illness, such as mycobacterial adenitis.

Chronic granulomatous disease. Chronic granulomatous disease (see Chapter 41) comprises a group of rare inherited disorders of neutrophil function, characterized by recurrent pyogenic infections that are often accompanied by lymphadenopathy and/or abscess formation. Most cases are inherited in an X-linked manner; 30% are autosomal recessive. Chronic granulomatous disease should be considered in a young child (often a boy) who presents with recurrent fevers and infection, pneumonia, adenopathy, and abdominal pain. Family history often reveals another relative with the disease or recalls a death from an infection in a young child. Common pathogens contain catalase and include *S. aureus* and *Aspergillus* species.

The diagnosis is made by performing neutrophil function tests, such as dihydrorhodamine or nitroblue tetrazolium testing, which demonstrate the defective neutrophil oxidation. Positive findings on neutrophil function tests are confirmed via immunoblot or genetic assays.

Human immunodeficiency virus. Initial infection with HIV may manifest as a heterophile-negative mononucleosis-like syndrome that is an acute retroviral syndrome consisting of diffuse lymphadenopathy, fever, sore throat, rash, myalgias, diarrhea, leukopenia, thrombocytopenia, and general malaise. Many patients with HIV infection go on to have weight loss or poor weight gain and a history of thrush and opportunistic infections, such as pneumonia caused by *Pneumocystis jirovecii*. HIV-infected children are also more likely than immunocompetent hosts to have other infectious causes of lymphadenopathy, such as tuberculosis, atypical mycobacterium, CMV, fungi, or noninfectious causes, such as lymphoma or Kaposi sarcoma (human herpesvirus type 8 [HHV-8]). *Regional* lymphadenopathy is not a common manifestation of HIV infections unless the regional adenopathy represents a distinct focal infection. HIV infection is typically established via a rapid antibody assay that if positive is confirmed via Western blot; the early, acute, retroviral syndrome is diagnosed by viral RNA or DNA load because antibodies may not be present with early infection.

Mycobacterial infections. Tubercular cervical adenitis is not common in the United States, though can be associated with ingestion

(See *Nelson Textbook of Pediatrics,* p. 1590.)

(See *Nelson Textbook of Pediatrics,* p. 1423.)

of raw, contaminated milk and infection with *M. bovis*. Regional or diffuse lymphadenopathy caused by infection with *M. tuberculosis* is also unusual in developed countries; it is increasing in frequency in children in the United States as a result of an increase in the number of adults actively infected with tuberculosis. This increase is attributable to several issues, including immigration from endemic areas, reduction in tuberculosis control programs, the likelihood of HIV-infected individuals to have a high mycobacterial burden, noncompliance by infected individuals with multidrug treatment regimens, and drug resistance by the organism. Most adenitis caused by mycobacteria in the United States is caused by atypical strains that are not serious pathogens in the immunocompetent host.

Several historical and clinical criteria can be used to differentiate tuberculous adenitis from atypical mycobacterial infections. Most children with tuberculosis have a history of exposure to an adult with active tuberculosis. Infection with atypical mycobacteria is more common in the southern parts of the United States. Children with tuberculous adenitis may have hilar lymphadenopathy because the lungs are usually the source of primary infection. Evidence of extralymphatic disease is also common in children with tuberculosis; such disease includes pneumonia, pleural effusions, bone marrow suppression, liver function abnormalities, and miliary disease. Disseminated (miliary) tuberculosis may manifest with diffuse lymphadenopathy and should be considered if pulmonary infiltrates and systemic symptoms are present. Such extralymphatic disease and diffuse lymphadenopathy are rare in immunocompetent children with adenitis caused by atypical mycobacteria but may occur in the setting of HIV infection.

The most common mycobacterial infection in children in the United States is the infection of the lymph nodes with the atypical mycobacteria, primarily *M. avium-intracellulare* complex, *M. kansasii*, *M. scrofulaceum*, and *M. marinum*. The lymph nodes involved are usually tender, unilateral and cervical in most infections, presumably because the organism enters via the oropharynx. Most frequently, a previously healthy child presents with a mass that is really unilateral lymphadenitis or adenopathy in the cervical, submandibular, or submaxillary region (Fig. 36.9). Although fever may be present, other significant systemic symptoms are usually not present. In a small number of patients, the affected node spontaneously ruptures and drains before the visit to the physician. The drainage is not usually grossly purulent and may be a clue that atypical mycobacteria are the cause of the infected node. Regional adenopathy may also be seen after immunization with bacille Calmette-Guérin (BCG) vaccine.

The gold standard for diagnosis of lymphadenitis caused by atypical mycobacteria is acid-fast staining and culture of the excised node. Incision and drainage or needle aspiration of these nodes may lead to chronically draining sinus tracts, which may leave scars; thus, this method is contraindicated. Fine-needle aspiration may be beneficial. The usual scenario involves a young, preschool-aged child with an enlarged cervical node that responds poorly to antibiotics. The child has no history of contact with cats and is otherwise well. A tuberculin skin test often yields 5-9 mm of induration because atypical mycobacteria have antigens cross-reactive to those of tuberculosis. This amount of induration is considered indeterminate for tuberculosis in low-risk patients and suggests that the adenopathy is caused by an atypical mycobacterium. Skin tests with antigens from the various atypical mycobacteria are very sensitive and specific for infection; however, these antigens are not consistently available. In rare cases, infection with atypical mycobacteria yields skin test results in the positive range of more than 15-mm induration, which mandates a more extensive work-up that focuses on the possibility that the adenitis is caused by

FIGURE 36.9 Nontuberculous mycobacterial infection in a 10-year-old male with left neck swelling. Axial contrast-enhanced computed tomography image shows a cluster of enlarged nodes in the left neck containing low-attenuation necrotic centers *(arrow)*. (From Lowe LH, Smith CJ. Infection and inflammation. In: Coley BD, ed. *Caffey's Pediatric Diagnostic Imaging.* 12th ed. Philadelphia: Elsevier; 2013;1:139.)

M. tuberculosis infection. **Interferon gamma release assays** will be positive for *M. tuberculosis*, *M. bovis*, and some atypical mycobacterium (*M. marinum*, *M. kansasii*) but will be negative for BCG and infection with *M. avium* complex. Gradual resolution of lymphadenitis sometimes occurs in children with atypical mycobacterial infections. Excisional biopsy is not necessary if the diagnosis is made presumptively from skin test results of less than 10-mm induration, if other infections are ruled out, if resolution occurs, and if the child is at low risk for infection with *M. tuberculosis* (see Chapter 2). If the node does not improve, continues to enlarge, or spontaneously drains, excision is recommended and is usually curative. Fine-needle aspiration (for culture and acid-fast staining) may also be used, if the node is in an area where excision is impractical.

Toxoplasmosis.   *T. gondii* is a protozoan organism that is a parasite of cats. Many other animals, including humans, can be incidentally and chronically infected hosts in which the parasite cannot complete its life cycle. Human acquisition of toxoplasmosis can result from contact with cat feces or soil that contains oocysts, which infect the host upon ingestion. Alternatively, the ingestion of raw or undercooked meat containing tissue cysts, particularly lamb or pork, may lead to infection. Adults in the United States are more likely to be infected from ingestion of raw meat than from contact with oocysts in cat feces or soil. Finally, infection can be transmitted to the fetus, especially when a pregnant woman is acutely infected with toxoplasmosis. Although many fetal infections are asymptomatic, transplacental infection with toxoplasmosis can result in severe neurologic damage, chorioretinitis, aseptic meningitis, and significant systemic illness manifesting with the classic triad of hepatosplenomegaly, intracranial calcifications, and hydrocephalus. Although lymphadenopathy can occur in the newborn

with congenital toxoplasmosis, it is a more common symptom of acute toxoplasmosis in older children and young adults.

The most common symptoms in children who acquire toxoplasmosis are lymphadenopathy, fever, malaise, myalgia, and pharyngitis. The most commonly affected nodes include the anterior and posterior cervical and axillary, which may be tender; involvement is usually bilateral. The lymph node enlargement seen in toxoplasmosis is caused by reticular hyperplasia and inflammation. Most laboratory results are normal, but the white blood cell count may show an absolute lymphocytosis with atypical lymphocytes, which can cause confusion with EBV, HIV, or CMV mononucleosis.

The diagnosis is made primarily with serologic studies. Various diagnostic techniques can be used on the patient's serum, including indirect immunofluorescence, complement fixation, and enzyme-linked immunosorbent assay. A 4-fold rise in IgG titer or the presence of IgM antibodies is diagnostic. In neonatal infections, tests measuring IgM have become more sensitive and specific. If biopsy is performed, actual parasite forms can sometimes be demonstrated. Antigen tests and cultures that grow the parasite are also available but primarily on an investigational level.

Syphilis. Syphilis, caused by the spirochete *Treponema pallidum*, is common in the United States (see Chapter 18). The natural course of noncongenital syphilis includes 3 major clinical manifestations:

- Primary syphilis, in which the individual develops a painless chancre at the site of inoculation
- Secondary syphilis, in which the organism disseminates hematogenously to many organs
- Tertiary syphilis, in which gummatous lesions develop in end organs, such as the brain, heart, and bones

Lymphadenopathy can be seen as 1 of the manifestations of syphilis in several situations. In primary syphilis, in which the inoculation site is usually the genital area, regional lymphadenopathy with painless, firm nodes occurs at the time that a chancre is observed. Thus, inguinal adenopathy in an adolescent who is sexually active mandates further examination and work-up for sexually transmitted infections such as syphilis. In secondary syphilis, the organism has disseminated, causing multiple organs to be involved. The classic manifestations are protean and usually include nonvesicular rashes. Lymphadenopathy, regional or generalized, is common and often includes epitrochlear nodes. Systemic symptoms may include fever, malaise, anorexia, and weight loss. Syphilis therefore should be at the top of the differential diagnosis in sexually active adolescents with rash and lymphadenopathy.

Pregnant women with syphilis who are untreated readily transmit the disease to the fetus, causing congenital syphilis, often with significant sequelae. Infants with congenital syphilis may also have generalized lymphadenopathy, although this finding is less common than other systemic symptoms, such as hepatosplenomegaly, snuffles, and periosteal reactive disease.

The diagnosis has been complicated by the inability to grow the organism in vitro. Dark-field examination of tissue from chancres or mucous lesions shows numerous spirochetes, but dark-field methods are often unavailable to routine laboratories. Serologic study continues to be the primary mode of diagnosis. Nontreponemal serologic studies rely on host production of antibodies to nonspecific lipoidal host tissue antigens that arise as a result of infection with the spirochete. These tests include the Venereal Disease Research Laboratory (VDRL) test, the serologic test for syphilis, and the rapid plasma reagin (RPR) test. Levels of these antibodies decline after adequate treatment and are useful in confirming eradication of the infection. False-positive reactions can occur, particularly in individuals with connective tissue disorders or mononucleosis. In contrast, the fluorescent treponemal antibody absorption test (FTA-ABS) measures antibodies directed specifically to *T. pallidum* and can be used as a confirmatory test in individuals with positive results on screening tests. These antibodies usually remain present for the life of the infected individual, even if the patient receives adequate therapy. Thus, in contrast to the VDRL test, the FTA-ABS has little use in monitoring the efficacy of treatment.

Acute leukemia, lymphoma, and other malignancies. Lymphadenopathy is frequently among the presenting findings in patients with leukemia or lymphoma. Enlarged lymph nodes may be noted in an isolated, regional, or generalized distribution, with or without classic systemic symptoms, such as fever, malaise, night sweats, weight loss, and anorexia. Malignant nodes are usually firm, rubbery, fixed, and nontender, and may be matted. Unlike many of the acute lymphadenopathies caused by infectious agents, most lymph nodes that are malignant increase in size gradually. Additional findings suggestive of malignancy include age >10 years, size >2.5 cm, duration >6 weeks (and increasing in size), and supraclavicular location.

Approximately 50% of children with acute **lymphoblastic leukemia** have adenopathy at the time of diagnosis. Nodal disease may be either generalized or localized to regional nodal groups, often the cervical chains. Nodal disease is frequently accompanied by other signs and symptoms, including fevers, malaise, weight loss, pallor, bone pain, petechiae and bruising, splenomegaly, or hepatomegaly. The complete blood count usually demonstrates anemia, thrombocytopenia, leukocytosis or leukopenia, circulating blasts, or some combination thereof. Some patients may have normal peripheral blood laboratory results on initial evaluation. Acute myelogenous leukemia is less common in children but may manifest in a similar manner. Bone marrow biopsy and aspiration must be performed, and the findings are diagnostic.

Non-Hodgkin lymphoma is a relatively common childhood malignancy and often manifests with mediastinal or pleural disease. Adenopathy in the supraclavicular, cervical, or axillary regions is usually present and may occur in the absence of chest involvement. Systemic symptoms are variable at the time of diagnosis. Lymph nodes, as with other malignancies, tend to be firm, nontender, and rubbery. Their size may increase relatively rapidly over several weeks. Because lymphoblastic lymphoma may represent a variant of acute lymphoblastic leukemia, the signs and symptoms of leukemia and lymphoma may merge. Non-Hodgkin lymphoma of B cell origin (Burkitt and non-Burkitt lymphoma) in children in the United States usually originates in an intraabdominal site, and regional adenopathy, if present, is then in the inguinal or iliac regions. The African variety of Burkitt lymphoma often manifests as an expanding jaw mass.

Hodgkin disease often manifests with painless cervical or supraclavicular lymphadenopathy in older school-aged children and adolescents. Nodes are firmer than those seen in patients whose nodes are enlarged in reaction to infections. In a small number of children with Hodgkin disease, the size of the nodes may wax and wane for several months before a definitive diagnosis is made. Supraclavicular nodes usually indicate intrathoracic disease, which is present in 60-70% of patients at the time of diagnosis. Axillary or inguinal nodes may also be the sites of presenting lymphadenopathy. Approximately 30% of patients with Hodgkin disease have systemic symptoms at presentation, including fatigue, weight loss, fevers, night sweats, and poor appetite. Some patients with Hodgkin disease also have unusual symptoms, such as pruritus, hemolytic anemia, and chest pain after alcohol ingestion. Such systemic symptoms with lymphadenopathy are red flags for immediate work-up for malignancy. Diagnosis is confirmed by biopsy of involved nodes and/or bone marrow aspiration, if the tumor has spread to the bone marrow.

Disseminated neuroblastoma may manifest as diffuse adenopathy in younger children. Such children often have primary adrenal or

paraspinal masses with bone metastasis and have nonspecific systemic symptoms, abdominal mass, bone pain, and sometimes, symptoms of spinal cord compression. Other tumors, such as rhabdomyosarcoma and thyroid cancer, manifest in rare cases with lymphadenopathy caused by local or disseminated metastasis.

Ulceroglandular disorders. Ulceroglandular (lymphocutaneous) disorders usually involve an initial injury or bite to an extremity with a resulting cutaneous lesion (ulcer, eschar, papule) and enlarged regional nodes, with or without lymphangitis (Table 36.6). In some, the cutaneous lesion is secondary to hematogenous spread; in these circumstances the lymph node enlargement may then be generalized (monkeypox).

Kimura disease. Asymptomatic, unilateral, chronic, cervical lymphadenopathy in Asian boys is suspect for Kimura disease. This benign condition is characterized by peripheral eosinophilia and elevated immunoglobulin E levels. Biopsies should be performed to rule out malignancy. Histologic specimens show a massive eosinophilic infiltration of the nodal architecture. This benign condition necessitates no therapy unless the adenopathy creates functional disability.

Kikuchi-Fujimoto disease (histiocytic necrotizing lymphadenitis). Kikuchi-Fujimoto disease (KFD) is a rare, usually self-limiting disease that was originally reported in patients of Asian heritage. Cases are now described in all ethnic groups. KFD occurs in children 11-16 years of age usually as firm unilateral posterior cervical adenitis, fever (30-50%), malaise, elevated erythrocyte sedimentation rate, atypical lymphocytosis, and leukopenia. Nodes range in size from 1-3 cm, are painful or tender in only 50% of cases, may be multiple, and must be differentiated from lymphoma. Node involvement may occasionally be bilateral or present in axillary or supraclavicular regions.

The etiology is unknown, but evidence supports an abnormal immune response; the diagnosis is made by lymph node biopsy. Histologic features include necrosis with karyorrhexis, a histiocytic infiltrate, crescentic plasmacytoid monocytes, and an absence of neutrophils. The disease is self-limiting and usually spontaneously resolves within 6 months, although relapses may occur. Therapy with systemic steroids is reserved for cases with severe symptoms. Many autoimmune diseases have been associated with Kikuchi-Fujimoto disease, most commonly systemic lupus erythematosus.

Sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman disease). This usually self-limited disease is most common in Africa and the Caribbean. Patients have massive bilateral painless and mobile cervical lymphadenopathy with associated fever, leukocytosis, and elevated erythrocyte sedimentation rate; polyclonal elevation of IgG may be present. Night sweats and weight loss are common. Autoimmune hemolytic anemia is an uncommon associated finding.

Other nodal chains may be involved; extranodal involvement occurs in 40% of cases. The most common sites are the skin, followed by the nasal cavity and sinuses, palate, orbit, bone, and central nervous system. Histology demonstrates pale histiocytes containing engulfed lymphocytes, and immunoreactivity to S100 protein in large histiocytes, in conjunction with expected clinical features, is diagnostic.

Castleman disease. Castleman disease is an uncommon lymphoproliferative disease that is also called *angiofollicular lymph node hyperplasia*. There is an association with human herpesvirus 8, which is thought to stimulate excessive production of interleukin 6 (IL-6). The disease is usually seen in adolescents or young adults. Enlargement of a single node, most often in the mediastinum or abdomen, is the most common localized presentation. Some patients may have fever, night sweats, weight loss, and fatigue. Management includes surgery and/or radiation therapy.

Multicentric Castleman disease is a systemic lymphoproliferative disorder that causes lymphadenopathy, hepatosplenomegaly, fever, anemia, overexpression of IL-6, and polyclonal hypergammaglobulinemia. Multicentric Castleman disease may be associated with HIV infection and autoimmune disease–associated lymphadenopathy.

SUMMARY AND RED FLAGS

Lymphadenopathy is a common manifestation of many childhood illnesses. Most often, regional adenopathy is associated with a bacterial infection in the vicinity of the node or with a viral pharyngitis. Generalized adenopathy does not always indicate a serious underlying disease. Adenopathy usually resolves either spontaneously or after appropriate antibiotic therapy. When adenopathy is accompanied by weight loss, recurrent fevers, night sweats, or other systemic signs or symptoms, a more serious cause must be vigorously sought. The presence of supraclavicular nodes is usually a red flag for serious illness.

Adenopathy associated with hepatomegaly, splenomegaly, or an abdominal mass must be quickly investigated. Furthermore, if the adenopathy does not diminish or resolve after antibiotic therapy or after 3 weeks, a more thorough evaluation is necessary. In children with known immunodeficiency, the cause of the adenopathy may be far more serious. These children are more prone to opportunistic infections; malignancies also occur at a higher frequency in immunosuppressed children than in the general population.

Pallor and Anemia

Amanda M. Brandow

INTRODUCTION

Pallor, a perceptible reduction in the usual color and tone of the skin and/or mucosa, may result from alterations of cutaneous blood flow, anemia, or unknown mechanisms. Under normal circumstances the pink appearance of the lips, mucosa, and skin is influenced by the nature and character of these tissues, the adequacy of vascular perfusion, and the level of hemoglobin. Pallor is a highly nonspecific finding that may be a manifestation of a diversity of diseases or it may be normal for a given individual. Parental perception of pallor frequently generates considerable anxiety. Although pallor is most often intuitively associated with anemia by families and physicians, a broad diagnostic perspective is appropriate (Table 37.1). Anemia is the condition in which hemoglobin level (or hematocrit) is more than 2 standard deviations below the mean for age. Anemia is clinically relevant only when the low hemoglobin level results in decreased oxygen-carrying capacity of the blood. By definition, 2.5% of the general population has a hemoglobin or hematocrit level below the defined limits of normal. This fact must be kept in mind when evaluating children with mild anemia for which no explanation can be identified. Hemoglobin level varies considerably with age and sex (Table 37.2). Newborns have relatively high levels of circulating hemoglobin due to intrauterine adaptation to a relatively hypoxic environment. During the 1st 2 months of life, hemoglobin production markedly diminishes and a physiologic nadir occurs. The mean hemoglobin level rises gradually during childhood equally for both boys and girls until puberty when boys achieve a level approximately 20% higher than that of girls. Anemia occurs as the result of 1 or a combination of 3 pathophysiologic mechanisms:

- Acute blood loss
- Impaired bone marrow production of red blood cells (RBCs)
- Increased peripheral destruction of RBCs (hemolysis)

Under normal conditions, the body's RBC mass is maintained at a level appropriate to support tissue oxygen needs through the oxygen-sensing regulatory feedback stimulus of the hormone erythropoietin. Produced in the kidney, erythropoietin stimulates the production of mature RBCs within the bone marrow. Over a 3- to 5-day period, RBC precursors mature into reticulocytes that are released into the peripheral blood. In 24-48 hours, reticulocytes become mature RBCs that circulate in the peripheral blood for approximately 120 days. Senescent RBCs are removed from the circulation by reticuloendothelial cells within the spleen, liver, and bone marrow. A metabolic by-product of hemoglobin catabolism is bilirubin.

◆ History

There are several important aspects of the history that can assist in the evaluation of a patient with pallor and suspected anemia. A child with pallor is not necessarily anemic. Assessment of sun exposure and familial patterns of complexion are crucial because many patients are intrinsically pale. A careful evaluation of the medical history is fundamental in the assessment of a patient with suspected pallor (Table 37.3).

Obtaining a dietary history is very important when evaluating a patient for anemia. Infants delivered prematurely or exclusively breast-fed infants without adequate iron supplementation from infant foods in the 2nd half of their 1st year of life are at risk for iron or iron deficiency anemia. Toddlers who consume large amounts of cow's milk and children and adolescents who consume little meat are also at risk for iron deficiency anemia. In addition, patients and breast-fed infants of mothers who follow a strict vegan diet may become deficient in vitamin B_{12}.

A neonatal history of hyperbilirubinemia supports a possible diagnosis of congenital hemolytic anemia such as hereditary spherocytosis. This can be further supported by a family history of anemia, blood transfusions, splenectomy, and/or cholecystectomy.

Medication history is pertinent because certain drugs, including antimalarial agents and sulfonamide antibiotics, can induce oxidant-associated hemolysis in the patient deficient in glucose-6-phosphate dehydrogenase (G6PD), whereas other medications may cause immune hemolysis (penicillin) or decreased RBC production (chloramphenicol). Travel history may suggest exposure to infections such as malaria.

◆ Physical Examination

The general appearance of the child can provide clues to the severity and chronicity of the problem. Severe anemia that develops slowly over weeks or months is often well tolerated. Vital signs (including orthostatic blood pressure), height, weight, and growth offer further insight into the severity of the problem. Isolated pallor in a well-appearing child who does not have evidence of systemic disease is usually much less ominous than pallor noted in a child who is ill-appearing, has bruising, petechiae, lymphadenopathy, hepatosplenomegaly, or abdominal mass. Pallor at any site increases the likelihood of anemia; pallor of the face, nail beds, tongue, palms and palmar creases as well as conjunctival pallor enhance the likelihood of anemia. Conjunctival rim pallor when compared to the usually more fleshlike pallor of the deeper posterior region of the palpebral conjunctiva is highly specific in adult patients with anemia. Table 37.4 outlines physical examination findings that may provide clues to the underlying cause of the anemia.

Prominent cheekbones, dental malocclusion, and frontal bossing may occur in patients with chronic hemolytic anemias (i.e., thalassemia major) because of the expansion of bone marrow space. Tortuosity of conjunctival vessels occurs in sickle cell disease. Splenomegaly is often present in children with congenital hemolytic anemia. Lymphadenopathy and hepatosplenomegaly may indicate the presence of infiltrative disease of the bone marrow and visceral organs such as

leukemia. Purpura in the anemic child is suggestive of associated thrombocytopenia that may accompany aplastic anemia or leukemia.

Many congenital anomalies and/or dysmorphic features have been associated with hematologic syndromes. Patients with Fanconi anemia are often short, have hyperpigmentation, hypoplastic "finger-like" thumbs, radial bone anomalies, and structural renal abnormalities. Patients with Diamond–Blackfan anemia are often short and have a "curious, intellectual" facial expression.

When pallor and anemia are seen in the context of other signs that suggest chronic inflammation, infection or systemic disease, a diligent general physical examination may yield substantive information. Hypertension and short stature may suggest chronic renal disease. Joint swelling and/or pain may suggest rheumatologic disorders. Digital clubbing may suggest advanced cyanotic cardiopulmonary diseases. Abdominal pain, diarrhea, and poor growth may suggest inflammatory bowel disease.

Recent onset of pallor is suggestive of anemia. The child who has always appeared somewhat pale but is otherwise well with normal growth and development likely has an intrinsic constitutional characteristic. In such instances, the child and other family members often have light hair and skin complexion. An unremarkable general medical history and physical examination support a physiologic explanation for pallor. Some children may appear pale as a result of limited sun exposure as might occur during the winter in cooler climates.

Children with malignant disease or chronic illness (e.g., rheumatologic disorders, inflammatory bowel disease, chronic cardiopulmonary disorders, diabetes) may have a pale appearance that is unrelated or out of proportion to the degree of associated anemia. Atopic children often have distinctly pale mucosa as a result of local edema. Children with generalized edema caused by hypoproteinemia, congestive heart failure, or vasculitis often appear pale as a result of excess interstitial fluid within the mucosal or cutaneous tissues. Patients with hypothyroidism are pale because of myxedematous changes in the skin, subcutaneous tissue, and mucosa.

◆ Laboratory Evaluation

The initial laboratory test in a child with pallor should be a complete blood cell count (CBC) including a manual white blood cell (WBC) differential. Significant pallor from anemia usually does not occur until the hemoglobin level falls below 8 g/dL. "False anemia" (resulting from laboratory error, sampling difficulty, or "statistical anemia") should be

---

TABLE 37.1 Causes of Pallor in Children Based on Etiologic Mechanism

I.   Anemia
II. Decreased Tendency of the Skin to Pigment
  A. Physiologic (fair-skinned individuals)
  B. Limited sun exposure
III. Alteration of the Consistency of the Subcutaneous Tissue
  A. Edematous states, increased intravascular hydrostatic pressure (e.g., congestive heart failure), decreased intravascular oncotic pressure (hypoproteinemia), increased vascular permeability (e.g., vasculitis)
  B. Hypothyroidism
IV. Decreased Perfusion of the Cutaneous/Mucosal Vasculature
  A. Hypotension, cardiogenic shock (pump failure or rhythm disturbance), hypovolemia (blood loss, dehydration), anaphylaxis, sepsis, acute adrenal insufficiency, vasovagal syncope
  B. Vasoconstriction, increased sympathetic activity (hypoglycemia, pheochromocytoma), neurologic complications (head trauma, seizures, migraine)
V.   Chronic Medical Conditions
  A. Malignant disease
  B. Atopy
  C. Chronic inflammatory disease, juvenile idiopathic arthritis, inflammatory bowel disease
  D. Cardiopulmonary disease (including cystic fibrosis)
  E. Diabetes mellitus
  F. Congenital and acquired immunodeficiencies

TABLE 37.3 Historical Clues in Evaluation of Anemia

Variable	Comments
Age	Iron deficiency rare in the absence of blood loss before 6 mo in term or before doubling birth weight in preterm infants Neonatal anemia with reticulocytosis suggests hemolysis or blood loss: with reticulocytopenia it suggests bone marrow failure Sickle cell anemia and β-thalassemia appear as fetal hemoglobin disappears (4–8 mo of age)
Family history and genetic considerations	X linked: G6PD deficiency Autosomal dominant: spherocytosis Autosomal recessive: sickle cell, Fanconi anemia Family member with early age of cholecystectomy (bilirubin stones) or splenectomy: hemolysis Ethnicity: (thalassemia with Mediterranean origin), (G6PD deficiency in blacks, Greeks, and Sephardic Jews) Race: (β-thalassemia in whites; α-thalassemia in blacks and Asians; SC and SS in blacks)
Nutrition	Cow's milk diet and iron deficiency Strict vegetarian and vitamin B_{12} or iron deficiency Goat's milk and folate deficiency Pica: plumbism and iron deficiency Cholestasis: malabsorption and vitamin E deficiency
Drugs	G6PD-susceptible agents Immune-mediated hemolysis (e.g., penicillin) Bone marrow suppression Phenytoin: increases folate requirements
Diarrhea	Malabsorption of vitamins B_{12} and E and iron Inflammatory bowel disease and anemia of chronic disease or blood loss Milk protein allergy-induced blood loss Intestinal resection and vitamin B_{12} deficiency
Infection	*Giardia* and iron malabsorption Intestinal bacterial overgrowth (blind loop) and vitamin B_{12} deficiency Fish tapeworm and vitamin B_{12} deficiency Epstein–Barr virus, cytomegalovirus and bone marrow suppression *Mycoplasma* and hemolysis Parvovirus and bone marrow suppression Chronic infection Endocarditis Malaria and hemolysis Hepatitis and aplastic anemia

G6PD, glucose-6-phosphate dehydrogenase.

considered whenever a child is said to be anemic and laboratory findings are not consistent with clinical impressions. Capillary blood sampling can be associated with substantial error, depending on the difficulty in performing the procedure and the use of mechanical force necessary to promote blood flow. When laboratory or sampling errors are suspected, a venipuncture sample should be obtained for confirmation. By definition, 2.5% of the general population has hemoglobin levels below the lower limit of normal, which is termed "statistical anemia." This phenomenon should be considered when mild, unexplained normocytic anemia is identified in a healthy child.

Almost all laboratories perform CBCs with automated technology systems. Hemoglobin level (grams per deciliter), RBC count (cells per cubic millimeter), and mean corpuscular volume (MCV) (expressed in femtoliters [fL]) are directly measured. Hematocrit value, mean corpuscular hemoglobin (MCH), and MCH concentration (MCHC) are derived values and therefore are less accurate. Other important information reported includes RBC distribution width (RDW), WBC count (cells per cubic millimeter), and platelet count. In addition to the hemoglobin values, careful attention should be given to the MCV, RDW, RBC morphology, platelet count, and WBC count.

CLASSIFICATION OF ANEMIA

Reticulocyte Count

The reticulocyte count, reported as a percentage of total RBCs, is essential in categorizing anemia. An elevated reticulocyte count implies a bone marrow response to either increased RBC destruction (hemolysis) or acute or chronic blood loss. In cases of acute blood loss, there is an average delay in bone marrow response of 3-4 days. Thus, in the setting of acute blood loss, the reticulocyte count is most helpful when the bleeding and subsequent anemia have been present for more than a few days.

Anemias are categorized on the basis of the adequacy of the reticulocyte response. The reticulocyte count is expressed as a percentage of the total number of RBCs. In the setting of a normal hemoglobin, the reticulocyte count is about 1-2%. In patients with moderate or severe anemia, the reticulocyte count may appear elevated, but in absolute terms, it may be insufficient for the degree of anemia. Therefore, the reticulocyte count must be corrected using the following formula:

$$\text{Corrected reticulocyte count} = \frac{\text{reticulocyte count} \times \text{hemoglobin}}{(\text{normal hemoglobin for age})}$$

If the corrected reticulocyte count is greater than 2%, then the bone marrow is producing RBCs at an accelerated pace (Fig. 37.1).

Red Blood Cell Size

The MCV is vital to the classification of anemia. High MCV is termed *macrocytosis,* and low MCV is termed *microcytosis.* Normal standards for MCV are age related; a simple guideline is that the lower normal limit of MCV for children older than 6 months is 70 fL plus the patient's age in years until the adult standard of 80-100 fL is reached (Table 37.2). The MCV must always be interpreted in conjunction with a review of the peripheral blood smear, RDW, and reticulocyte count. A varied population of both smaller and larger RBCs (e.g., reticulocytes) may yield a falsely normal MCV and be diagnostically misleading. A high RDW in the setting of a normal MCV is a clue that 2 populations of RBCs exist. Microcytosis is associated with iron deficiency, thalassemia, and long-standing anemia of inflammation (Table 37.5). Macrocytosis, an unusual finding in children, is associated with vitamin B_{12} or folate deficiency, bone marrow failure syndromes (Fanconi anemia, Diamond–Blackfan anemia), and some cases of hypothyroidism (Table 37.5).

An individual with small RBCs may have a normal or near-normal hemoglobin level if the RBC count is increased as occurs in patients with thalassemia minor who often have RBC counts of more than 5×10^6. The MCHC reflects the level of hemoglobin per cell and would be expected to be low in patients with anemias in which RBCs are "underhemoglobinized," such as the hypochromic anemia of iron deficiency.

The RDW is derived from the histogram of RBC volumes. A normal RDW (11.5-14.5%) implies a uniform population of RBCs that are similar in size. In α-thalassemia trait or β-thalassemia trait, a uniform population of small cells exists; hence, the MCV is low and

TABLE 37.4	Physical Findings in the Evaluation of Anemia	
System	**Observation**	**Significance**
Skin	Hyperpigmentation	Fanconi anemia, dyskeratosis congenita
	Café-au-lait spots	Fanconi anemia
	Vitiligo	Vitamin B_{12} deficiency
	Partial oculocutaneous albinism	Chèdiak–Higashi syndrome
	Jaundice	Hemolysis, hepatitis
	Petechiae, purpura	Bone marrow infiltration, autoimmune hemolysis with autoimmune thrombocytopenia, hemolytic uremic syndrome
	Erythematous rash	Parvovirus, Epstein–Barr virus
	Butterfly rash	SLE
Head	Frontal bossing	Thalassemia major, severe iron deficiency, chronic subdural hematoma
	Microcephaly	Fanconi anemia
Eyes	Microphthalmia	Fanconi anemia
	Retinopathy	Hemoglobin SS, SC disease
	Optic atrophy, blindness	Osteopetrosis
	Blocked lacrimal gland	Dyskeratosis congenita
	Kayser–Fleischer ring	Wilson disease
	Blue sclera	Iron deficiency
Ears	Deafness	Osteopetrosis
Mouth	Glossitis	Vitamin B_{12} deficiency; iron deficiency
	Angular stomatitis	Iron deficiency
	Cleft lip	Diamond–Blackfan syndrome
	Pigmentation	Peutz–Jeghers syndrome (intestinal blood loss)
	Telangiectasia	Osler–Weber–Rendu syndrome (blood loss)
	Leukoplakia	Dyskeratosis congenita
Chest	Shield chest or widespread nipples	Diamond–Blackfan syndrome
	Murmur	Endocarditis; prosthetic valve hemolysis
Abdomen	Hepatomegaly	Hemolysis, infiltrative tumor, chronic disease, hemangioma, cholecystitis
	Splenomegaly	Hemolysis, sickle cell disease (early), thalassemia, malaria, lymphoma Epstein–Barr virus, portal hypertension, hemophagocytic syndromes
	Nephromegaly	Fanconi anemia
	Absent kidney	Fanconi anemia
Extremities	Absent thumbs	Fanconi anemia
	Thenar eminence hypoplasia; triphalangeal thumb	Diamond–Blackfan syndrome
	Spoon nails	Iron deficiency
	Beau line (nails)	Heavy metal intoxication, severe illness
	Mees line (nails)	Heavy metals, severe illness, sickle cell anemia
	Dystrophic nails	Dyskeratosis congenita
	Edema	Milk-induced protein-losing enteropathy with iron deficiency, renal failure
Rectal	Hemorrhoids	Portal hypertension
	Heme-positive stool	Intestinal hemorrhage
Nerves	Irritable, apathy	Iron deficiency
	Peripheral neuropathy	Deficiency of vitamins B_1, B_{12}, and lead poisoning
	Dementia	Deficiency of vitamins B_{12} and E
	Ataxia, posterior column signs	Vitamins B_{12} and E deficiency
	Stroke	Sickle cell anemia, paroxysmal nocturnal hemoglobinuria

SLE, systemic lupus erythematosus.
Modified from Scott JP. Hematology. In: Behrman RE, Kliegman RM, eds. *Nelson Essentials of Pediatrics*. 2nd ed. Philadelphia: WB Saunders; 1994:520.

the RDW is normal or minimally elevated. An elevated RDW is seen in iron deficiency where the population of small cells is variably sized; hence, the MCV is low and the RDW is elevated. In some hemolytic anemias the RDW is elevated because of the presence of large reticulocytes (Table 37.6). An elevated RDW in the setting of a normocytic anemia suggests 2 populations of RBCs, namely large cells (elevated MCV) and small cells (low MCV) and is concerning for a combined anemia (i.e., concomitant iron deficiency and vitamin B_{12} or folate deficiency).

Red Blood Cell Morphology

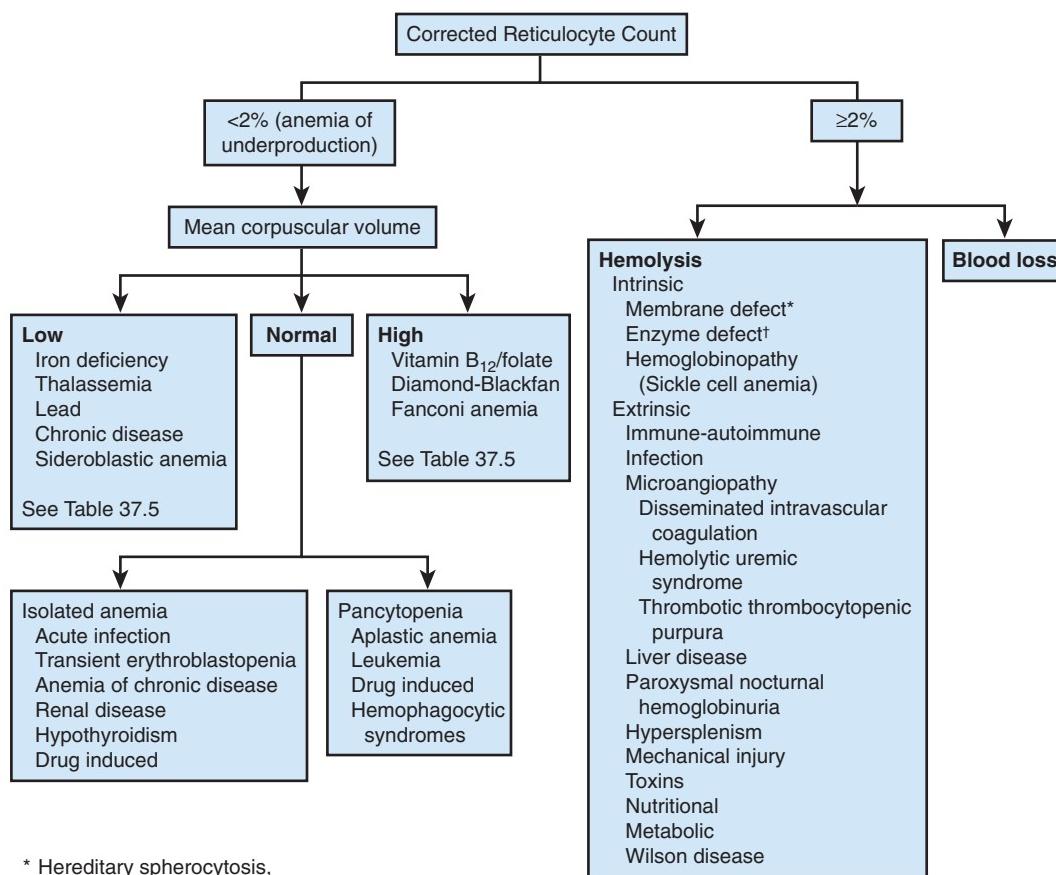
Abnormalities of RBC structure may be readily apparent on inspection of the peripheral blood smear and provide helpful diagnostic hints (Table 37.7 and Fig. 37.2).


FIGURE 37.1 Diagnostic approach to anemia.

Other Laboratory Abnormalities Associated with Anemia

Evaluation of the WBC count, differential, and platelet count is imperative in the setting of anemia. For example, leukopenia, neutropenia, and/or thrombocytopenia occurring in a patient with anemia of underproduction are suggestive of aplastic anemia or infiltrative bone marrow disease such as leukemia. The presence of immature leukocytes on a smear associated with either a high or a low WBC count is suggestive of leukemia. Thrombocytosis may be present in patients with iron deficiency, blood loss, inflammatory disease, infection, malignancy, or asplenia.

Elevated serum indirect bilirubin, lactate dehydrogenase, and urinary urobilinogen levels occur in patients with increased rates of RBC destruction (hemolysis). Immune-mediated hemolytic anemia should be suspected when anemia, jaundice, reticulocytosis, splenomegaly, and microspherocytes are noted. To investigate the underlying cause of the hemolysis, a direct Coombs test should be performed to detect the presence of an autoantibody on the RBC surface. A low serum iron level, elevated total iron-binding capacity, and a low percentage of iron saturation (% saturation = serum iron/total iron-binding capacity × 100) and/or decreased serum ferritin level are helpful in establishing a diagnosis of iron deficiency. Hemoglobin identification via electrophoresis or high-performance liquid chromatography is necessary to identify hemoglobinopathies such as sickle cell disease or thalassemia. Assessment of RBC enzyme levels (e.g., G6PD) may be necessary when infection- or medication-related hemolytic anemia is suspected in a male of Mediterranean or African descent. True macrocytic anemia should prompt assessment for vitamin B_{12} or folate deficiency. Bone marrow aspirate and biopsy should strongly be considered when other cytopenias exist such as thrombocytopenia or neutropenia.

DIAGNOSTIC WORK-UP

From a clinical perspective, it is best to consider the differential diagnosis of pallor in the context of the acuity and severity of the clinical findings (Fig. 37.3). The well-appearing child may only need a CBC to confirm normal counts and provide reassurance. The pale child who appears mildly or moderately ill requires a CBC and other potential studies to detect any suspected underlying disease. The pale child who appears seriously ill requires urgent evaluation and appropriate therapeutic intervention. A CBC should be obtained for all children with other laboratory assessments dictated on the basis of the suspected diagnosis. If hemorrhage or severe anemia is suspected, a type and cross-match must be sent to the blood bank, 2 large intravenous lines

must be secured, and frequent serial evaluations of hemoglobin, blood pressure, pulse, perfusion, and end-organ function must be performed.

DIFFERENTIAL DIAGNOSIS OF ANEMIA

The classification of anemia is presented in Figs. 37.1 and 37.4.

Anemia Secondary to Acute Blood Loss

Significant blood loss on an acute or subacute basis results in anemia. In subacute bleeding, the fall in hemoglobin occurs gradually and a period of about 24 hours may be required for full intravascular equilibration after acute blood loss. When severe acute blood loss occurs,

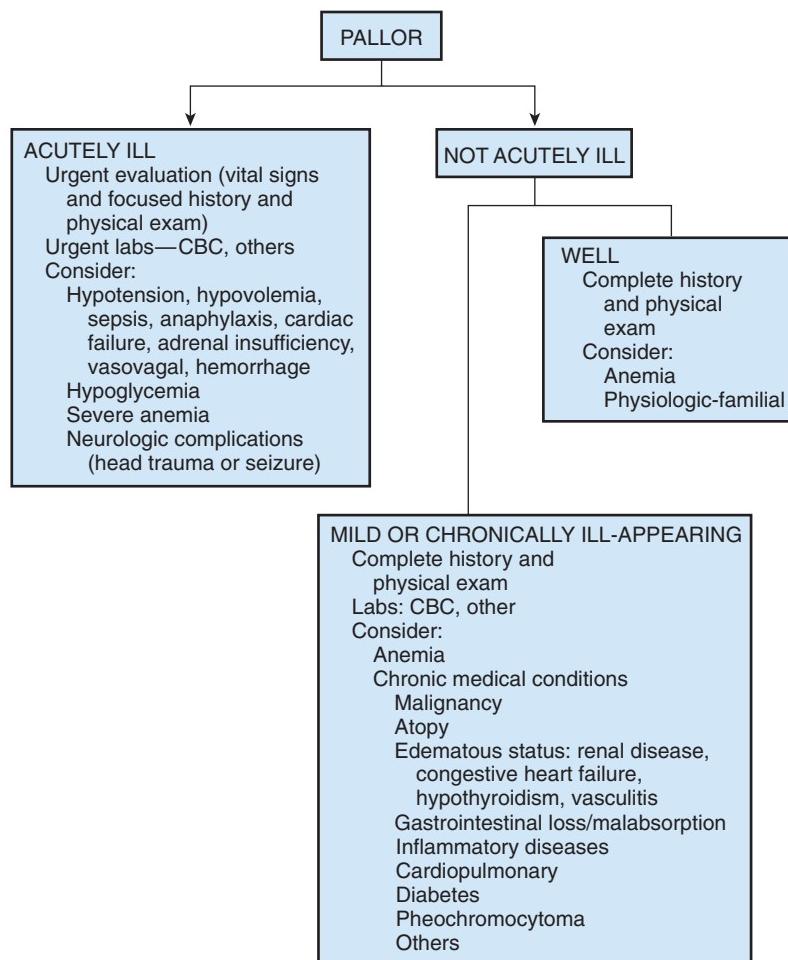
intravascular volume depletion is the primary concern, which cannot be assessed by hemoglobin level. Therefore, in the setting of severe blood loss, blood pressure, heart rate, adequacy of peripheral perfusion, and mental status are the best ways to assess patients. In most instances, an obvious history of blood loss is apparent (epistaxis, hematemesis, lower gastrointestinal bleeding, trauma). In some cases, intraabdominal bleeding can occur that is not clinically apparent. Large amounts of blood may accumulate in the gastrointestinal tract before the development of hematemesis, hematochezia, or melena. Intraabdominal bleeding may occur after trauma or may result from an ulcer (see Chapter 13) and may be associated with progressive anemia in the absence of an obvious source of bleeding. The clinical


FIGURE 37.3 Approach to the pale child. CBC, complete blood count.

history coupled with the physical examination (including rectal examination) and tests for occult blood in the stool generally define the source of blood loss.

In anemia associated with blood loss, the RBC size and morphology are normal and appropriate reticulocytosis should occur within 3-5 days from the start of the blood loss. If hemorrhage has ceased, the hemoglobin level should gradually increase unless supervening factors such as iron deficiency exist.

Severe hemorrhage associated with intravascular volume depletion warrants immediate intervention to avoid shock. RBC transfusions are necessary until hemorrhage has ceased. Less severe hemorrhage that is not associated with intravascular volume depletion will likely manifest with moderate to severe anemia. Transfusions may be necessary when the oxygen-carrying capacity of the blood is diminished to the point of impending tissue hypoxia. In these cases, the need for transfusion therapy is based on clinical symptoms including tachycardia, dyspnea, heart failure, fatigue, or lightheadedness. If hemorrhage has ceased, intravascular volume is replete, and if the patient is not manifesting signs of cardiorespiratory compromise, transfusion therapy can often be avoided. In such instances, it is appropriate to supply therapeutic doses of iron to ensure adequacy of the reticulocyte response (Table 37.8).

Anemia Secondary to Underproduction

Anemia caused by the underproduction of RBCs (see Figs. 37.1 and 37.4) is characterized by a suboptimal bone marrow response to the

---

TABLE 37.8 **Therapy for Iron Deficiency**

Infants and Children

3–6 mg/kg of elemental iron/day, given in divided doses 2 or 3 times/day (mild nutritional anemia deficiency in infants may be treated with a single daily dose of 3 mg/kg before breakfast)

Adolescents

3–6 mg/kg/day of elemental iron (maximum, 200 mg) given in divided doses 2 or 3 times/day

Duration of Prescription

Continue *therapeutic dose* of iron for 2–3 mo after hemoglobin level has been corrected (to replete stores), after which maintenance nutritional needs must be met.

---

anemia reflected by a corrected reticulocyte count of less than 2%. Associated clinical symptoms can provide clues to the etiology of underproduction, especially for nonhematologic causes of anemia. Common nonhematologic causes of underproduction include chronic renal disease, chronic inflammation, or infection. Hematologic causes of underproduction are outlined in subsequent text. Anemia due to underproduction of RBCs should be evaluated in the context of RBC size: microcytic, normocytic, or macrocytic.

I. Acute blood loss with hemodilution

II. Anemia of RBC underproduction (i.e., inadequate reticulocyte count)
   A. Microcytic
      1. Iron deficiency
      2. Lead intoxication
      3. Thalassemia syndromes
      4. Anemia of chronic diseases

   B. Normocytic

1. With pancytopenia
- Aplastic anemia
- Malignant disease (bone marrow infiltration)

2. Isolated anemia
- Anemia of acute inflammation/infection
- Transient erythroblastopenia of childhood
- Renal failure
- Hypothyroidism

C. Macrocytic
- Vitamin B$_{12}$/folate deficiency
- "Stress erythropoiesis"
  - Isolated anemia (Diamond-Blackfan)
  - Pancytopenia-Fanconi or aplastic anemia

III. Anemia due to increased destruction = hemolysis (i.e., adequate reticulocyte count)
   A. Intrinsic RBC defect
      1. Hemoglobinopathies (sickle cell anemia, unstable hemoglobins)
      2. Membrane defects (hereditary spherocytosis, elliptocytosis)
      3. Enzymopathies (G6PD, pyruvate kinase deficiency)

   B. Extrinsic defects
      1. Immune hemolysis
      2. Infection (bacterial, viral, other)
      3. Microangiopathy (disseminated intravascular coagulation, hemolytic uremic syndrome, thrombotic thrombocytopenic purpura)
      4. Liver disease
      5. Paroxysmal nocturnal hemoglobinuria
      6. Hypersplenism
      7. Mechanical injury (e.g., burns)
      8. Toxins
      9. Nutritional (vitamin E deficiency)
     10. Metabolic (galactosemia)
     11. Wilson disease

FIGURE 37.4 Differential diagnosis of anemia. G6PD, glucose-6-phosphate dehydrogenase; RBC, red blood cell.

Microcytic Anemias

Hemoglobin, the chief intracellular component of the RBC, is composed of heme (iron and protoporphyrin IX) and globin chains (α and β). Any factor that diminishes the availability or utilization of these components results in microcytic anemia. The automated MCV represents the mean RBC volume and does not address variations in cell size. The RDW, however, describes variation in RBC size and if normal defines a relatively uniform population of cells. Review of the peripheral blood smear also provides additional evidence regarding variability in cell size and shape. It is important to note that MCV is age related (Table 37.2). Common hematologic causes of microcytic anemia are discussed in subsequent text. When the diagnosis is not immediately apparent, it is helpful to carefully select from a variety of available

laboratory studies to further differentiate the cause of the microcytic anemia (Table 37.9).

Iron deficiency anemia. Iron deficiency is the most common nutritional deficiency that causes anemia. Iron deficiency results when nutritional intake is insufficient to meet demands associated with growth and/or blood loss. Iron is a key component of the hemoglobin molecule; its deficiency leads to anemia associated with reduced hemoglobin production (hypochromia) and small RBCs (microcytosis). Infants are at particular risk for the development of iron deficiency since their rapid growth and expanding blood volume impose considerable iron demands. Premature infants are at the highest risk because most in utero iron is transferred to the fetus during the last trimester of pregnancy and postnatal growth rate is rapid. In addition, exclusively breast-fed infants are also susceptible to iron deficiency in the later months of their 1st year of life if sufficient solid food intake high in iron does not keep up with iron demands. Toddlers are also at high risk for the development of iron deficiency due to excessive cow's milk intake leading to poor iron absorption, decreased intake of dietary sources of iron, and gastrointestinal blood loss from milk protein sensitivity. Thus, appropriate counseling should be provided to the family to ensure that cow's milk is limited to no more than 24 oz/day. Adolescent females are at very high risk due to menstrual blood loss and inadequate nutrition. Risk for iron deficiency is high in adolescent females especially during the 1st year after menarche. *When iron deficiency occurs outside of the setting of infancy, toddlers, or adolescent females a pathologic source of blood loss must be strongly considered and occult gastrointestinal bleeding is an important source to consider as iron deficiency anemia can be the first clue to the presence of inflammatory bowel disease.*

Nutritional sources of iron include iron-fortified infant formula (12 mg/L), iron-fortified infant cereal, beef, fish, and fowl. Ascorbic acid (vitamin C) enhances the absorption of iron. The American Academy of Pediatrics recommends iron-fortified infant formula or breast milk until the age of 1 year and the introduction of iron-rich foods after 6 months of age. Cow's milk is a very poor source of nutritional iron and should not be given to infants less than 1 year of age. After 1 year of age, infants should consume no more than 24 oz/day. Iron supplementation is necessary for preterm infants, most adolescent females, and pregnant women and should be strongly considered for all exclusively breast-fed infants regardless of diet. Iron deficiency must be viewed as a systemic deficiency disorder, only 1 manifestation of which is anemia (Table 37.10).

Iron deficiency is usually detected by routine hemoglobin screening. This should be performed initially in children between 9-12 months of age and again between 18-24 months of age as toddlers are especially vulnerable to iron deficiency anemia during the transition from

TABLE 37.10 **Nonhematologic Consequences of Iron Deficiency**

formula to cow's milk. Adolescent females should be screened 1-2 years after menarche. Laboratory confirmatory studies are necessary when iron deficiency anemia is suspected in patients who are not at high risk for nutritional deficiency or in those in whom anemia is moderately severe (Table 37.9). A serum ferritin level of less than 12 ng/dL or an iron saturation of less than 10% confirms the diagnosis.

Symptomatic iron deficiency is infrequent, but when it occurs, it is generally noted in infants who consume large amounts of cow's milk and have intestinal blood loss as a result of asymptomatic milk protein–induced enterocolitis. Such children may have pallor, irritability, fatigue, glossitis, blue sclera, and in extreme cases signs and symptoms of high-output cardiac failure (dyspnea, diaphoresis, pallor, tachycardia, gallop rhythm, and hepatomegaly). Blood loss may be intermittent; a negative stool test for blood does not rule out the diagnosis. Mild anemia in otherwise well infants between 6-24 months of age, particularly in association with ingestion of large amounts of cow's milk, is most likely caused by iron deficiency.

When mild anemia is detected in the healthy, menstruating adolescent female, chronic blood loss is usually the etiology. Empirical iron therapy is often prescribed in such circumstances (Table 37.8). If the hemoglobin level has normalized after 1 month of therapy, a presumptive diagnosis has been established and the patient should receive an additional 2-3 months of therapeutic doses of iron to replete stores. An appropriate response to iron therapy is the diagnostic "gold standard."

Recurrent iron deficiency anemia in infants and children, despite limitation of cow's milk intake and compliance with supplemental iron, should raise the suspicion for **pulmonary hemorrhage** as a source of chronic blood loss. This condition is called Heiner syndrome and is due to severe cow's milk protein hypersensitivity. Heiner syndrome should be considered when chronic iron deficiency anemia exists with associated cough, wheeze, or diagnosis of "asthma." Chest radiograph reveals pulmonary infiltrates consistent with hemorrhage.

The treatment of iron deficiency anemia is outlined in Table 37.8. Intravenous iron therapy is rarely necessary, although it may be useful in certain situations (iron malabsorption in patients with celiac disease, intestinal bacterial overgrowth syndrome, inflammatory bowel disease, and genetic causes affecting iron absorption; children receiving hemodialysis). The optimal approach to iron deficiency anemia in infants and children is prevention.

Thalassemia syndromes. The thalassemia syndromes represent a heterogeneous group of inherited disorders of decreased globin production that lead to microcytic anemia, which can be mistaken for iron deficiency. The child with microcytic anemia, without evidence of iron deficiency, should be evaluated for thalassemia.

Two genes, one inherited from each parent, code for the production of the β-globin chains of hemoglobin. When 1 gene is affected by the β-thalassemia mutation, a moderate diminution in the production of the β-globin chain occurs, resulting in mild microcytic anemia of underproduction. β-Thalassemia occurs most commonly in individuals of Mediterranean, Asian, or African descent. Patients with **β-thalassemia trait** are asymptomatic and the diagnosis is frequently made when anemia and microcytosis are noted at the time of routine screening for iron deficiency or incidentally when a CBC is obtained for the assessment of acute or chronic symptoms. Typically patients have mild anemia and a low MCV. For an equivalent degree of anemia, the MCV is substantially lower than that seen in iron deficiency.

This phenomenon is reflected in the Mentzer index calculated by dividing the MCV by the RBC count (in millions). The RBC count is usually elevated in thalassemia. Thus, an index of less than 13 is suggestive of thalassemia trait, whereas an index of more than 13 is generally suggestive of iron deficiency anemia. A normal MCV virtually excludes a diagnosis of β-thalassemia. A normal or mildly elevated RDW is usually seen in thalassemia and reflects a relatively uniform population of microcytic RBCs. This is in contrast to iron deficiency wherein the RDW is uniformly elevated reflecting variation in cell size.

The peripheral blood smear demonstrates microcytosis, hypochromia, and target cells. Occasional fragments may be seen. The significance of diagnosing β-thalassemia trait is twofold: (1) its confusion with iron deficiency (hence, patients may be treated unnecessarily with repeated courses of iron and undergo repeated unnecessary blood studies) and (2) its genetic implications. A mating between 2 individuals with β-thalassemia trait carries a 25% risk per pregnancy of offspring with homozygous β-thalassemia (thalassemia major), a severe hematologic disorder. Parents and siblings of a child with a diagnosis of β-thalassemia trait should be appropriately screened and counseled. For purposes of screening, a normal, age-adjusted MCV essentially excludes a diagnosis of β-thalassemia trait.

Homozygous β-Thalassemia, also known as β-thalassemia major or Cooley anemia, results from the inheritance of the β-thalassemia trait mutation from each parent. This results in a severe deficiency of β-globin chain production. Excess α-globin chains precipitate within developing erythroid elements in the marrow and lead to brisk intramarrow destruction of developing erythroid elements (ineffective erythropoiesis). As a result, patients with β-thalassemia major present during infancy at 6-12 months of age with severe anemia and an inadequate reticulocyte count during the time when transition from fetal hemoglobin to adult hemoglobin occurs. The child with β-thalassemia major typically presents with fatigue, irritability, pallor, jaundice, and marked hepatosplenomegaly that is caused by extramedullary hematopoiesis. Frontal bossing and prominent cheek bones (maxillary hyperplasia) may be noted and result from expansion of the marrow space in an attempt to compensate for the severe anemia. Most patients are of Mediterranean or Asian descent.

Laboratory findings include severe anemia and a decreased age-adjusted MCV. The peripheral blood smear is markedly abnormal, demonstrating severely underhemoglobinized RBCs, target cells, and wide variability in cell shape and size (increased RDW). Long-term transfusion therapy sufficient to suppress ineffective erythropoiesis (maintaining hemoglobin level >10 g/dL) may be associated with relatively normal growth, development, and functional capabilities. Long-term iron chelation to prevent iron overload allows for prolonged survival and avoidance of transfusional hemosiderosis (hepatic, endocrine, and cardiac dysfunction). Bone marrow transplantation is curative and a potential treatment option for younger patients who have a human leukocyte antigen–identical healthy sibling or matched unrelated donor.

Four genes code for the α-globin chains of hemoglobin: 2 genes on each chromosome 16. Deletions of 1, 2, 3, or 4 of these genes account

for the variable laboratory and clinical findings associated with the α-thalassemia **syndromes**. Decreased α-globin chain production leads to an excess of β-globin chains, which tend to precipitate within developing RBCs in the bone marrow leading to destruction. Mature RBCs are mildly hypochromic and microcytic and may appear to be targeted.

Deletion of 1 α-thalassemia gene is known as the "silent carrier" state because it is not associated with anemia or microcytosis. This occurs in about 30% of African-Americans as well as individuals of Asian descent.

Deletion of 2 genes represents **α-thalassemia trait**. Such patients manifest mild anemia and microcytosis with MCVs generally in the mildly decreased range (less microcytosis than is generally seen in β-thalassemia trait).

A 3-gene deletion leads to **hemoglobin H disease**, which is associated with moderate hemolytic anemia, microcytosis, reticulocytosis, and splenomegaly.

A 4-gene deletion represents **α-thalassemia major** or hemoglobin Bart's disease, in which the fetus is unable to produce any α-chains. Hence, nearly all in utero hemoglobin is Bart's type (composed of 4 β-chains). Hemoglobin Bart's has an extremely high oxygen affinity and leads to severe tissue hypoxemia and resultant fetal hydrops and death. On occasion, babies with hemoglobin Bart's disease have been saved by extraordinary measures (intrauterine transfusion and early delivery), but they are then committed to lifelong transfusion support and/or bone marrow transplantation.

Hemoglobin H disease and α-thalassemia major occur almost exclusively in individuals of Asian descent. This is because Asians and Africans have different chromosomal arrangements of the abnormal genes. When α-thalassemia minor (2-gene deletion) occurs in the Asian population, deletions may be *cis* (both genes deleted from the same chromosome) or *trans* (each chromosome missing 1 gene). In individuals of African descent, α-thalassemia minor (2-gene deletion) occurs only on the basis of a *trans* distribution; hence, a mating between 2 individuals with the African variety of α-thalassemia trait produces offspring with only 2 α genes deleted (α-thalassemia minor). A mating between 2 individuals of Asian descent who have α-thalassemia minor may produce an offspring with all 4 genes deleted (α-thalassemia major). The implication of a diagnosis of α-thalassemia trait in individuals of African descent usually relates primarily to its confusion with iron deficiency. Individuals of Asian descent must be appropriately counseled regarding the potential for transmission of serious hematologic disease if a mating between 2 individuals with α-thalassemia trait occurs.

Lead poisoning. The occurrence of elevated serum and total body burdens of lead is a major public health problem. This is of particular importance for infants and young children from lower socioeconomic families living in old housing with lead-based paint. Elevated lead levels may decrease erythropoiesis because lead inhibits several enzymes along the path of protoporphyrin synthesis. Lead may also produce hemolysis.

Anemia is usually seen in association with lead levels of 60-70 μg/dL or higher. Anemia is mild, variably microcytic, and associated with prominent basophilic stippling of RBCs. Coexistent iron deficiency is common because iron deficiency promotes increased lead absorption. The presence of mild microcytic anemia in children with mild to moderate lead burdens is usually due to concomitant iron deficiency. Lead chelation therapy is appropriate when lead levels are higher than 40-45 μg/dL. Additional features of marked lead toxicity include intestinal colic, lead lines in long bone radiographs, behavioral changes, renal tubular defects, and lead encephalopathy associated with increased intracranial pressure.

Anemia of inflammation. In a wide variety of chronic inflammatory or infectious disorders, mild to moderate anemia, termed **anemia of inflammation** (previously known as anemia of chronic disease), may be present. The MCV is usually normal to mildly decreased. Chronic inflammation or infection impairs the transfer of iron from reticuloendothelial cells within the marrow to developing erythroid elements. This results in some degree of iron-deficient erythropoiesis despite adequate marrow stores of iron. This impaired transfer of iron is thought to be due in part to the molecule hepcidin that is elevated during times of inflammation. Often the history and physical examination findings point to chronic illness, but occasionally patients have no obvious manifestations of systemic disease. The presence of unexplained normocytic or mild microcytic anemia should alert the clinician to the possibility of occult systemic disease. An elevated erythrocyte sedimentation rate is usually noted in patients with chronic inflammatory or infectious states. Anemia of inflammation is characterized by no specific abnormalities on peripheral smear other than mild hypochromia and microcytosis. Serum ferritin level is often elevated as a result of the inflammatory state and is thus a poor reflection of iron status. Serum iron level and total iron-binding capacity are generally decreased, but the percentage of iron saturation is often within the low to normal range distinguishing it from iron deficiency anemia.

Rare causes of microcytic anemia. **Sideroblastic anemias** are a group of very rare congenital (often X linked) inherited diseases associated with impairment of protoporphyrin synthesis and variable microcytic anemia. The bone marrow examination demonstrates evidence of developing erythroid cells with excess iron deposited in mitochondria that tend to form a circular appearance around the nucleus; hence, the term *ringed sideroblast*. **Copper deficiency** is another rare cause of microcytic anemia. Associated features include neutropenia and scurvy-like bone changes (periosteal elevation). Only under unusual circumstances, when prominent microcytic anemia is otherwise unexplained, should these rare disorders be considered.

Normocytic Anemia Secondary to Underproduction

When normocytic anemia secondary to underproduction is identified in a patient, the key issue is whether anemia is occurring in isolation or is associated with other cytopenias (Table 37.11 and Fig. 37.5; Fig. 37.4). Normocytic anemia with an inadequate reticulocyte response and pancytopenia raises the possibility of serious primary or secondary bone marrow disease (Table 37.11) including malignancy. The history and physical examination findings are often predictive of the presence of thrombocytopenia (easy bruising, petechiae, ecchymosis) and/or neutropenia (fever, signs of infection). Adenopathy and hepatosplenomegaly are suggestive of bone marrow infiltration caused by malignancy.

Acquired aplastic anemia is a rare disorder of childhood characterized by pancytopenia (neutropenia, anemia, thrombocytopenia) and a markedly hypoplastic bone marrow. Clinical manifestations may include pallor, fatigue, purpura, bleeding (cutaneous petechiae and ecchymosis, epistaxis, gingival oozing), and/or recurrent infection. The physical examination may reveal purpura and pale mucosa and skin. Adenopathy and hepatosplenomegaly are not features of this condition. The cause is often obscure but may be related to prior infection (hepatitis, Epstein–Barr virus), toxin exposure (benzene, other volatile compounds), or medications (chloramphenicol, anticonvulsants). Postinfectious, drug-related, or idiopathic acquired aplastic anemia is most likely mediated by immunologic mechanisms. The peripheral blood smear demonstrates normal-appearing RBCs, an absence of polychromasia, and few leukocytes and platelets. The MCV may be elevated. A bone marrow biopsy demonstrates hypoplasia involving all cell lines. Severe acquired aplastic anemia is most appropriately treated by bone

TABLE 37.11 Differentiation of Red Blood Cell Aplasias and Aplastic Anemias

Disorder	Age at Onset	Characteristics	Treatment
Congenital			
Diamond–Blackfan syndrome (congenital hypoplastic anemia)	Newborn–1 mo 90% <1 yr age	Pure red cell aplasia, autosomal recessive, autosomal dominant or sporadic, elevated fetal hemoglobin, fetal i antigen present, macrocytic; some have thrombosis, short stature, webbed neck, cleft lip, triphalangeal thumb; late-onset leukemia	Prednisone, transfusion
Acquired			
Transient erythroblastopenia	6 mo–5 yr 85% >1 yr age	Pure red blood cell defect; no anomalies, fetal hemoglobin or i antigen; spontaneous recovery; normal MCV	Transfusion for symptomatic anemia
Idiopathic aplastic anemia (S/P hepatitis, drugs, unknown)	All ages	All cell lines involved; chloramphenicol, phenylbutazone, radiation	Bone marrow transplantation, antithymocyte globulin, cyclosporine, androgen
Familial			
Fanconi anemia	Before 10 yr; mean, 8 yr	Absent thumbs, cafè-au-lait spots, cutaneous hyperpigmentation, short stature; chromosomal breaks, high MCV and hemoglobin F; horseshoe or absent kidney, leukemic transformation; autosomal recessive trait	Androgens, corticosteroids, bone marrow transplantation
Paroxysmal nocturnal hemoglobinuria	After 5 yr	Initial hemolysis followed by aplastic anemia; increased complement-mediated hemolysis; thrombosis, iron deficiency	Iron, bone marrow transplantation, androgens, steroids
Dyskeratosis congenita	Mean for skin, 10 yr; mean for anemia, 17 yr	Pancytopenia; hyperpigmentation, dystrophic nails, leukoplakia; X-linked recessive; lacrimal duct stenosis; high MCV and fetal hemoglobin	Androgens, splenectomy, bone marrow transplantation
Familial hemophagocytic lymphohistiocytosis	Before 2 yr	Pancytopenia; fever, hepatosplenomegaly, hypertriglyceridemia, CSF pleocytosis	Transfusion (often lethal), VP-16, bone marrow transplantation
Infections			
Parvovirus	Any age	Superimposed on any chronic hemolytic anemia, typically sickle cell; new-onset reticulocytopenia	Transfusion
Epstein–Barr virus (EBV)	Any age; usually <5 yr	X-linked immunodeficiency syndrome, pancytopenia	Transfusion; bone marrow transplantation
Virus-associated hemophagocytic syndrome (CMV, HHV-6, EBV)	Any age	Pancytopenia; hemophagocytosis present in marrow	Transfusion, antiviral therapy, intravenous immunoglobulin

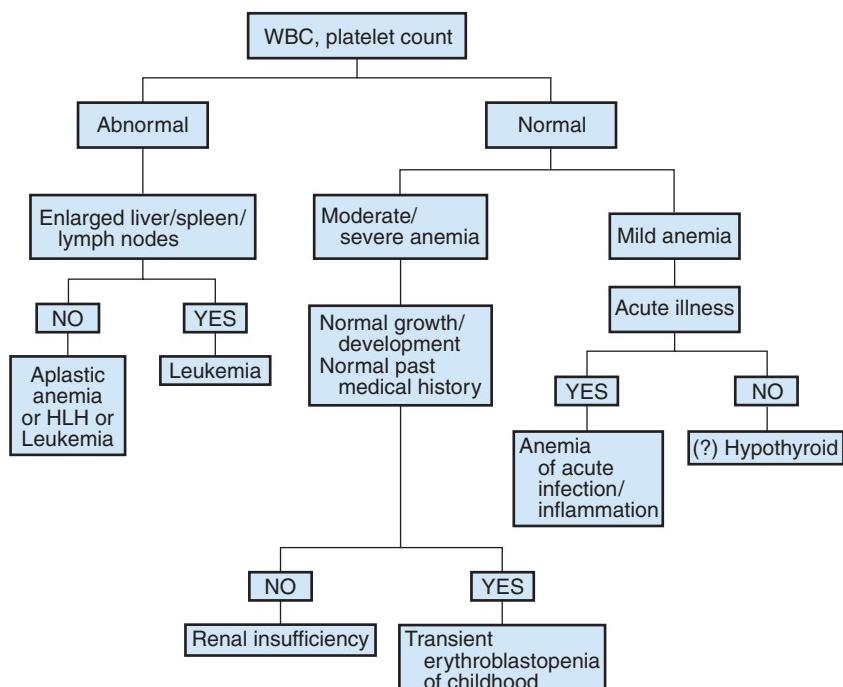
CMV, cytomegalovirus; CSF, cerebrospinal fluid; HHV-6, human herpesvirus-6; MCV, mean corpuscular volume; S/P, status post; VP-16, etoposide. Modified from Scott JP. Hematology. In: Behrman RE, Kliegman RM, eds. *Nelson Essentials of Pediatrics*. 2nd ed. Philadelphia: WB Saunders; 1994:525.


FIGURE 37.5 Diagnostic scheme of normochromocytic anemia of underproduction. HLH, hemophagocytic lymphohistiocytosis; WBC, white blood cell.

marrow transplantation when a human leukocyte antigen–matched sibling marrow donor is available. Unrelated matched donors offer another possibility for bone marrow transplantation. If marrow transplantation is not feasible, immunosuppressive therapies, including anti-lymphocyte globulin, corticosteroids, and cyclosporine, have been used with variable success. Aplastic anemia should always be considered when anemia occurs in association with thrombocytopenia and neutropenia in the absence of adenopathy and hepatosplenomegaly.

Disorders associated with bone marrow infiltration including **leukemia** and **metastatic malignancy** often manifest with normocytic anemia secondary to underproduction, thrombocytopenia, and either neutropenia, or leukocytosis. Teardrop erythrocytes may be present in the peripheral smear. The MCV may be elevated. Many children with leukemia come to medical attention because of pallor, fatigue, and purpura. Limping and skeletal pain are also common with childhood leukemia. Pallor, purpura, adenopathy, and hepatosplenomegaly are often seen on physical examination. Peripheral blood smear may show leukemic blasts. Bone marrow examination findings are diagnostic.

When normocytic anemia secondary to underproduction is isolated without associated thrombocytopenia or neutropenia, several diagnostic entities must be considered. Mild anemia commonly accompanies **acute infections** and inflammatory illness. Children are often incidentally found to be anemic several days to a few weeks after having childhood infectious illnesses including viral upper respiratory tract infections, gastroenteritis, or undifferentiated febrile illnesses. Anemia reflects impaired erythrocyte production as a result of the bone marrow–suppressive mediators of the immune/inflammatory response including interleukins, interferons, and tumor necrosis factor. Cessation of RBC production leads to a fall in hemoglobin level of about 1 g/dL/wk. Mild anemia discovered during or shortly after acute illness does not necessitate an extensive evaluation; rather a follow-up hemoglobin determination should be obtained several weeks later. Persistent anemia necessitates further evaluation.

Transient erythroblastopenia of childhood, occurring predominantly in infants and toddlers, represents a temporary arrest of erythropoiesis that is likely secondary to IgG antibodies that cross-react with early erythroid precursor cells. Infection is thought to be 1 impetus for the development of this condition. Patients present with pallor and fatigue that occurs gradually over several weeks to months. Because of the very gradual fall in hemoglobin, most affected children are remarkably well compensated. Physical examination usually shows only marked pallor and mild tachycardia. Adenopathy and hepatosplenomegaly are not present. Congestive heart failure occurs only if anemia is very severe. The CBC demonstrates a normocytic anemia and profound reticulocytopenia. The WBC and platelet counts are normal in most patients; however, 25% of patients have mild neutropenia at the time of presentation. The peripheral blood smear is unremarkable. Recovery is spontaneous. Blood transfusion is indicated only for patients with severe, symptomatic anemia. Transient erythroblastopenia of childhood may be difficult to differentiate from congenital hypoplastic anemia (Diamond–Blackfan anemia), particularly in children younger than 1 year (Table 37.11). In Diamond–Blackfan anemia, a constitutional RBC aplasia syndrome, MCV and fetal hemoglobin levels are usually elevated for the patient's age providing clues to the diagnosis.

The patient with previously undiagnosed chronic hemolytic anemia (sickle cell anemia, hereditary spherocytosis) may present with normocytic anemia and severe reticulocytopenia if transient RBC hypoplasia occurs on the basis of a viral infection such as commonly seen with parvovirus B19. Because of a shortened RBC life span in patients with chronic hemolysis, a transient arrest of RBC production can cause severe anemia that evolves over several days. Patients may have a history of neonatal jaundice and/or intermittent icterus, and they often have splenomegaly and an abnormal peripheral smear related to the underlying hemolytic disease.

Isolated anemia secondary to underproduction occurs in children with **chronic renal disease** as a result of erythropoietin deficiency. Clinical and laboratory findings often suggest a diagnosis of renal insufficiency such as poor growth, hypertension, edema, abnormal urinalysis, and elevated serum urea nitrogen and creatinine levels. The anemia of chronic renal disease can be successfully treated by recombinant human erythropoietin.

Macrocytic Anemia (Figs. 37.1 and 37.4)

Diamond–Blackfan anemia is a constitutional pure RBC aplasia syndrome that manifests during the 1st year of life with isolated severe anemia and reticulocytopenia (Table 37.11). The remainder of the CBC is unremarkable. Because synthesis of RBCs containing adult hemoglobin is markedly impaired, RBCs generally manifest fetal characteristics, including elevated MCV, increased levels of fetal hemoglobin, and the "i" surface antigen. Bone marrow aspirate demonstrates pure RBC aplasia. Two-thirds of patients with Diamond–Blackfan anemia initially respond to corticosteroid treatment; the remaining patients require long-term transfusion therapy. In patients who initially respond to steroid therapy, the anemia may become refractory over time. Bone marrow transplantation has been curative in selected steroid-resistant patients.

Fanconi anemia usually manifests with macrocytic anemia secondary to underproduction and pancytopenia. It is a constitutional disorder frequently, but not invariably, associated with physical stigmata (Table 37.11). Most patients do not present with overt hematologic manifestations until 4 or 5 years of age. Thumb and radial anomalies should alert the clinician to possible Fanconi anemia even in the absence of cytopenias. RBCs tend to have fetal characteristics including increased MCV and elevated fetal hemoglobin level. Patients usually initially respond to androgen therapy, however, mortality rates are high due to evolving resistance to treatment over time in addition to predisposition to myeloid leukemia and other malignancies. Bone marrow transplantation can be curative based on the hematologic manifestations. Fanconi anemia is among the chromosomal breakage disorders wherein DNA is unusually fragile and susceptible to injury. Thus, the diagnostic laboratory abnormality is an increased chromosomal breakage when cells are cultured in the presence of a clastogenic agent, such as diepoxybutane, commonly known as the DEB test. There are at least 15 genes responsible for Fanconi anemia; sequencing may confirm the diagnosis.

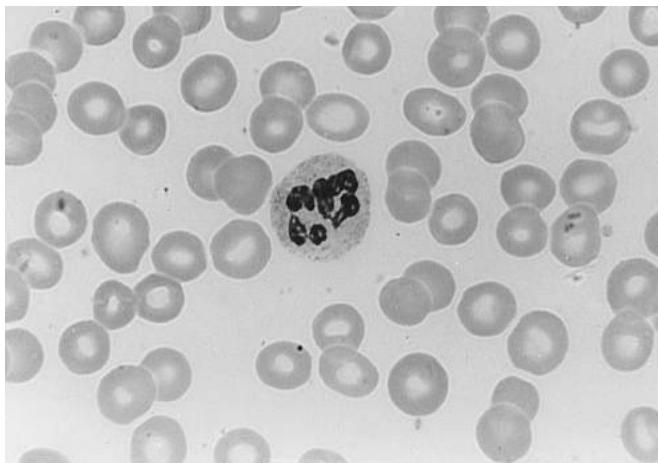
Megaloblastic anemia (vitamin B_{12} deficiency or folate deficiency). Megaloblastic anemia, characterized by macrocytic RBCs with variable abnormalities of WBCs and platelets, is usually caused by vitamin B_{12} deficiency or folate deficiency. Albeit rare in children, it can occur secondary to nutritional or congenital etiologies. If severe, associated pancytopenia can occur. In addition to large ovoid RBCs, hypersegmented neutrophils (more than 5 lobes/cell) are often seen on the peripheral smear (Fig. 37.6); large platelets can be present. It is appropriate to suspect vitamin B_{12} deficiency or folate deficiency in patients with otherwise unexplained macrocytic anemia. Documenting the presence of vitamin B_{12} deficiency or folate deficiency requires an exhaustive etiologic search, including assessment of nutrition and gastrointestinal absorption. Prompt diagnosis of vitamin B_{12} deficiency is imperative due to the associated neurologic manifestations that can occur. Importantly, the degree of anemia can be inversely proportional to the neurologic symptoms; thus, a high index of suspicion is needed in order to not miss the diagnosis. The diagnosis of vitamin B_{12} deficiency and folate deficiency cannot be made solely on the levels of


FIGURE 37.6 Hypersegmented polymorphonuclear leukocyte as seen in vitamin B$_{12}$ deficiency or folate deficiency.

vitamin B$_{12}$ deficiency or folate. The precursors of methylmalonic acid (MMA) and homocysteine must also be evaluated since normal vitamin B$_{12}$ levels can still be associated with vitamin B$_{12}$ deficiency. Elevated MMA despite normal B$_{12}$ levels is diagnostic of B$_{12}$ deficiency. RBC folate and not serum folate should be evaluated to accurately assess folate levels.

Nutritional vitamin B$_{12}$ deficiency may occur in breast-feeding infants of mothers on strict vegetarian diets that exclude milk and egg products.

Congenital pernicious anemia is a rare syndrome associated with vitamin B$_{12}$ malabsorption that is caused by gastric intrinsic factor deficiency. Children who have had resection of the terminal ileum, the site of absorption of vitamin B$_{12}$, may develop megaloblastic anemia. Vitamin B$_{12}$ malabsorption may occur with inflammatory disease involving the terminal ileum such as Crohn disease or ulcerative colitis. Rare congenital disorders that affect vitamin B$_{12}$ transport, absorption, or metabolism can also occur.

Unlike body stores of vitamin B$_{12}$, which may provide several years' reserve, folate stores are limited to several weeks' supply. Folate is ubiquitous in food sources; hence, nutritional deficiency is unusual. Infants fed unsupplemented goat's milk may develop profound folate deficiency. Malabsorption of folate can occur in children who have limited small bowel absorptive capacity as a result of surgical resection or inflammatory disease.

Anemia caused by increased red blood cell destruction. The hemolytic disorders (Figs. 37.1 and 37.4) are characterized by shortened RBC survival and compensatory reticulocytosis. Normal RBCs survive approximately 120 days in the circulation. New RBCs are manufactured at a rate equivalent to the destruction of senescent RBCs so that under normal circumstances an appropriate hemoglobin level is maintained. Intrinsic or extrinsic RBC factors can lead to accelerated RBC destruction. Several clinical and laboratory hallmarks are associated with hemolysis (Table 37.12). It is imperative that a technically adequate peripheral blood smear be examined whenever hemolysis is suspected. Although normal RBC structure does not exclude a diagnosis of hemolytic anemia, most hemolytic diseases are associated with morphologic abnormalities (Table 37.13). Depending on the cause of the hemolysis, RBCs may be removed from the circulation by reticuloendothelial cells (extravascular hemolysis) or may lyse within the circulation (intravascular hemolysis). With intravascular hemolysis, hemoglobin is released into the plasma and bound by the serum protein haptoglobin. In states of brisk intravascular hemolysis,

TABLE 37.13 Hemolytic Anemia: Diagnostic Clues Based on Red Blood Cell Structure

Sickle cells: sickle cell disease
Target cells: hemoglobinopathies (HbC, HbS, thalassemia), liver disease
Schistocytes/burr cells/helmet cells/RBC fragments: microangiopathic hemolytic anemia—DIC, HUS, TTP
Spherocytes: hereditary spherocytosis, autoimmune hemolytic anemia
Cigar-shaped cells: hereditary elliptocytosis
"Bite" cells: G6PD deficiency
Poikilocytosis, microcytosis, fragmented erythrocytes, elliptocytes: hereditary pyropoikilocytosis

DIC, disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase; Hb, hemoglobin; HUS, hemolytic uremic syndrome; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura.

haptoglobin may be depleted and free hemoglobin may be filtered by the kidney resulting in a pink appearance of the urine. A urinary dipstick test result is positive for blood, but the microscopic examination of the urinary sediment does not demonstrate intact RBCs.

Disturbances of any of the 3 key components of the RBC—the membrane, enzymes, and hemoglobin—may lead to ongoing or intermittent hemolysis.

Membrane defects. The prototypic intrinsic membrane defect is **hereditary spherocytosis**, which is an inherited disorder that can be inherited as autosomal dominant or autosomal recessive, or be a new mutation. This disorder occurs in approximately 1/5000 live births. It is seen most typically in individuals of Northern European descent, but may be identified in any population. The basic defect is an abnormality of a membrane protein (spectrin, protein 3, or ankyrin) that allows the RBC membrane to lose its redundancy and the usual biconcave disk shape resulting in a small, dense cell of spheroid configuration (Fig. 37.2D). Hemolysis occurs because the spheroid RBCs are far less distensible and are unable to successfully traverse the microcirculation of the spleen. Characteristic clinical findings include anemia, reticulocytosis, and the presence of abundant microspherocytes on peripheral smear. Associated nonspecific findings of chronic hemolysis are often

present including pallor, icterus, and splenomegaly. The family history is often positive for anemia, splenectomy, or cholecystectomy.

Newborns with hereditary spherocytosis frequently develop jaundice within the first 24 hours after birth necessitating phototherapy and occasionally exchange transfusion. Diagnosis may be confirmed by an osmotic fragility test reflecting the limited capacity of the RBC to expand when incubated in a hypotonic solution. The clinical spectrum of disease is broad. Some patients have mild, well-compensated hemolysis and their condition is detected during their adult years after a diagnosis in 1 of their children. Other patients may have brisk hemolysis during infancy necessitating intermittent transfusion support. Most patients have a disease course characterized by mild to moderate anemia, reticulocytosis, and splenomegaly. Patients are susceptible to exacerbations of anemia as a result of virus-induced hyperhemolysis or transient RBC hypoplasia. Parvovirus B19 may cause superimposed transient RBC hypoplasia of about 1 week's duration, resulting in moderate to severe anemia that requires transfusion.

Hereditary elliptocytosis represents a heterogeneous group of inherited disorders characterized by variable chronic hemolysis and abundant elliptical RBCs on peripheral smear. The clinical and laboratory findings are similar to those seen in hereditary spherocytosis. Splenectomy is appropriate in patients with moderate to severe hemolytic disease.

Hereditary pyropoikilocytosis is an autosomal recessive membrane disorder that manifests in the newborn period and is characterized by marked jaundice and anemia, reticulocytosis, and striking aberrations of RBC structure (Table 37.13). Hemolysis lessens with advancing age.

Enzyme defects. The most common RBC enzyme defect is G6PD deficiency. An X-linked disorder, G6PD deficiency occurs most commonly in individuals of African and Mediterranean descent and should always be considered in the differential diagnosis of acute hemolytic anemia in boys. Deficiency of G6PD activity renders hemoglobin susceptible to oxidant insult leading to precipitation of hemoglobin, membrane damage, and ultimately RBC destruction. Oxidant injury may occur because of intercurrent infection or ingestion of various substances, including medications (i.e., classically sulfa drugs), toxins, and foods such as fava beans (Table 37.14).

The common African variant of G6PD, termed *G6PD deficient variant A−*, is not necessarily associated with chronic hemolysis but usually manifests as mild acute hemolytic anemia related to specific precipitating factors. Rarely is hemolysis sufficiently severe to warrant transfusion therapy. Patients are often incidentally found to be anemic with evidence of an appropriate reticulocyte response. A peripheral blood smear may demonstrate "bite" cells as portions of the RBC (precipitates of hemoglobin) are removed by reticuloendothelial cells (Fig. 37.7). G6PD enzyme assay is necessary for the establishment of a diagnosis, but the test must be performed on a sample that has been depleted of reticulocytes because newly released RBCs have large amounts of G6PD. The Mediterranean variety of G6PD deficiency tends to be more severe and may be associated with chronic hemolysis as well as with superimposed acute events caused by infection or medication leading to symptomatic anemia and the occasional need for transfusion therapy.

Although rare, **pyruvate kinase deficiency (PKD)** is the second most common enzyme deficiency after G6PD deficiency. Inheritance of PKD is autosomal recessive. PKD is characterized by absence of or significantly reduced levels of the intracellular RBC enzyme, pyruvate kinase. Lack of this enzyme leads to decreased levels of ATP and subsequent brisk hemolysis. The clinical spectrum of PKD is variable but can result in severe chronic hemolytic anemia that is present in utero and postnatally. In its most severe form, hemolysis

is extremely brisk, and it is not uncommon for patients with PKD to maintain reticulocyte counts of 40% or higher. Peripheral blood smear may demonstrate spiculated RBCs. Specific enzyme assay can be performed by specialized laboratories to aid in the diagnosis. Patients with PKD usually require lifelong RBC transfusions that often result in transfusional iron overload. Splenomegaly is often present and splenectomy can ameliorate the condition and decrease the number of required transfusions. Patients with PKD are also extremely susceptible to transient RBC hypoplasia caused by parvovirus B19 infection.

Hemoglobinopathies. Hemoglobinopathies usually occur as a result of a single amino acid substitution in α- or β-globin chains.

Hemoglobinopathies are among the most common causes of chronic hemolytic disease. α- and β-Thalassemia syndromes were previously discussed. Sickle cell syndromes are the most frequently encountered hemoglobinopathies.

The sickle hemoglobinopathy syndromes are a group of genetically inherited disorders encountered most frequently in individuals of African descent. Thus, a form of **sickle cell disease** should be considered in the differential diagnosis of anemia in any African-American child. These disorders occur less frequently in individuals of Mediterranean or Arabic background.

Sickle hemoglobin is characterized by a single amino acid substitution of the β-globin chain, namely valine for glutamic acid in the number 6 position. Sickle hemoglobin has a tendency to form insoluble fibers and polymerization within the RBC when deoxygenated. This ultimately leads to the formation of the characteristic crescent-shaped sickled erythrocytes (Fig. 37.8). When sickle hemoglobin trait is inherited from both parents in an autosomal recessive fashion the child has homozygous Hemoglobin SS disease. This is the most severe form of sickle cell disease. Sickle hemoglobin may also be co-inherited with other β-globin gene defects such as hemoglobin C or β-thalassemia and give rise to other heterozygous forms of sickle cell disease that can be less severe than Hemoglobin SS disease. Approximately 1/400 African-Americans has sickle cell disease.

Approximately 8% of African-Americans are carriers of the hemoglobin S gene, which is also termed **sickle cell trait**. Sickle cell trait is rarely associated with clinical disease except under states of unusually severe arterial hypoxemia. Spontaneous hematuria may occasionally occur in sickle trait as a result of the induction of sickling in the extremely hypertonic environment of the renal medulla. Patients with sickle cell trait are distinctly not anemic and have a normal peripheral blood smear.

The diagnosis of sickle cell disease is usually straightforward. Children are variably anemic with reticulocytosis. The peripheral blood smear demonstrates characteristic sickled erythrocytes (Fig. 37.8). The definitive diagnosis must be established by hemoglobin identification methods (Table 37.15). The hemoglobin solubility test (sickle preparation, Sickledex) should not be used to make the diagnosis as false-negative tests can occur. Diagnosis in newborns is routinely and accurately performed in most locations within the United States as a component of state-mandated universal neonatal screening programs.

Sickle cell disease is a multiorgan system disease. The clinical manifestations are extremely broad but generally include (1) chronic hemolytic anemia, (2) vasoocclusion resulting in ischemic injury to tissue, and (3) susceptibility to infection (Table 37.16). Infants younger than 4-6 months usually show no clinical manifestations because of naturally high levels of fetal hemoglobin. By 1-2 years of age, most affected patients have had a specific sickle cell–related manifestation.

Patients may appear variably pale and icteric depending on the degree of hemolysis. Splenomegaly can be seen in children between 6 and 36 months of age in patients with hemoglobin SS disease and may persist into adolescence in some patients with milder variants (SC disease, S-β+-thalassemia). Autoinfarction from microvascular occlusion ultimately leads to fibrosis of splenic tissue by age 3-4 years in most patients with hemoglobin SS disease. Gallstones occur regularly and may lead to symptoms of cholelithiasis, acute cholecystitis, biliary tract obstruction, and/or pancreatitis. Many patients have delayed growth and pubertal development, but ultimately achieve normal adult height. Exacerbation of anemia can occur as a result of infection-induced hyperhemolysis or transient RBC aplasia commonly associated with parvovirus B19 infection. Hyperhemolytic episodes may also occur in male patients with concomitant G6PD deficiency. RBC

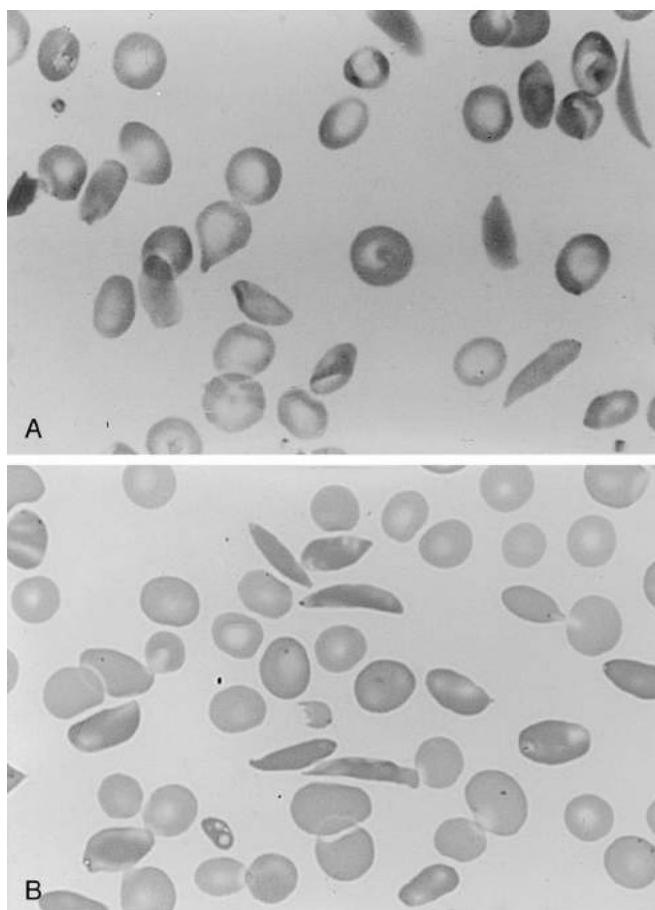

FIGURE 37.8 Sickle cell anemia. *A and B,* Sickled erythrocytes and target cells.

TABLE 37.15	**Hemoglobin Electrophoresis Diagnosis of Sickle Hemoglobinopathy**
Disease	**Hemoglobin Type**
Normal	A
SS disease	S (no hemoglobin A)
S trait	A + S (about equal proportions)
SC disease	S + C (about equal proportions)
S-β-thalassemia	S > A (S predominant hemoglobin)

transfusions are necessary when progressive anemia is accompanied by significant clinical symptoms and definitely in the context of RBC aplasia.

Hemoglobin E is seen with considerable frequency among individuals of Asian descent. Hemoglobin E trait is characterized by mild anemia and mild microcytosis. There are no significant clinical implications. The diagnosis is confirmed by hemoglobin electrophoresis. When hemoglobin E occurs in the double heterozygous state with β-thalassemia, patients often have a moderately severe thalassemic syndrome; hence, genetic counseling is advisable.

Acquired autoimmune hemolytic anemia. This condition may occur as a transient, postviral process or in conjunction with underlying immunologic dysfunction (immunodeficiency, human immunodeficiency virus [HIV] infection, lymphoid malignancy). Hemolysis is usually brisk; thus, most patients are symptomatic and present with pallor, jaundice, fatigue and tachycardia. Splenomegaly is variably

TABLE 37.16 Clinical Manifestations of Sickle Cell Anemia*

Manifestation	Comments
Anemia	Chronic onset, 3–4 mo of age; folate therapy may be required for chronic hemolysis; hematocrit usually 18–26%
Aplastic crisis	Parvovirus infection, reticulocytopenia, acute and reversible
Sequestration crisis	Massive splenomegaly, shock; treat with transfusion
Hemolytic crisis	May be associated with G6PD deficiency
Dactylitis	Hand-foot swelling in early infancy
Painful crisis	Microvascular painful vasoocclusive infarctions of muscle, bone, bone marrow, lung intestines
Cerebral vascular accidents	Large- and small-vessel sickling and thrombosis (stroke); necessitates chronic transfusion
Acute chest syndrome	Infection, infarction, hypoventilation, bone marrow emboli, severe hypoxemia, infiltrate, dyspnea, rales
Chronic lung disease	Pulmonary fibrosis, restrictive lung disease, cor pulmonale
Priapism	Causes eventual impotence; treat with transfusion, oxygen, or corpora cavernosa to spongiosa shunt, local injection of α-adrenergic agents
Ocular	Retinopathy
Gallbladder disease	Bilirubin stones; cholecystitis
Renal	Hematuria, papillary necrosis, renal-concentrating deficit; nephropathy
Cardiomyopathy	Heart failure (fibrosis)
Leg ulceration	Seen in older patients
Infections	Functional asplenia, defects in properdin system; pneumococcal bacteremia, meningitis and arthritis; deafness from meningitis in 35%, *Haemophilus influenzae* sepsis. *Salmonella* and *Staphylococcus aureus* osteomyelitis; severe *Mycoplasma* pneumonia; *Escherichia coli*; urinary tract infection; transfusion-acquired (HIV; hepatitis A, B, C, D and E; EBV; CMV)
Growth failure, delayed puberty	May respond to nutritional supplements
Psychologic problems	Narcotic addiction, dependence unusual, chronic illness

*Clinical manifestations with sickle cell trait are unusual but include renal papillary necrosis (hematuria), sudden death on exertion, intraocular hyphema extension, and sickling in unpressurized airplanes.

CMV, cytomegalovirus; EBV, Epstein–Barr virus; G6PD, glucose-6-phosphate dehydrogenase; HIV, human immunodeficiency virus.

Modified from Scott JP. Hematology. In: Behrman RE, Kliegman RM, eds. *Nelson Essentials of Pediatrics.* 2nd ed. Philadelphia: WB Saunders; 1994:530.

present. The degree of anemia is highly variable, and the reticulocyte count is elevated in most patients; however, a minority of patients present with a low reticulocyte count because of immune destruction of reticulocytes. The peripheral smear demonstrates microspherocytes. The direct Coombs test is positive confirming the diagnosis.

Consideration should be given to evaluating immunologic dysfunction, infection, and malignancy (immunoglobulin [Ig] levels, T and B lymphocyte counts, HIV and Epstein–Barr virus studies, chest radiography). The characteristics of the antibody types are noted in Table 37.17. Warm antibodies (usually IgG) may be idiopathic or associated with lymphoma, HIV or Epstein–Barr virus infections, rheumatologic disorders, or most likely a nonspecific infectious phenomenon. Cold antibodies (usually IgM) may also be seen in response to viral infections, *Mycoplasma pneumoniae* and syphilis infections, or in the context of autoimmune disorders.

Aggressive therapy is recommended because life-threatening anemia is known to occur. Corticosteroids (prednisone) should be administered if the patient is found to have warm autoimmune hemolytic anemia. RBC transfusion should be considered based on the degree of the anemia; however, cross-matching blood is likely to be difficult due to the autoantibody. Intravenous immunoglobulin and high-dose steroids (methylprednisolone) should be considered in severe cases. Frequent hemoglobin monitoring and reticulocyte counts should be done to follow the rate of hemolysis. The role of steroids in the treatment of cold autoimmune hemolytic anemia is less clear and is classically reserved for prolonged cases requiring frequent RBC transfusions. Recombinant antibodies directed to B lymphocytes such as rituximab have been effective in refractory cases.

ANEMIA IN THE NEONATE

Neonatal anemia should be viewed in the context of 3 possible pathophysiologic pathways (Table 37.18): (1) acute blood loss, (2) anemia of underproduction, and (3) anemia associated with increased destruction. Familial genetic disorders may manifest in the neonatal period or any time during infancy (Table 37.19).

The full-term infant has a normal hemoglobin value (hemoglobin, 15-21 g/dL; hematocrit, 45-65%) that is substantially higher than that in older infants and young children. This finding represents a functional adaptation to the relatively hypoxic in utero environment. The reticulocyte count is elevated to about 7-8% during the 1st 3 days of life, after which there is an abrupt cessation of erythropoiesis until 2 months of age, when a physiologic hemoglobin nadir of about 9.5-10 g/dL is reached. This physiologic anemia of infancy is exaggerated in preterm infants whose hemoglobin levels may fall to approximately 7 g/dL at about 1-1.5 months of age. This fall in hemoglobin value represents a physiologic response to the oxygen-rich extrauterine environment.

Neonatal Anemia Caused by Blood Loss

Anemia caused by blood loss is often obvious. It occurs in placenta previa, abruptio placentae, or a large cephalohematoma. Other etiologies of hemorrhage may be occult and include intracranial and intrahepatic hematomas. Internal hemorrhage is much more likely to occur in difficult, traumatic deliveries. Twin-twin transfusion may occur leading to anemia in 1 infant and polycythemia in the other. Fetal–maternal hemorrhage is sufficiently severe to cause anemia in only a small percentage of neonates. The Kleihauer–Betke test may detect the presence of fetal RBCs in the maternal circulation, but may yield false-negative results, particularly in mothers with type O blood who have antibodies against infant A, B, or AB blood cells. Fetal–maternal hemorrhage must always be suspected when otherwise unexplained anemia occurs in a newborn.

The time course and extent of blood loss determine the clinical presentation. If blood loss is mild or chronic, infants may appear normal or have mild pallor and tachycardia. In the event of severe acute blood loss, the newborn may present with signs of acute illness

TABLE 37.17 Characteristics of Antibodies in Immune Hemolytic Anemia

	Warm-Antibody	Cold Agglutinin Disease	Paroxysmal Cold Hemoglobinuria	Drug Related Immune, Type 1	Drug Related Immune, Type II
Antibody isotype	IgG(rarely IgA)	IgM	IgG	IgG	IgM, IgG
Optimum temperature of reaction	37°C	0°C	0°C	37°C	37°C
Direct Coombs test	IgG ± C3	C3 only	C3 only	IgG only	C3 only
Agglutination in saline	None (rarely +)	++++	+	0 to +	0 to ++ (with drug)
Lysis by complement in vitro	Rare	Poor	Well	None	Sometimes well
Clinical severity	Mild to very severe	Mild to moderate	Moderate to severe	Mild to moderate	Mild to severe
Response to prednisone	Often	None	Often	If needed	Not needed
Response to splenectomy	Often	Rare	None	Not needed	Not needed

TABLE 37.18 Anemia in the Neonate

Blood Loss (Common)
Placenta previa
Abruptio placentae
Twin-twin transfusion
Fetal–maternal hemorrhage (acute versus chronic)
Neonatal hemorrhage

Decreased RBC Production (Unusual)
Diamond–Blackfan anemia
Congenital leukemia
Transient myeloproliferative syndrome in Down syndrome
Osteopetrosis

Hemolysis
Intrinsic RBC defect (uncommon)
    Membrane (hereditary spherocytosis or elliptocytosis)
    Enzyme (G6PD, PK)
    Hemoglobin (α or γ chain abnormality)
Extrinsic RBC defect
    Immune (ABO, Rh, minor group incompatibilities) (common)
    Infection (intrauterine infection, bacterial, viral, protozoal)
    DIC
    Kasabach–Merritt syndrome
    Galactosemia

DIC, disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase; PK, pyruvate kinase; RBC, red blood cell.

including lethargy, tachycardia, hypotension, and respiratory distress. The hemoglobin value is a poor index of the severity of acute blood loss because equilibration of fluid compartments may take 24-36 hours. Blood loss as a cause of anemia should always be suspected in cases of obstetric complications, multiple births, or difficult and traumatic deliveries. In cases of severe blood loss, emergency transfusion therapy is appropriate. In the neonate who is hemodynamically stable but has experienced significant blood loss, a more conservative approach is recommended.

Neonatal Anemia Caused by Decreased Red Blood Cell Production

Anemia caused by decreased RBC production in the newborn is unusual. Infants with congenital hypoplastic anemia (Diamond–

Blackfan anemia) are usually only mildly anemic during the newborn period. Congenital leukemia is a rare disorder characterized by infiltration of the bone marrow leading to anemia, thrombocytopenia, and leukocytosis in association with hepatosplenomegaly and occasionally cutaneous leukemic infiltrates manifesting as blue papular lesions ("blueberry muffin" spots). Infants with Down syndrome may present with a clinical and hematologic picture identical to that of congenital leukemia, which is a transient myeloproliferative process that spontaneously remits over several months. Infantile osteopetrosis (marble bone disease), a disorder characterized by a limited ability to degrade bone, usually does not cause pancytopenia until a few months after birth.

Neonatal Anemia Caused by Increased Red Blood Cell Destruction

Anemia caused by increased RBC destruction (hemolytic anemia) places the neonate at risk for indirect hyperbilirubinemia as a result of the limited hepatic bilirubin-conjugating ability during the 1st weeks of life. Even relatively small increases in the rate of RBC destruction can lead to marked increases in serum bilirubin level. All infants who have elevations of indirect bilirubin levels above the normal range during the 1st 3 days of life should be evaluated for possible hemolysis, with a CBC, reticulocyte count, peripheral blood smear, maternal and infant blood type assessments, and direct Coombs test.

Intrinsic disorders of the erythrocyte may manifest in the neonate. Infants with hereditary spherocytosis, pyropoikilocytosis, or elliptocytosis may develop anemia and extreme hyperbilirubinemia that necessitates phototherapy and, rarely, exchange transfusion. A peripheral blood smear and family history may be helpful in identifying an intrinsic RBC membrane defect.

G6PD deficiency can occur in newborn boys (rarely girls) of African or Mediterranean descent. Because of the increased susceptibility of neonatal RBCs to oxidant injury, anemia, reticulocytosis, and hyperbilirubinemia may occur without an obvious precipitating oxidant insult. Hemoglobinopathies rarely manifest during the neonatal period. β-globin chain defects such as sickle cell disease and thalassemia are not clinically apparent until about 4-6 months of age because of the predominance of fetal hemoglobin in the perinatal period.

Severe α-thalassemia, including α-thalassemia major or hemoglobin Bart's disease, can affect the fetus. Such infants develop severe in utero anemia with resultant hydrops fetalis because of the limited ability of hemoglobin Bart's to release oxygen to tissues.

Isoimmune hemolytic anemia is the most common cause of hemolytic anemia in the newborn. It is caused by incompatibility

TABLE 37.19 **Genetic Disorders Associated with Anemia in the Neonate**

Syndrome	Genetic Characteristics	Hematologic Phenotype
Diamond–Blackfan syndrome	Autosomal recessive (AR); sporadic mutations and autosomal dominant (AD) inheritance have been described	Steroid-responsive hypoplastic anemia after 5 mo of age
Fanconi anemia	AR, probably abnormalities in multiple genes (at least 5 genetic subtypes have been identified)	Steroid-responsive hypoplastic, macrocytic anemia DNA is hypersensitive to injury
Aase syndrome	AR, possible AD	Steroid-responsive hypoplastic anemia; macrocytic; improves with age
Pearson syndrome	Mitochondrial DNA abnormalities, X-linked or AR	Hypoplastic sideroblastic anemia unresponsive to pyridoxine
Lethal osteopetrosis	AR, caused by defective resorption of immature bone	Hypoplastic anemia due to marrow encroachment
Congenital dyserythropoietic anemia (CDA)	AR	Type I: megaloblastoid erythroid and nuclear chromatin bridges between cells Type II: hereditary erythroblastic multinuclearity and positive acidified serum test results (HEMPAS) Type III: erythroblastic multinuclearity and macrocytosis
Peutz–Jeghers syndrome	AD	Iron deficiency, anemia from chronic blood loss
Dyskeratosis congenita	X-linked recessive, locus on Xq28; some cases with AD inheritance	Hypoplastic anemia; usually present between 5 and 15 yr of age
X-linked α-thalassemia/ mental retardation (ATR-X and ATR-16) syndromes	ATR-X: X-linked recessive, mapped to Xq13.3; ATR-16: mapped to 16p13.3; deletions of α-globin locus	ATR-X: hypochromic, microcytic anemia, mild form of hemoglobin H disease; ATR-16: more significant hemoglobin H disease and anemia are present
Thrombocytopenia with absent radius (TAR) syndrome	AR	Hemorrhagic anemia, possibly hypoplastic anemia as well
Osler hemorrhagic telangiectasia syndrome	AD, mapped to 9q33-34	Hemorrhagic anemia

From Ohls RK. Evaluation and treatment of anemia in the neonate. In: Christensen RD, ed. *Hematologic Problems of the Neonate*. Philadelphia: Saunders; 2000:153.

between maternal and fetal blood groups, including Rh, ABO, or minor blood group antigens. In Rh incompatibility, the mother is Rh negative and the infant is Rh positive (inherited from the father). If the mother has been exposed to Rh-positive blood cells through prior pregnancy, miscarriage, therapeutic abortion, or mismatched blood transfusion, IgG antibodies may develop that traverse the placenta and cause immune destruction of fetal Rh-positive cells. In such instances hemolysis occurs in utero and in the neonatal period. In severe circumstances the fetus may be extremely anemic, which results in heart failure, hydrops fetalis, and death. In less serious instances infants may be born quite anemic and develop brisk hyperbilirubinemia, which can lead to kernicterus. The severity of Rh immune hemolytic disease increases with successive pregnancies. This disorder is uncommon because of the routine practice of administering Rh immunoglobulin to Rh-negative mothers who are 28-30 weeks pregnant and within 72 hours of delivery or after spontaneous or therapeutic abortion. Prenatal management of the affected fetus may include spectrophotometric assessment of amniotic fluid as an assessment of fetal bilirubin level and in high-risk situations serial fetal hemoglobin levels obtained by ultrasonographically guided aspiration of umbilical cord blood (cordocentesis). When the fetus demonstrates progressive in utero severe anemia, intrauterine intravascular blood transfusion therapy has been shown to decrease the risk for fetal demise. Management of the neonate relates largely to the severity of the hemolysis. Hyperbilirubinemia must be treated aggressively with phototherapy and if severe, exchange transfusion. RBC transfusions are appropriate for symptomatic anemia. On occasion, anemia is detected several weeks after Rh hemolysis and may be associated with a profoundly depressed reticulocyte count. This late anemia is of uncertain origin, but inappropriately low erythropoietin levels have been noted. Symptomatic infants may require transfusion therapy. Affected infants have been successfully treated with human recombinant erythropoietin.

Immune incompatibility in the ABO system is common and usually occurs when mothers with type O blood have newborns whose blood type is A or B. The degree of hemolysis is usually much less severe than in Rh disease. Fetal hydrops is extremely rare. Most babies with ABO incompatibility manifest jaundice from indirect hyperbilirubinemia during the 1st 1-2 days after birth. Hemoglobin levels are often within the normal to mildly anemic range, but moderate anemia occasionally occurs. The reticulocyte count is usually mildly elevated, and the peripheral blood smear may show microspherocytes. Results of the Coombs test are usually weakly or moderately positive, but false-negative results do occur. Treatment is generally directed toward hyperbilirubinemia and may require phototherapy. Intravenous immunoglobulin therapy has been helpful in some selected patients. Exchange transfusion is rarely necessary. Anemia occasionally necessitates blood transfusion. Immune incompatibility may also occur on the basis of minor blood groups antigens such as the Duffy or Kell antigen systems. Clinical and laboratory findings are similar to those in ABO hemolytic disease except that the direct Coombs test result is usually strongly positive.

Other causes of hemolytic anemia in the newborn include bacterial sepsis and intrauterine infection (cytomegalovirus, toxoplasmosis, herpes, rubella, and syphilis). Intrauterine infectious syndromes can cause mild to moderate hemolytic anemia of several months' duration.

Such infants may demonstrate physical stigmata including small size for gestational age, microcephaly, chorioretinitis, hepatosplenomegaly, intracranial calcifications, and "celery stalking" of the long bones on radiographic study.

Microangiopathic hemolytic anemia can occur in the newborn as a result of disseminated intravascular coagulation (DIC). In the neonate, DIC is usually caused by serious infection, hypoxemia resulting from respiratory distress syndrome in the preterm infant, or ischemic tissue injury related to birth asphyxia. Newborns with hemolysis resulting from infection or DIC are often extremely ill and require RBC transfusion support.

Microangiopathic hemolytic anemia and consumptive thrombocytopenia can occur in the Kasabach–Merritt syndrome, which is associated with cavernous hemangiomas and localized intravascular coagulation. Some infants have obvious expansive cutaneous and subcutaneous lesions, but occult visceral hemangiomas, particularly in the liver, can occur. The peripheral blood smear demonstrates evidence of RBC fragments and burr cells. Kasabach–Merritt syndrome may necessitate treatment with plasma and platelet transfusions if consumptive coagulopathy is severe. Corticosteroids and interferon therapy have been helpful in some affected infants.

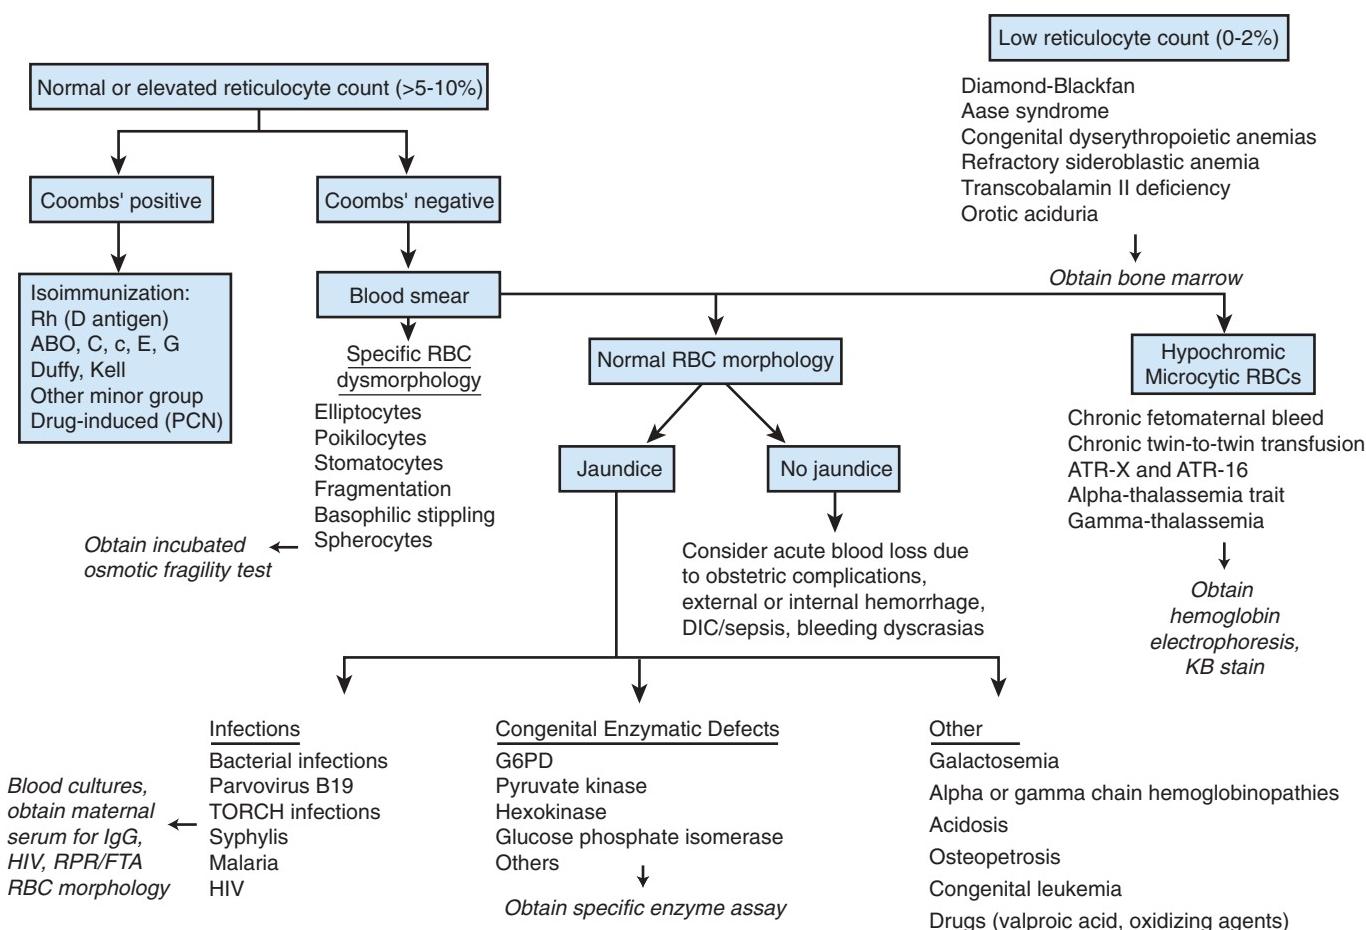
The diagnostic approach to anemia in the neonate requires a careful assessment of maternal, prenatal, and perinatal history as well as the clinical status of the neonate (Fig. 37.9). CBC, reticulocyte count, peripheral blood smear, maternal and infant blood types, and direct Coombs tests are virtually always necessary laboratory studies. Other studies must be dictated by the clinical and initial laboratory findings.


FIGURE 37.9 Differential diagnosis of neonatal anemia. The physician first seeks information from the family, maternal, and labor and delivery histories and then obtains initial laboratory tests: hemoglobin, reticulocyte count, blood type, direct Coombs test, peripheral smear, red blood cell (RBC) indices, and bilirubin concentration. Results are used to navigate the diagnostic flow chart. ATR-16, α-thalassemia retardation syndrome, chromosome 16–linked; ATR-X, α-thalassemia retardation syndrome, X-linked; DIC, disseminated intravascular coagulation; FTA, fluorescent treponemal antibody test; G6PD, glucose-6-phosphate dehydrogenase; HIV, human immunodeficiency virus; KB, Kleihauer–Betke; PCN, penicillin; RPR, rapid plasma reagin test; TORCH, toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes simplex. (From Ohls RK. Evaluation and treatment of anemia in the neonate. In: Christensen RD, ed. *Hematologic Problems of the Neonate*. Philadelphia: Saunders; 2000:162.)

SUMMARY AND RED FLAGS

Anemia is a common finding in children. A complete and thorough evaluation of clinical findings by a detailed history and physical examination is the most important element in the establishment of a diagnosis and in defining appropriate therapy.

Anemia may be a primary event reflecting intrinsic hematologic disease or it may be a manifestation of a wide variety of systemic disorders involving virtually any organ system. Anemia must always be fully evaluated in view of the potential diagnostic and therapeutic implications. Patients who appear acutely ill should have a more thorough and prompt evaluation because acute blood loss must be treated quickly. If acute blood loss is not suspected, acute hemolysis or splenic sequestration of RBCs must be considered.

Anemia is often a sign of underlying acute or chronic disease. In such cases, anemia is not usually an isolated finding. Therefore, symptoms such as shortness of breath, extreme pallor, weight loss, fevers, lethargy, and fatigue should prompt a thorough evaluation of the patient.

On physical examination, the findings of abnormal vital signs, failure to thrive, bleeding or bruising, adenopathy, or organomegaly should lead the examiner to suspect that a potentially serious underlying disorder is present (Table 37.20). When a CBC is obtained, a low hemoglobin value accompanied by any abnormality of MCV, WBC, or platelet count should be taken seriously and should be more thoroughly investigated. The work-up should be directed accordingly based on these abnormal findings.

TABLE 37.20   **Red Flags**
Anemia Accompanied by
Abnormal vital signs (tachycardia, hypotension, hypertension)
Neutropenia and/or thrombocytopenia
High MCV with normal RDW
Blasts on the peripheral smear
Firm adenopathy
Bruising or bleeding
Weight loss, failure to thrive
Shortness of breath, fatigue
Fever
Hypoxia
Organomegaly
Edema
Oliguria-anuria
Bloody diarrhea
Red urine (hemoglobinuria)
Family history of anemia

MCV, mean corpuscular volume; RDW, red blood cell distribution width.

Bleeding and Thrombosis

Veronica H. Flood and J. Paul Scott

Hemostasis is a process that maintains normal blood flow through healthy vessels but, when a vessel is damaged, rapidly generates a clot at the site of vascular injury. The major components of the hemostatic mechanism are the platelets, the anticoagulant proteins, the procoagulant proteins, and the various components of the vascular wall. Normal hemostasis is an interactive process in which each element cooperates closely to generate a rapid, cohesive, focused reaction. An abnormality of 1 element destabilizes the system, but significant clinical symptoms often manifest only when 2 components are affected. Typical examples include the patient with hemophilia who bleeds after sustaining trauma and the antithrombin (AT) 3–deficient woman in whom thrombosis develops during pregnancy. The astute clinician is aware of situations that may exacerbate preexisting conditions. Pretreatment of known predisposing conditions can prevent complications, as exemplified by infusion of factor 8 concentrate before and after surgery to a patient with hemophilia A to prevent excessive bleeding. Table 38.1 shows common bleeding symptoms and the most common disorders that trigger these symptoms.

COAGULATION CASCADE

Two opposing systems generate local clots but limit the clot to the area of vascular damage. Fig. 38.1 shows the sequence of activation of coagulation. The cascade is capable of rapid response because generation of a small number of activated factors at the "top" of the cascade leads to thousands of molecules of thrombin. Deficiencies of proteins at or below factors 11 or 7 in the coagulation cascade sequence result in clinical bleeding symptoms, whereas deficiencies of factor 12, prekallikrein, and high–molecular-weight kininogen do not. The coagulation mechanism is continuously generating a small amount of thrombin. If there is trauma, tissue factor and factor 7 combine to activate factor 10 to factor 10a both directly and indirectly via factor 9. Factor 10a then forms a complex on a membrane surface (provided by the activated platelet) with factor 5 and calcium, which results in more thrombin generation. Platelets stick to areas of vessel injury, thus restricting thrombin generation and clot formation to the area of damage.

Thrombin exerts positive feedback on the system by acting on factor 11 to trigger the intrinsic system, cleaving factors 5 and 8 to activate them, further accelerating thrombin generation, aggregating platelets, and activating factor 13. In this model, coagulation is always "turned on" and therefore, reacts faster than if it were static and suddenly had to initiate a series of reactions to trigger clot formation. This dynamic concept underscores the impact of deficiencies in anticoagulant protein as the system is continuously generating thrombin. A deficiency of an inhibitory enzyme or a cofactor removes part of the "brakes" on the system and causes increased thrombin generation.

COAGULATION INHIBITORS

Four key systems interact to inhibit the coagulation mechanism:
- AT
- Protein C/S system
- Fibrinolytic system
- Tissue factor pathway inhibitor (TFPI)

Antithrombin

AT is a member of the serine protease inhibitor family (serpins) that inhibits thrombin, factor 10a, and, less efficiently, factors 9a and 11a. When AT is bound to heparin, this reaction is accelerated 1000-fold. AT is the active anticoagulant operative during heparin therapy; if AT is deficient, heparin therapy may fail. Heparin-like molecules are synthesized by endothelial cells and interact with AT on the vessel wall to inhibit coagulation. Both congenital and acquired AT deficiencies are associated with a predisposition toward thrombosis. AT is consumed during clotting.

Protein C/Protein S System

The protein C/protein S system is complex and limits clot extension by inactivating the rate-limiting coenzymes of the coagulation cascade, factors 5 and 8. To prevent extension of the clot, the anticoagulant mechanism must limit thrombin formation to areas of vascular damage. As a 1st step, thrombin binds to the protein thrombomodulin on intact endothelial cells. Thrombomodulin-bound thrombin then converts protein C into its activated form, activated protein C (APC). APC then combines with protein S to inactivate factors 5 and 8. In addition, APC may promote fibrinolysis. Thrombin itself is inactivated when bound to thrombomodulin and simultaneously augments the anticoagulant response by generating APC. APC limits the amount of thrombin that can be generated subsequently.

AT3, protein C, and protein S are important inhibitors of clotting because deficiencies of each of these proteins, either inherited or acquired, are associated with an increased risk for thrombosis. A mutation in factor 5 (factor 5 Leiden) that makes it less susceptible to proteolysis by APC (resistance to APC) is the most common hereditary predisposition to thrombosis. TFPI is an inhibitor of factor 7a (Fig. 38.2).

Fibrinolytic System

The fibrinolytic system dissolves and removes clots from the vascular system so that normal flow through vessels can be restored. Endothelial cells synthesize 2 activators of plasminogen: tissue-type plasminogen activator (TPA) and urokinase, both of which convert plasminogen to plasmin, the enzyme that degrades fibrin. Normally, plasminogen activator and its inhibitor, plasminogen activator inhibitor, are synthesized in equimolar amounts and are released from endothelial cells in

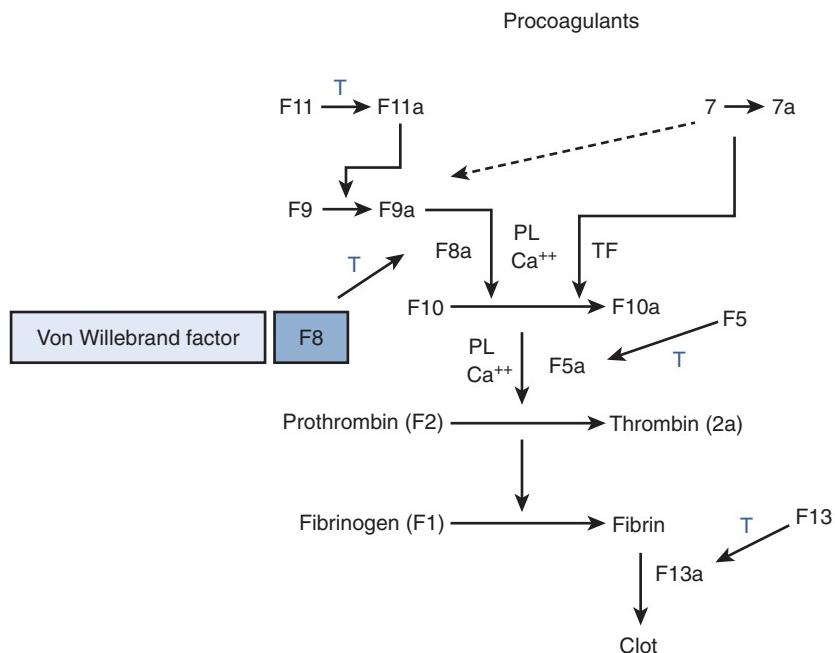
Procoagulants


FIGURE 38.1 The coagulation cascade and the critical positive feedback role of factor IIa (thrombin) (T) on multiple aspects of the coagulation cascade. In addition, thrombin aggregates platelets and thereby contributes to platelet plug formation. The *dotted line* connecting factor 7a with factor 9 depicts the physiologic pathway of factor 9 activation *in vivo*. Factor 8 circulates bound to von Willebrand factor. After activation by thrombin, factor 8a can participate with factor 9a in the activation of factor 10. Factor 13a cross-links fibrin and stabilizes the fibrin clot. Ca^{2+}, calcium; PL, platelet phospholipid surface; TF, tissue factor. (Modified from Montgomery RR, Scott JP. Hemorrhage and thrombotic diseases. In: Behrman RE, Kliegman RM, Jenson HB, eds. *Nelson Textbook of Pediatrics*. 16th ed. Orlando, FL: WB Saunders; 1999:1505.)

Liver disease
Uremia

parallel, leading to minimal amounts of active fibrinolysis. Increased activation or damage to the vascular system can alter this balance and result in increased TPA release, thus generating plasmin and lysing local clots. Plasminogen activator has been synthesized in a recombinant form (rTPA) and is an effective pharmacologic fibrinolytic agent in vivo.

PLATELET-ENDOTHELIAL CELLS AXIS

Clotting is initiated when platelets adhere to damaged endothelium (Fig. 38.3). In areas of vascular damage, the adhesive protein, von Willebrand factor (VWF), binds to the exposed subendothelial collagen matrix and undergoes a conformational change. VWF then binds to its platelet receptor, glycoprotein Ib, and activates platelets. Activated platelets secrete adenosine diphosphate (ADP), which induces nearby circulating platelets to aggregate. Platelet-to-platelet cohesion is mediated by the binding of fibrinogen to its platelet receptor, glycoprotein IIb/IIIa. Therefore, both VWF and fibrinogen play essential roles in normal platelet function *in vivo*. Simultaneously with the platelet adhesion-aggregation response, coagulation is being activated. The platelet membrane brings the reactants of the cascade into close proximity, promoting rapid, effective factor catalysis and accelerating the reactions 1000-fold faster than would occur in the absence of the appropriate surface.

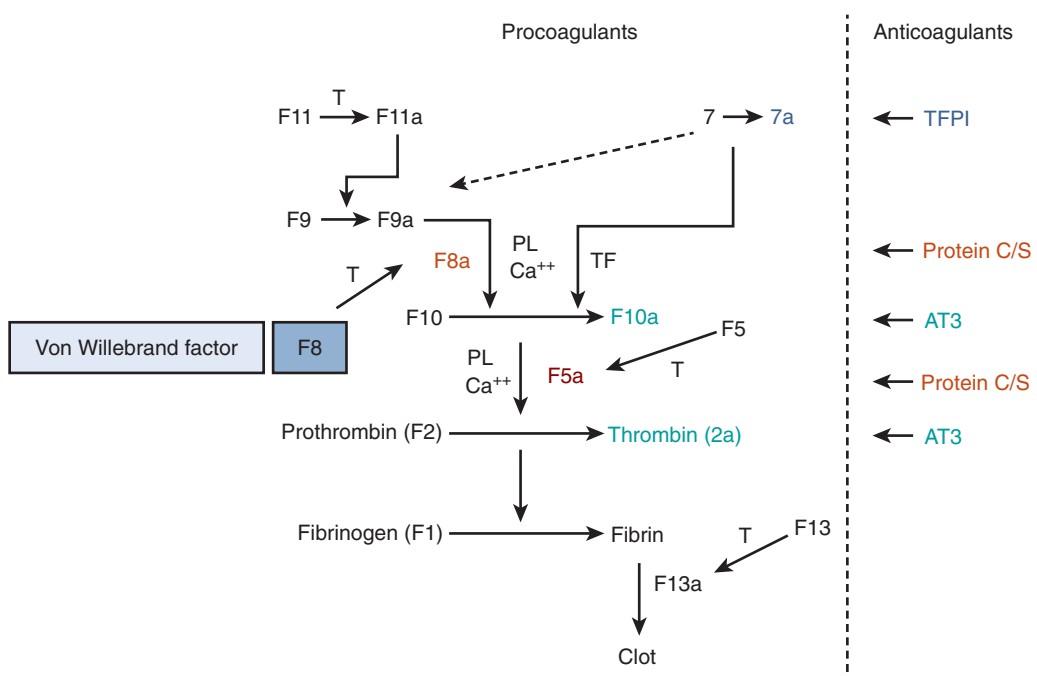
Normally, endothelial cells provide an antithrombotic surface through which blood flows without interruption. The endothelial cell is capable of a rapid change in function and character so that it can augment coagulation after stimulation with a variety of modulating agents, including lymphokines and cytokines, as well as noxious agents such as endotoxin and infectious viruses (Fig. 38.4). Widespread


FIGURE 38.2 The major sites of action of the physiologic anticoagulants. Antithrombin (AT) irreversibly binds and inactivates factor 10a and thrombin. Thrombin binds to endothelial thrombomodulin and activates protein C. The activated protein C/protein S complex (P-C/S) proteolyses and inactivates factors 5a and 8a. The tissue factor pathway inhibitor (TFPI) binds to the complexes of factor 7a–tissue factor–factor 10a and inactivates factor 7a. Ca^{2+}, calcium; PL, platelet phospholipid surface; TF, tissue factor. (Modified from Montgomery RR, Scott JP. Hemorrhage and thrombotic diseases. In: Behrman RE, Kliegman RM, Jenson HB, eds. *Nelson Textbook of Pediatrics.* 16th ed. Orlando, FL: WB Saunders; 1999:1505.)

alteration of endothelial cell function can shift and dysregulate the hemostatic response and promote activation of clotting, which is the probable mechanism by which sepsis induces the clinical syndrome of disseminated intravascular coagulation (DIC).

DEVELOPMENTAL HEMOSTASIS

Hemostatic disorders in newborns are more common than at any other pediatric age. The neonate is relatively deficient in most procoagulant and anticoagulant proteins. Platelet function may also be impaired. Blood flow characteristics in the newborn are unique because of the high hematocrit, small-caliber vessels, low blood pressure, and special areas of vascular fragility. Table 38.2 presents the normal values for coagulation screening tests and procoagulant proteins in preterm and full-term infants, as well as in older children. Table 38.3 presents age-specific values for the anticoagulant and fibrinolytic proteins.

Levels of factors 5 and 8, fibrinogen, VWF, and platelets become normal by 28 weeks of gestation. Protein S levels are also normal at birth, but levels of other anticoagulant proteins, especially protein C, AT3, and plasminogen, are low in full-term infants and are even lower in premature neonates. The levels of most procoagulant and anticoagulant proteins increase throughout gestation; therefore, the most immature infant has the lowest levels of these proteins and is at the highest risk for either bleeding or thrombotic complications.

Vitamin K deficiency is a particular problem of the newborn. Vitamin K is a fat-soluble vitamin that induces the post-translational γ-carboxylation of the vitamin K-dependent substances (factors 2, 7, 9, and 10; protein C; and protein S). This carboxylation step occurs after the protein is synthesized in the liver and must occur for the vitamin K-dependent coagulation factor to bind calcium, the bridge to the membrane surface on which these proteins form complexes with other members of the clotting cascade and catalyze subsequent reactions. Vitamin K deficiency effectively renders these proteins unable to bind to a surface. Most of the vitamin K in adults originates from the diet and from bacterial production in the intestine. The breast-fed neonate is at high risk for vitamin K deficiency because human milk is relatively deficient in vitamin K, the neonatal liver itself is immature, and the newborn's gut requires several days to develop normal bacterial flora.

Severe vitamin K deficiency in neonates, **hemorrhagic disease of the newborn** (HDN), occurs in breast-fed infants who have not received intramuscular vitamin K prophylaxis. Such infants may experience diffuse bleeding and even central nervous system hemorrhage at 3-5 days of life. HDN is an extraordinarily rare event in the United States because of nearly universal neonatal administration of vitamin K. In the evaluation of bleeding in a newborn, the clinician should confirm that vitamin K has been administered. Patients with disorders of the gastrointestinal tract, those taking broad-spectrum antibiotics, those born of mothers who received phenobarbital or phenytoin during pregnancy (very–early-onset HDN), and those with cholestasis and malabsorption (late-onset HDN) are at higher risk for vitamin K deficiency.

CLUES FROM HISTORY AND PHYSICAL EXAMINATION

◆ History

Table 38.4 is an outline of historical questions that are important for the diagnosis of bleeding disorders as it is critical to obtain quantifiable, precise information. Easy bruising and nosebleeds are common in children, although the presence of large (>2 inches in diameter) bruises at multiple sites, prolonged nosebleeds (>15-30 minutes), and hematoma formation are seen in up to 20-40% of children with a bleeding disorder. Bleeding post-circumcision should raise the suspicion of hemophilia, while bleeding from the umbilical cord stump is associated with factor 13 deficiency. Some helpful questions include "What was the biggest bruise you ever had, and what caused it?" and "Have you ever noted little red dots [petechiae] on your skin?"

A personal or family history of gynecologic bleeding is often valuable. Menorrhagia causing iron deficiency anemia, bleeding after childbirth, or need for transfusion or early hysterectomy because of bleeding is often inappropriately assumed to have anatomic causes ("dysfunctional uterine bleeding"). The clinician must ascertain the number of pads used per day, in addition to the length and the frequency of each menstrual cycle. If the majority of women in a family have an underlying bleeding disorder, then that family's "normal menstrual periods" may be quite abnormal. Many adolescent girls with menorrhagia caused by an underlying bleeding disorder respond to oral contraceptive agents; *therefore, improvement in bleeding symptoms after starting oral contraceptive agents does not rule out a bleeding disorder.*

Historical information is equally important in deciding who requires evaluation for a predisposition to thrombosis. Virtually all pediatric patients in whom a blood clot develops in the absence of major vascular instrumentation, catheter placement, underlying infection, or other inflammatory state merit careful laboratory screening for a prothrombotic state (a hereditary or acquired disorder that predisposes to clotting). Even in the situation of a provoked thrombosis, a detailed family history should be documented for early-onset stroke; early myocardial infarction; and blood clots in the veins, arteries, or lungs.

◆ Physical Examination

The most important determination is whether the patient appears acutely or chronically ill, including vital signs and growth parameters. The nose should be examined for ulcers or anatomic bleeding sites, and the heart should be examined for the presence of murmurs (as occur in anemia and endocarditis). Joints should be examined for chronic arthropathy (as occurs in hemophilia) or joint laxity (as occurs in Ehlers–Danlos syndrome), and the extremities are examined for thumb or radial anomalies (thrombocytopenia–absent radius syndrome, or Fanconi anemia). The abdomen and lymph nodes should be examined for the presence of hepatosplenomegaly and adenopathy.

The examination of the skin should include a search for pallor, hematomas, petechiae, ecchymoses, telangiectasias, poor wound healing (large or abnormal scars), lax (loose) skin, and varicose veins (possible deep venous thrombosis). Petechiae are pinpoint, flat, dark red lesions caused by capillary bleeding into the skin. Ecchymoses

Data from Andrew M, Paes B, Johnston M. Development of the hemostatic system in the neonate and young infant. *Am J Pediatr Hematol Oncol.* 1990;12:95-104; and Andrew M, Vegh P, Johnston M, et al. Maturation of the hemostatic system during childhood. *Blood.* 1992;80:1998-2005.

are larger lesions (bruises) that are flat and usually not palpable. Hematomas are accumulations of blood in the skin or deeper tissues; in the skin, hematomas are raised and palpable. Bruises should be described in detail, including whether hematomas are associated with bruises and whether petechiae are present. Petechiae and ecchymoses are usually painless. Purpura refers to any group of disorders characterized by the presence of dark-red, purplish, or brown lesions of the skin and mucous membranes. The discoloration is caused by the leakage of red blood cells from affected vessels. Purpuric lesions can be caused by abnormalities of the platelets, of coagulation proteins, or of vessel walls.

Coagulation Screening Tests

After obtaining a history and performing a physical examination, the clinician must determine the need for a hemostatic evaluation. The history is likely to be the most sensitive screening tool for a significant bleeding disorder, although its use in a very young child, especially before toddler age, is limited and attention must shift to the perinatal and family history. For patients with clinical clues of a coagulation disorder, the initial screening studies should assess the clotting factors and platelet function. No set of screening tests is complete and capable of detecting the panorama of hemorrhagic disorders, but the screen should include:
- Complete blood count (CBC) to evaluate hemoglobin and platelet count
- Prothrombin time (PT)
- Partial thromboplastin time (PTT)

- Functional fibrinogen level or thrombin time
- VWF testing

If there is high suspicion for an underlying bleeding disorder, screening for von Willebrand disease and platelet function defects should be considered. There are no satisfactory tests to screen for a thrombotic tendency.

Prothrombin Time and Partial Thromboplastin Time

The PT and PTT (Fig. 38.5) are measures of all the coagulation factors except factor 13. Fibrinogen function should be measured as fibrinogen activity or thrombin time. The PTT is the screening test that checks for deficiency of all clotting factors except factors 7 and 13. The PTT can be prolonged either by a deficiency of a clotting factor or by the presence of an agent in the plasma that delays the clotting time (an inhibitor). The PT is especially sensitive to deficiencies of factor 7.

To test for an inhibitor, 1 part of the patient's plasma is mixed with 1 part of pooled normal plasma obtained from 20-50 healthy adults. Pooled normal plasma provides a 100% level of each clotting factor. If mixed 1:1 with plasma that is deficient in 1 or several factors, the mixture should possess at least a 50% level of each factor and the PTT should correct to the normal range. If an inhibitor is present, the PTT usually does not correct to normal. The most common types of inhibitors include anticoagulants, such as heparin, and autoantibodies directed against either specific clotting factors (factor 8 inhibitors) or the phospholipid substances used in the PTT (lupus-type anticoagulants).

TABLE 38.4   History of a Bleeding Disorder

I. History of Disorder
  A. Onset of symptoms
    1. Age
    2. Acute versus lifelong
    3. Triggering event
    4. Timing of bleeding after injury: immediate vs delayed
  B. Sites of bleeding
    1. Mucocutaneous*
      a. Epistaxis (1) Duration, frequency, seasonal tendency
      (2) Associated trauma (nose picking, allergy, infection)
      (3) Resultant anemia, emergency department evaluation, cautery
      b. Oral (gingiva, frenulum, tongue lacerations, bleeding after tooth brushing, after dental extractions requiring sutures/packing)
      c. Bruising (number, sites, size, **raised** [other than extremities], spontaneous versus trauma, knots within center, skin scarring)
      d. Gastrointestinal bleeding
    2. Deep
      a. Musculoskeletal (1) Hemarthroses, unexplained arthropathy (2) Intramuscular hematomas
      b. Central nervous system hemorrhage
      c. Genitourinary tract
    3. Surgical
      a. Minor (sutures, lacerations, poor or delayed wound healing)
      b. Major (1) Tonsillectomy and adenoidectomy (2) Abdominal surgery
  C. Perinatal history
    a. Superficial (bruising, petechiae)
    b. Deep (1) Circumcision (2) Central nervous system bleeding (3) Gastrointestinal bleeding (4) Cephalohematoma (5) Unexplained anemia or hyperbilirubinemia (6) Delayed cord separation, bleeding after cord separation
    c. Vitamin K administration
    d. Maternal drugs
  D. Obstetric/gynecologic bleeding
    1. Menorrhagia
      a. Onset, duration, amount (number of pads), frequency, persistence after childbirth
      b. Resultant anemia, iron deficiency
    2. Bleeding at childbirth (onset, duration, **transfusion requirement**, history of traumatic delivery, recurrences with subsequent pregnancies, spontaneous abortions)
  E. Medications
    a. Aspirin and nonsteroidal antiinflammatory drugs
    b. Anticoagulants
    c. Antibiotics
    d. Anticonvulsants
  F. Diet
    a. Vitamin K
    b. Vitamin C
II. Family History
Draw family tree. The items just listed should be applied to immediate family members, especially a history of easy bruising, epistaxis, excessive bleeding after surgery, menorrhagia, excessive bleeding after childbirth, or a family history of others with diagnosed or suspect bleeding disorders. Attempt to deduce inheritance pattern.

*Significant historical information is presented in boldface type.

The PTT is especially sensitive to deficiencies of factors 8, 9, and 11 (hemophilia A, B, and C, respectively). A prolonged PTT in an asymptomatic child is most commonly caused by factor 12 deficiency or by a lupus-type anticoagulant. The PTT can also yield a false result:

1. When poor venipuncture technique, by adding tissue factor to the blood, activates clotting and artifactually shortens the PTT.
2. When insensitive laboratory reagents fail to detect clinically significant deficiencies (most common in mild factor 9 deficiency).
3. When the citrate concentration is not corrected for blood with a high hematocrit (in neonates and in patients with cyanotic congenital heart disease), leading to a prolonged PTT.

Bleeding Time

The bleeding time is an indirect measure of platelet number and a more direct measure of platelet function, vascular integrity, and platelet interaction with the vascular subendothelium. As such, the bleeding time should be abnormal in patients with thrombocytopenia, platelet function abnormalities, abnormal collagen (Ehlers–Danlos syndrome), and von Willebrand disease. Unfortunately, because of its insensitivity and high level of variability, the bleeding time is a relatively poor tool for detecting the milder forms of these hemostatic disorders and cannot be used to rule out von Willebrand disease and mild or moderate platelet function deficits.

Platelet Function Analysis

Platelet function analysis was originally recommended as a screening test for von Willebrand disease and platelet function defects. Its sensitivity and specificity are insufficient for diagnosis, but it may have utility as a screen for severe platelet function defects in very small infants where rapid results are needed and size prohibits collection of large volumes of blood needed for platelet aggregation testing.

Figs. 38.6 and 38.7 provide an approach to evaluate the patient with an isolated prolongation of the PT or PTT.

Thrombin Time and Reptilase Time

The thrombin time and reptilase time are tests that measure the conversion of fibrinogen to fibrin. The thrombin time is sensitive to heparin effect, whereas the snake venom reptilase time remains normal in the presence of heparin. Both the thrombin time and the reptilase time are prolonged by uremia, by dysfibrinogenemia, and by low fibrinogen levels (<75 mg/dL).

MUCOCUTANEOUS BLEEDING

Mucocutaneous bleeding occurs within the skin or mucous membranes. Common complaints include prolonged, frequent nosebleeds; gum bleeding; prolonged bleeding after tooth extraction; menorrhagia; and easy bruising with or without petechiae formation. Mucocutaneous bleeding is usually associated with abnormalities of platelet number or function, of platelet cofactors, or of the vessel wall. The well-appearing child who presents with the acute onset of petechiae and purpura, often in association with nosebleeds or bleeding gums, and otherwise normal examination findings typically has **acute immune thrombocytopenic purpura (ITP)**. The majority of affected children have an antecedent viral illness. After exposure to the viral infection, an antibody that binds to the platelet membrane develops, leading to the premature destruction of the antibody-coated platelets in the spleen.

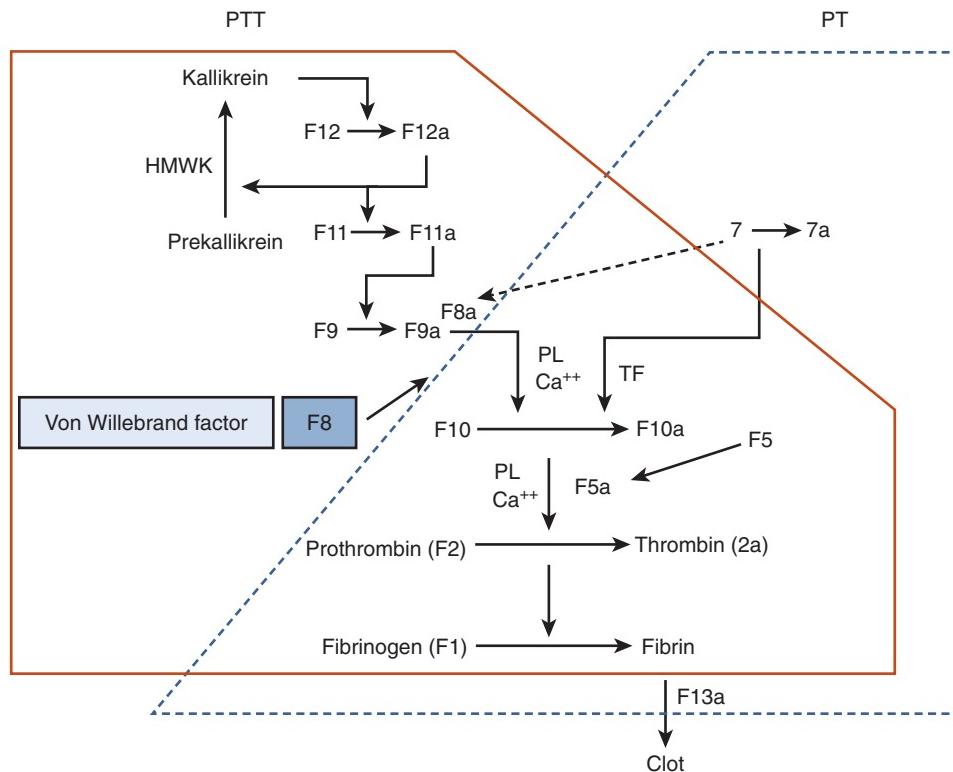
The peak ages for the presentation of ITP are 1-4 years of age and adolescence, but ITP occurs throughout childhood and adolescence. Girls are more commonly affected in adolescence but not in childhood. The work-up of a child with thrombocytopenia should include a


FIGURE 38.5 Elements of the coagulation cascade measured by the prothrombin time (PT) and the partial thromboplastin time (PTT). Note that prekallikrein (PK), high-molecular-weight kininogen (HMWK), and factor 12 are shown in this figure and not in the depiction of the coagulation cascade in Fig. 38.1, because a deficiency of PK, HMWK, or factor 12 can cause a prolongation of the PTT. However, a deficiency of any of these proteins alone is not associated with a clinical bleeding disorder. Ca^{2+}, calcium; PL, platelet phospholipid surface; TF, tissue factor. (Modified from Montgomery RR, Scott JP: Hemorrhage and thrombotic diseases. In: Behrman RE, Kliegman RM, Jenson HB, eds. *Nelson Textbook of Pediatrics.* 16th ed. Orlando, FL: WB Saunders; 1999:1505).
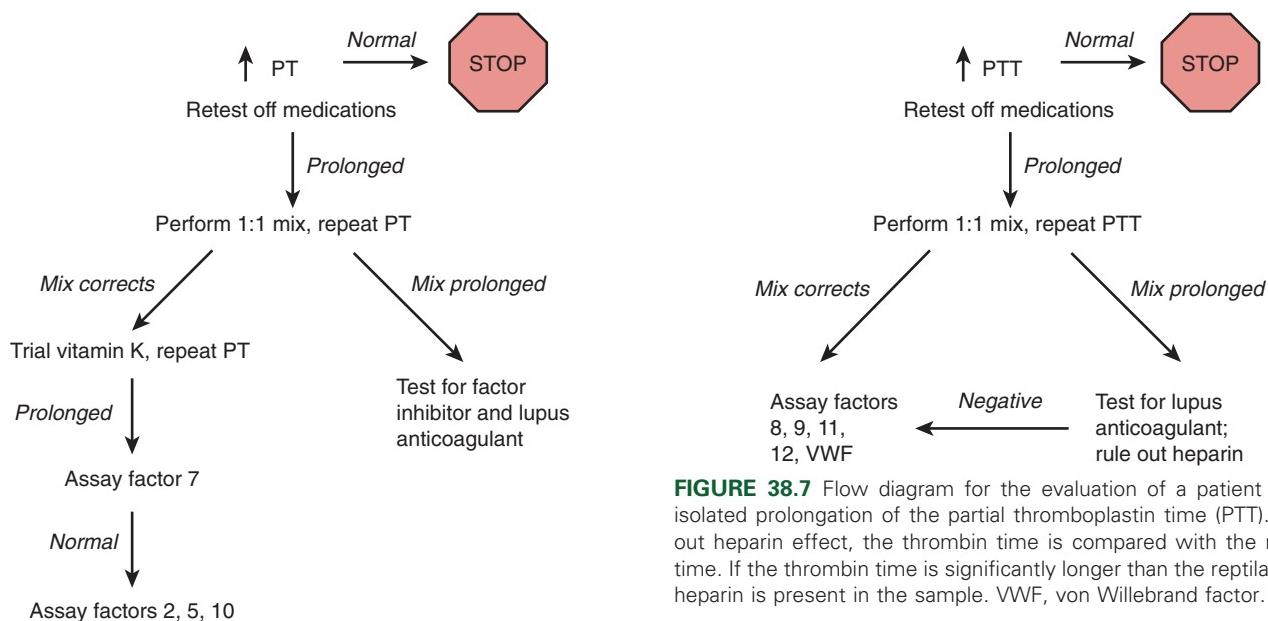

FIGURE 38.6 Flow diagram for the evaluation of a patient with an isolated prolongation of the prothrombin time (PT).

FIGURE 38.7 Flow diagram for the evaluation of a patient with an isolated prolongation of the partial thromboplastin time (PTT). To rule out heparin effect, the thrombin time is compared with the reptilase time. If the thrombin time is significantly longer than the reptilase time, heparin is present in the sample. VWF, von Willebrand factor.

careful history aimed at detecting symptoms (e.g., weight loss, fever, bone pain, anorexia) of other preexisting illnesses (e.g., leukemia, systemic lupus erythematosus [SLE], endocarditis, human immunodeficiency virus [HIV]), exposures to drugs or toxins, and a personal or family history of thrombocytopenia. The physical examination must be detailed and include a search for signs of malignancy (e.g., lymphadenopathy, hepatosplenomegaly), chronic illness, and congenital malformations. When evaluating the CBC, the clinician should ensure that the hemoglobin, white blood cell count, differential, indices, and smear are normal, which would make the diagnosis of a hematologic malignancy or other marrow failure syndrome unlikely. The presence of large platelets on the smear or measured as a high mean platelet volume suggests accelerated thrombopoiesis and increased platelet destruction. The differential diagnosis of thrombocytopenia is noted in Table 38.5.

After the presumptive diagnosis of ITP, a Coombs test may be considered to rule out a simultaneous autoimmune hemolytic anemia. The role of studies for platelet antibodies is unclear; there are no data indicating that these studies are either diagnostic or prognostic in children. If the child is male, is young, and has a history of eczema or recurrent infection, immunoglobulin levels to rule out **Wiskott–**

Aldrich syndrome are indicated. Similarly, in older children, especially girls as they approach adolescence, an antinuclear antibody test to rule out **SLE** manifesting as thrombocytopenia may be considered, although it is more likely to yield positive results in children with chronic ITP. **HIV** infection occasionally manifests as ITP. The diagnostic yield of bone marrow examination in a child with normal findings on a careful physical examination (no lymphadenopathy or hepatosplenomegaly) and a completely normal CBC including a manual white blood cell differential, other than isolated thrombocytopenia, is negligible.

Once a diagnosis of ITP is made, several therapeutic options are available, including simple observation and education. The family should be advised that the child must avoid activities that increase the risk of head injury. Treatment should be reserved for children at high risk for clinical bleeding (platelet count <20,000/mm³ and children with petechiae and mucosal hemorrhages). Some authorities argue that patients with mucous membrane purpura are at higher risk and definitely require treatment. Treatment is not recommended for patients without bleeding symptoms. The major cause of mortality in ITP is related to intracranial hemorrhage, which has been observed in fewer than 0.5-1% of patients. Table 38.6 provides a perspective on treatment alternatives for ITP. Options for initial therapy for patients

TABLE 38.5   Differential Diagnosis of Thrombocytopenia in Children

I. Destructive Thrombocytopenias		**II. Impaired or Ineffective Production**	
Primary platelet consumption syndromes	Idiopathic thrombocytopenia purpura Drug–induced thrombocytopenia Infection-induced thrombocytopenia (human immunodeficiency virus)	Congenital and hereditary disorders	TAR syndrome Other congenital thrombocytopenias with megakaryocytic hypoplasia Fanconi aplastic anemia Bernard–Soulier syndrome*
Immunologic	Posttransfusion purpura Autoimmune or lymphoproliferative disorders Neonatal immune thrombocytopenias Allergy and anaphylaxis Posttransplantation thrombocytopenia Chronic microangiopathic hemolytic anemia and thrombocytopenia Hemolytic uremic syndrome	Primary hematologic processes	May–Hegglin anomaly* Wiskott–Aldrich syndrome* Miscellaneous hereditary thrombocytopenias (X-linked or autosomal)* Mediterranean thrombocytopenia Associated with trisomy 13 or 18
Nonimmunologic	Thrombotic thrombocytopenic purpura Catheters, prostheses, or cardiopulmonary bypass Congenital or acquired heart disease	Metabolic inborn errors	Holocarboxylase synthetase deficiency Isovaleric acidemia Some mitochondrial disorders Methylmalonic acidemia Ketotic glycinemia
Combined platelet and fibrinogen consumption syndromes	Disseminated intravascular coagulation Kasabach–Merritt syndrome Other causes of local consumption coagulopathy	Acquired disorders	Aplastic anemia Marrow infiltrative processes Drug or radiation induced Nutritional deficiency states (iron, folate, or vitamin B₁₂)
Miscellaneous causes	Phototherapy Perinatal aspiration syndromes Persistent pulmonary hypertension Rhesus alloimmunization	**III. Sequestration**	Hypersplenism Hypothermia
Specific to the neonate	Status post exchange transfusion Polycythemia Metabolic inborn errors of metabolism Maternal HELLP syndrome Glomerular disease Preeclampsia		

*These hereditary thrombocytopenias can be associated with normal or increased bone marrow megakaryocytes.
HELLP, hypertension, elevated liver enzymes, low platelets; TAR, thrombocytopenia–absent radius.

TABLE 38.6 Common Treatment Alternatives for Childhood Acute Immune Thrombocytopenic Purpura (ITP)

Drug	Route of Administration	Pros	Cons	Cost (Assuming Typical 15 kg Toddler)
IVIG	IV	Rapid onset of action Does not rely on patient/family giving medication at home Effective in 75–80% of patients	IV required Either inpatient or prolonged (4–6 hr) visit to clinic Does not alter long-term outcome	$3000 for 1 mg/kg dose
Prednisone	Oral (can also be given IV)	Outpatient administration Rapid onset of action Effective in 75–80% of patients Does not require placement of an IV Short course likely minimal side effects	Steroid side effects (GI, mood swings, growth issues with long-term use) May need multiple courses No effect on long-term outcome	2-wk course of 2 mg/kg/day: $15
Rituximab	IV	Durable remission in 40–60%	IV administration May cause reactivation of hepatitis	4 doses of 375 mg/m^2, approximately $5000–15,000
Splenectomy	Surgery	Curative in 80% of patients	Expensive Invasive Impairs host defense against encapsulated organisms Reserved for chronic ITP and/or serious bleeding complications	$10,000–$20,000
Thrombopoietin agonists	Oral (options also come as IV, SQ)	Noninvasive Outpatient treatment	Associated with elevation in liver enzymes Require frequent monitoring Not curative, most patients require ongoing administration	1-mo course of 25 mg/day, $3000

GI, gastrointestinal; IV, intravenous; IVIG, intravenous immunoglobulin; SQ, subcutaneous.

in need of treatment include intravenous immunoglobulin (IVIG) and prednisone. Transfusion of platelets should be reserved for life-threatening bleeding, because transfused platelets are rapidly destroyed. Thrombopoietin receptor agonists have been approved for use in adults.

Ten to 20% of children with ITP have persistence of thrombocytopenia for more than 6 months (**chronic ITP**). These patients are more likely to be older (adolescent) girls or to have had an insidious onset of symptoms. The clinician must look carefully for predisposing causes, including SLE, HIV infection, autoimmune lymphoproliferative syndrome (ALPS), or medications. The treatment of chronic ITP is evolving and includes repeated doses of IVIG, prolonged steroid use, and consideration of rituximab, thrombopoietin receptor agonists, or splenectomy. Because of improved medical therapy, splenectomy is limited to patients with severe, refractory chronic ITP.

Neonatal Thrombocytopenia

Thrombocytopenia is common, especially in sick newborns. The differential diagnosis of neonatal thrombocytopenia includes most of the causes seen in older children and a few additional specific to the newborn (Fig. 38.8, in the shaded areas; see also Table 38.5). When evaluating the thrombocytopenic newborn, the physician must know the perinatal history including the mother's health during this and previous pregnancies, history of current or previous low platelets, or of children dying of hemorrhage. A maternal history of fever, viral infection (cytomegalovirus, rubella), sexually transmitted infections (syphilis, HIV), medications, toxemia, or collagen vascular disease (SLE) is informative. The family history should be evaluated for bleeding disorders, recurrent infections, or malignancies, especially in siblings, both as neonates or any age.

During examination of the newborn, the most important element to determine is the child's general well-being. The examiner should look especially for signs of systemic illness, as well as lymphadenopathy, hepatosplenomegaly, mass lesions, hemangiomas, bruits, and congenital anomalies, especially of the radial bones. The examiner should carefully evaluate the hemoglobin, the white blood cell count, and the differential for the presence of abnormal cells (blasts). Red blood cell structure should be examined for signs of microangiopathy. Small platelets (low mean platelet volume) suggest abnormal thrombopoiesis, whereas large platelets are found with accelerated platelet destruction. *Thrombocytopenia can be caused by synthetic failure, sequestration, or destructive processes.* The destructive processes are most common and are either immune or nonimmune in origin. Nonimmune causes of platelet consumption—for example, DIC, sepsis, congenital infections, or thrombotic events—are usually associated with obvious clinical findings. When evaluating the ill-appearing neonate or child for thrombocytopenia, the examiner should perform coagulation studies to detect fibrinogen consumption (fibrinogen level, D-dimer). Neonates with immune-mediated platelet destruction usually appear healthy.

After the clinician obtains a thorough history, performs a careful physical examination, and evaluates the CBC, the initial step in management of the child with thrombocytopenia depends on the cause and severity of the thrombocytopenia. In the neonate with severe thrombocytopenia (platelet count <40,000/mm^3) delivered vaginally, an ultrasound study of the head should be done to rule out intracranial bleeding. Platelet transfusion for thrombocytopenia can serve both as a therapeutic tool for stopping the bleeding and as a diagnostic maneuver. In patients with decreased platelet synthesis, survival of transfused platelets should be normal, whereas in thrombocytopenic states caused

FIGURE 38.8 Differential diagnosis of childhood thrombocytopenic syndromes. The syndromes are initially separated by their clinical appearance. Clues leading to the diagnosis are presented in italics. The mechanisms and common disorders leading to these findings are shown in the lower part of the figure. Disorders that commonly affect neonates are listed in the shaded boxes. DIC, disseminated intravascular coagulation; HIV, human immunodeficiency virus; ITP, idiopathic immune thrombocytopenic purpura; MCV, mean corpuscular volume; NATP, neonatal alloimmune thrombocytopenic purpura; SLE, systemic lupus erythematosus; TAR, thrombocytopenia–absent radius (syndrome); TTP, thrombotic thrombocytopenic purpura; UAC, umbilical artery catheter; VWD, von Willebrand disease; WBC, white blood cell; 2°, secondary.

by platelet destruction, transfused platelets should be cleared rapidly. For this reason, platelet transfusions are usually contraindicated in thrombocytopenic states caused by accelerated platelet destruction, as in ITP and hemolytic uremic syndrome (except in the event of life-threatening bleeding such as intracranial hemorrhage). The yield and survival of the transfused platelets should be monitored with serial platelet counts after transfusion.

Antibody-mediated thrombocytopenia in the neonate is caused by transfer of maternal IgG antibodies that react with the neonate's platelets. A mother with active ITP or a history of previous ITP is at risk for delivering a thrombocytopenic baby. There is no definitive, noninvasive method to determine the newborn's risk of thrombocytopenia, although the actual risk for severe bleeding during delivery appears low. In contrast, children born to mothers who are sensitized to paternal alloantigens present on the fetal platelets have a higher risk

for perinatal hemorrhage and symptomatic thrombocytopenia. **Neonatal alloimmune thrombocytopenic purpura (NATP)**, the platelet equivalent of maternal Rh isoimmunization, differs from Rh disease in that first-born children are commonly affected. The importance of this diagnosis is that it is commonly associated with prenatal intracranial hemorrhage with a resultant high rate of morbidity and mortality (15%). Therefore, recognition of the diagnosis in the 1st pregnancy can have a major impact on the management of subsequent pregnancies. Transfusion of washed maternal platelets that lack the paternal alloantigen toward which the maternal antibody is directed will correct the platelet count and prevent further bleeding. Random donor platelets are rapidly destroyed. Newborns with NATP can be easily differentiated from thrombocytopenic newborns of mothers with ITP on the basis of the mother's platelet count. Mothers with ITP are thrombocytopenic unless they have had a splenectomy. Mothers of infants with NATP have normal platelet counts.

Although the initial diagnosis of NATP is usually made by studying the reaction of maternal sera against paternal platelets, prenatal diagnosis is performed with molecular biologic techniques to detect the allelic differences between the mother and the fetus by analysis of various fetal DNA sources. After prenatal diagnosis, treatment of the mother with IVIG has been shown to raise the fetal platelet count and prevent fetal bleeding. In addition, postnatal treatment of the neonate with IVIG and corticosteroids may be helpful after restoration of a normal platelet count by transfusion of washed maternal platelets. *All blood products administered to the neonate with thrombocytopenia should be radiated to prevent graft-versus-host disease, because some patients may have a congenital immunodeficiency syndrome manifested by thrombocytopenia.*

Child Abuse

The most common cause of remarkable bruising and bleeding with normal hemostatic screening studies in infancy is child abuse.

Chronic/Insidious Onset of Mucocutaneous Bleeding

When symptoms of skin and mucous membrane bleeding are lifelong, the most common cause is von Willebrand disease (VWD). Congenital platelet function defects are almost as common, while congenital thrombocytopenic syndromes, and abnormalities of the vessel wall are less common. Von Willebrand disease, the deficiency of VWF, is the most common hereditary bleeding disorder, with a prevalence of approximately 1/1000 in the milder forms. The inheritance of von Willebrand disease is usually autosomal dominant. VWF is a large, multimeric protein that functions as the bridge between platelets and damaged vessel walls; therefore, deficient or dysfunctional VWF causes delayed formation of the platelet plug (see Fig. 38.3). In addition, VWF serves as a carrier protein for factor 8. A profound deficiency of VWF is associated with low levels of factor 8, so that the patient with severe von Willebrand disease has the clinical manifestations of both von Willebrand disease and hemophilia.

The presentation of von Willebrand disease is highly variable. Mucocutaneous bleeding or no symptoms are the most common findings. Because neonatal VWF levels are often elevated after vaginal delivery, the onset of clinical symptoms for mild and moderate von Willebrand disease is usually during the toddler stage or later. The only presenting complaint may be abnormal preoperative coagulation studies. The laboratory diagnosis of the disease is particularly challenging because there is no single test that optimally measures VWF function.

The PTT and bleeding time are only abnormal in about half of patients with von Willebrand disease. A von Willebrand screen, including VWF antigen (to measure total protein) and activity (to measure

protein function) is recommended to fully assess for von Willebrand disease. The need for additional work-up is defined by the clinical clues, including the patient's personal history of bleeding, the family history, and the potential for surgery.

The diagnosis of von Willebrand disease is further complicated by the observation that VWF is a labile protein and levels can be increased by stress, medication, trauma, pregnancy, and difficult venipuncture. VWF levels are also elevated following vaginal delivery in infants with type 1 VWD. This can be helpful in terms of ability to perform circumcision in males with potential type 1 VWD, but problematic in terms of making an immediate diagnosis. It remains unclear whether there is a physiologically different hemostatic level of VWF for different blood groups. Age has been shown to influence VWF levels in adults, but this has not been adequately investigated in children. Furthermore, there are multiple variants of von Willebrand disease; the clinician should perform repeated studies if there is a high index of suspicion or abnormal positive screening tests.

Von Willebrand disease can be classified as type 1 (classic disease with mild or moderate deficiency), type 2 (a dysproteinemia), or type 3 (severe disease: virtual absence of VWF and low levels of factor 8). The treatment of the disease is dependent on the type and the response to 1-deamino(8-D-arginine) vasopressin (DDAVP). DDAVP is a synthetic vasopressin analog that induces the release of VWF and factor 8. Levels of these factors rise threefold to fourfold after a dose of 0.3 μg/kg. For most cases of von Willebrand disease, DDAVP is the treatment of choice. A therapeutic trial with measurements of VWF before and both 1 hour and 4 hours after DDAVP administration should be performed to document the efficacy of DDAVP before surgery. The late timepoint is useful to identify clearance defects that may have an initial response but lack the sustained response critical for clinical use of DDAVP. Patients with rare variant forms of von Willebrand disease (type 2A, type 2B, and platelet type) may have no response or an adverse response to DDAVP; therefore, full studies to identify the subtype are needed before a trial of DDAVP. These studies correlate functional levels of VWF with the amount of protein measured antigenically (the VWF antigen), the multimeric size of the protein (VWF multimers), and the aggregation response of the patient's platelet-rich plasma to high and low concentrations of ristocetin.

Most patients with mild and moderate type 1 von Willebrand disease have a satisfactory response to DDAVP; hemostasis for most surgical procedures can be provided with daily doses of DDAVP on consecutive days. For severely affected patients or those with variant forms of the disease noted previously (type 2A, type 2B, platelet type), treatment should be individualized. Some patients with type 2A respond to DDAVP. Severely affected patients with von Willebrand disease and those with the 2B variant should receive a clotting factor concentrate containing a full complement of normal VWF multimers (Humate-P or Wilate are the currently approved products) in doses similar to those outlined for factor 8 in Table 38.7.

Platelet Function Defects

For patients with mucocutaneous bleeding but a normal platelet count and normal VWF studies, platelet aggregation studies should be performed to evaluate for a primary or secondary platelet function defect. A large number of medications alter platelet function and may induce an acquired abnormality of platelet function. A careful history to elicit exposure to medications and to determine whether clinical symptoms correlate with exposure to specific drugs is critical. Common medications that alter platelet functions are aspirin, nonsteroidal antiinflammatory drugs, alcohol, penicillin in high doses, and valproic acid.

Most primary platelet function defects cause relatively mild mucocutaneous bleeding symptoms. In these disorders, there is most

commonly an abnormality of the storage granules or release mechanism within the platelet, causing delayed or diminished response to agonists that induce platelet aggregation, such as collagen. Platelet function defects, like most other hemostatic defects, are accentuated by medications that impair platelet function. In rare instances, a patient demonstrates impressive petechiae and hematomas at birth because of an absence of 1 of the essential platelet membrane receptors for the adhesive proteins VWF or fibrinogen. These disorders, Glanzmann thrombasthenia (deficiency of glycoprotein αIIbβ3, the fibrinogen receptor) and Bernard–Soulier syndrome (deficiency of glycoprotein Ib, the von Willebrand receptor), represent the most severe types of platelet function defects. The platelet count is normal in Glanzmann thrombasthenia thrombocytopenia, but patients with Bernard–Soulier syndrome usually have thrombocytopenia with remarkably large platelets.

Milder thrombocytopenia syndromes have been well characterized due to advances in genetics; a defect in the myosin heavy chain 9 gene (MYH9) causes congenital macrothrombocytopenia, associated in some cases with deafness, ocular abnormalities, or nephritis. Congenital amegakaryocytic thrombocytopenia is caused by a defect in the thrombopoietin receptor c-Mpl, while X-linked thrombocytopenia is caused by a defect in GATA-1. Patients with mild or moderate platelet function defects often respond to DDAVP, but more severe bleeding may necessitate platelet transfusions.

Chronic Thrombocytopenic Syndromes

Patients with long-standing thrombocytopenia usually present with mucocutaneous bleeding. Mechanisms of the thrombocytopenia include impaired marrow synthesis, sequestration, and increased destruction (see Fig. 38.8). These can be acquired or congenital. The **congenital thrombocytopenic syndromes** usually manifest at the time of birth or early in infancy. These syndromes may be associated with congenital anomalies (thrombocytopenia–absent radius syndrome and Fanconi anemia) or as part of a complex hereditary syndrome

(Wiskott–Aldrich syndrome with small platelets, eczema, and immunodeficiency) in addition to thrombocytopenia. Small platelets are a frequent finding in many of the syndromes associated with decreased platelet production. During the physical examination of patients with suspected congenital thrombocytopenia, the clinician must search not only for the signs of bleeding but also for subtle congenital anomalies, including abnormal growth parameters, the presence of skin hyperpigmentation or café-au-lait spots, and anomalies of the limbs, axial skeleton, and urinary tract.

The **acquired causes of thrombocytopenia** resulting from decreased production usually have an insidious onset of symptoms and are often associated with other abnormalities in the blood count. The aplastic syndromes (congenital aplastic anemia and acquired aplastic anemia) are associated with the gradual onset of thrombocytopenia, usually in association with a falling granulocyte count and anemia. Platelets are small, and the mean corpuscular volume is usually elevated.

Infiltration of the marrow by malignant cells or storage cells interferes with normal thrombopoiesis and commonly results in thrombocytopenia. Common malignancies associated with thrombocytopenia include acute lymphoblastic leukemia, lymphomas, Langerhans cell histiocytosis, and metastatic solid tumors (neuroblastoma). Abnormalities of other blood elements, as well as findings of adenopathy, hepatosplenomegaly, or masses, are clues to the presence of an infiltrative disorder.

Disorders of the vessel walls may present either acutely or chronically. Vasculitic disorders often manifest with lesions of the skin and mucous membranes that appear hemorrhagic and are associated with clinical symptoms related to involvement of other organ systems (gastrointestinal, renal, central nervous system). Paradoxically, patients with these disorders usually have normal coagulation studies and normal platelet counts. Henoch–Schönlein purpura is an example; it manifests with a purpuric rash, including both petechiae and larger palpable purpuric lesions of the lower extremities and buttocks, often found in association with arthritis, cramping abdominal pain, and focal glomerulonephritis.

Petechiae and ecchymoses are also common symptoms of disorders of the collagen matrix. Patients with Ehlers–Danlos syndrome have lax joints, hyperelastic skin, and abnormal wound healing. These patients frequently present with ecchymoses and rarely with petechiae. Bleeding time is usually prolonged and the diagnosis is made on the basis of clinical findings.

DEEP BLEEDING

Bleeding into the tissues of the muscles or joints is characteristic of hemophilia. The presentation of the patient with hemophilia varies with severity, age, and exposure to trauma. Only 30% of boys with hemophilia bleed excessively at circumcision, while neonatal intracranial bleeding is rare despite the trauma of a vaginal delivery. After the neonatal period, children with hemophilia usually present as toddlers with either intramuscular hematomas or hemarthroses. In the toddler stage, the most commonly affected joints are the ankles and elbows; the knees, hips, and shoulders are affected later. The affected children, who are usually boys, bruise easily and hematomas frequently develop over areas of common trauma (the forehead, arms, and legs, especially pretibial). Other common bleeding sites include the frenulum and sites of venipuncture. Sites of life-threatening bleeding include the central nervous system (the most common cause of death from hemorrhage); the mouth and throat, resulting in airway obstruction; and the retroperitoneal area or gastrointestinal tract, leading to exsanguination.

Red flags for the diagnosis of hemophilia are:
- Persistent bleeding after circumcision
- Hemarthrosis/intramuscular hematoma
- Bleeding frenulum

The deficiency of factor 8 (hemophilia A) or factor 9 (hemophilia B) causes bleeding because delayed thrombin formation results in a large, friable clot. Often there is an initial hemostatic plug that breaks down hours after the injury (secondary bleeding). Because factors 8 and 9 are necessary for normal wound healing, patients with inadequate replacement or untreated hemophilia frequently have poorly healed wounds.

Hemophilia A occurs in 1/10,000 live births and hemophilia B in about 1/40,000. The PTT is prolonged and should correct on 1:1 mix with normal plasma. Specific assays for factors 8 and 9 should be performed to identify the deficient factor. Severity is determined by the level of the deficient clotting factor. Severe hemophilia is defined as less than 1% factor activity, moderate as 1-5% activity, and mild as greater than 5% activity. These factor levels correlate approximately with clinical symptoms: Patients with severe deficiency bleed spontaneously; patients with moderate deficiency bleed with minor trauma; and patients with mild deficiency bleed only after significant trauma, and their condition may go undiagnosed for many years. Because hemophilias A and B are transmitted as X-linked traits, the family history may be informative if there is a history of male maternal relatives with a bleeding disorder. Approximately 33% of affected patients have new mutations and therefore have a negative family history. Bleeding complications have occurred in female carriers, especially at surgery; thus, all carriers should have factor levels measured.

Treatment of hemophilia requires prompt replacement or correction of the deficient factor with the safest available material. Table 38.7 provides dosing information and therapeutic alternatives for factors 8 and 9 deficiency. Treatment of bleeding episodes should be continued until the wound has healed. Recombinant factor 8 or 9 concentrate appears to be the current optimal treatment product, with purified plasma-derived factor as a 2nd choice. Long-acting factor products are being developed and may improve quality of life by reducing the frequency of infusions. For patients with mild hemophilia A who respond to DDAVP with adequate levels, DDAVP is the treatment of choice. Prophylaxis with factor concentrates has revolutionized the care of children with hemophilia by preventing chronic arthropathy and muscular atrophy. Patients with hemophilia should be monitored at comprehensive treatment centers that are experienced in the medical, social, physical, and financial impact of hemophilia care.

The common complications of hemophilia treatment can be divided into those of immunologic origin and those caused by infectious organisms. In 15-25% of patients with hemophilia A and a smaller percentage of patients with hemophilia B, inhibitors to clotting factor replacement material develop. These inhibitors, usually IgG antibodies, lead to rapid inactivation and clearance of infused replacement material. The presence of an inhibitor should be suspected and tested for in any patient with hemophilia who does not respond appropriately to factor replacement. The treatment of patients with inhibitors is problematic and should be relegated to experts in hemophilia care. The management of acute bleeding episodes may require administration of an activated clotting factor concentrate to "bypass" the inhibitor.

Infectious complications of hemophilia therapy were once exceedingly common but, fortunately, have been curtailed by donor screening, sophisticated viral inactivation processes, and chemical purification techniques used in the preparation of plasma-derived replacement material. Recombinant factor concentrates represent the culmination of these efforts. Older patients treated before 1983 with concentrates were exposed to HIV, hepatitis C, and sometimes to hepatitis B. Most

patients exposed to HIV became infected and manifested the spectrum of signs and symptoms of HIV infection. Viral inactivation techniques in conjunction with intense donor screening for hepatitis C antibody have greatly decreased the risk for hepatitis C exposure. Nevertheless, chronic non-A, non-B hepatitis is a common finding in older patients with hemophilia who were treated with concentrates.

The need for intravenous access to provide factor infusions creates another complication with the use of indwelling central venous catheters to facilitate factor delivery to young children with poor venous access. While some patients can be treated with less frequent dosing through peripheral veins, some patients undergo surgery for placement of a central venous catheter. Although these catheters undoubtedly increase adherence to prophylactic treatment, they can serve as a nidus for infection, thrombosis, or lead to complications due to surgery required for insertion or removal.

Surgical Bleeding

Aside from technical causes, most surgical bleeding results from a failure to recognize a preexisting coagulopathy. Von Willebrand disease and primary or secondary platelet dysfunction are the most common causes of bleeding after ear, nose, and throat surgery. Significant hemorrhaging after general surgery is often a manifestation of previously undiagnosed mild or moderate hemophilia or vitamin K deficiency.

When elective surgery is planned, the decision to perform preoperative hemostatic screening is influenced by the patient's age (and therefore previous exposure to trauma), personal and family histories of bleeding, and type of surgery. Certain surgeries, such as tonsillectomy, scoliosis repair, and central nervous system surgery, provide major challenges to hemostasis, having a high frequency of bleeding complications. In contrast, most general surgical procedures, such as hernia repair, rarely involve clinical bleeding. The diagnostic yield of preoperative studies before tonsillectomy and adenoidectomy remains controversial.

GENERALIZED BLEEDING

Generalized bleeding is a manifestation of a major disorder of hemostasis, usually caused by a deficiency of multiple factors in association with deficient or dysfunctional platelets. Generalized bleeding occurs most commonly in the context of DIC in seriously ill patients.

Disseminated Intravascular Coagulation

DIC is a generalized consumption of clotting factors, anticoagulant proteins, and platelets triggered by a life-threatening illness and usually accompanied by ischemia, hypoxia, and shock (Table 38.8). DIC may be either a hemorrhagic or a thrombotic disorder, or both, inasmuch

---

TABLE 38.8 Causes of Disseminated Intravascular Coagulation Infection

Infection	**Gastrointestinal Disorders**
Meningococcemia (purpura fulminans)	Fulminant hepatitis
Other gram-negative bacteria (*Haemophilus* species, *Salmonella* species, *Escherichia coli*)	Severe inflammatory bowel disease
	Reye syndrome
Gram-positive bacteria (group B streptococci, staphylococci)	
Rickettsiae (Rocky Mountain spotted fever)	**Hereditary Thrombotic Disorders**
Virus (cytomegalovirus, herpes, hemorrhagic fevers)	Antithrombin deficiency
Malaria	Homozygous protein C deficiency
Fungus	
	Neonatal Disorders
Tissue Injury	Maternal toxemia
Central nervous system trauma (massive head injury)	Group B streptococcal infections
Multiple fractures with fat emboli	Abruptio placentae
Crush injury	Severe respiratory distress syndrome
Profound shock or asphyxia	Necrotizing enterocolitis
Hypothermia or hyperthermia	Congenital viral disease (cytomegalovirus, herpes)
Massive burns	Erythroblastosis fetalis
Malignancy	**Miscellaneous Disorders**
Acute promyelocytic leukemia	Severe acute graft rejection
Acute monoblastic or myelocytic leukemia	Acute hemolytic transfusion reaction
Widespread malignancies (neuroblastoma)	Severe collagen vascular disease
	Kawasaki disease
Venom or Toxin	Heparin-induced thrombosis
Snake bites	Infusion of "activated" prothrombin complex concentrates
Insect bites	Hyperpyrexia/encephalopathy, hemorrhagic shock syndrome
Microangiopathic Disorders	
"Severe" thrombotic thrombocytopenic purpura or hemolytic uremic syndrome	
Giant hemangioma (Kasabach–Merritt syndrome)

as the clinical manifestations of this generalized coagulopathy are highly variable. Laboratory studies usually demonstrate a prolonged PT, decreased fibrinogen level, and decreased platelet level (these are the most reliable indicators of DIC), in addition to elevated D-dimer levels and a prolonged PTT.

Several mechanisms can trigger acute DIC, including widespread endothelial damage induced directly or indirectly by infectious organisms and release of procoagulant material after trauma. Virtually any life-threatening illness can trigger DIC. In acute DIC, activation of the clotting mechanism leads to consumption of clotting factors (1, 2, 5, 8), anticoagulant proteins (C, S, AT, plasminogen), and platelets. In the syndrome known as purpura fulminans, microvascular thromboses develop in the skin, causing painful purpuric lesions that progress to localized necrotic lesions. Table 38.9 presents laboratory findings in DIC in comparison with those in other acquired coagulopathies that potentially could be confused with DIC. Because DIC is virtually always seen in a child with a life-threatening illness, the clinical diagnosis is usually made on the basis of the child's clinical appearance in association with laboratory abnormalities. Clotting factor and anticoagulant protein levels are confirmatory but seldom necessary to reach a diagnosis of DIC. The only diagnosis difficult to differentiate from DIC in the laboratory is that of severe hepatic disease with impending liver failure. The patient with severe liver disease is markedly jaundiced and the thrombocytopenia is relatively mild.

The treatment of DIC focuses on the cause of the DIC, on the altered homeostasis that sustains the coagulopathy, and on the bleeding or thrombotic complications that ensue. Shock itself plays a critical role in DIC because shock reduces the reticuloendothelial clearance of activated clotting factors and complexes. Reduced hepatic blood flow causes decreased synthesis of depleted clotting and anticoagulant proteins.

To summarize the treatment of DIC:
1. Treat the initiating and propagating events.
2. Optimize cardiorespiratory status by improving perfusion and correcting acidosis.
3. Replace deficient platelets, clotting factors, and anticoagulant proteins (Table 38.10) if needed. Specific indications for replacement are variable and depend on the patient's clinical condition and severity of bleeding.

The following are rough guidelines for treatment:
- Fresh-frozen plasma, 10-15 mL/kg every 6-12 hours, to provide clotting factors
- Platelets, ½-1 single donor apheresis unit for platelet count less than 50,000/mm³
- Cryoprecipitate, 1 bag/5 kg for fibrinogen level less than 100 mg/dL
- Anticoagulant therapy for major vessel thrombosis

The efficacy of anticoagulant therapy in DIC has not been proved in controlled prospective studies. Heparin has been used for the

TABLE 38.9   Differential Diagnosis of Coagulopathies That Can Be Confused with Disseminated Intravascular Coagulation

	Prothrombin Time	Partial Thromboplastin Time	Fibrinogen	Platelets	Clinical Keys
DIC	Increased	Increased	Decreased	Decreased	Shock
Liver failure	Increased	Increased	Decreased	Normal or decreased	Jaundice
Vitamin K deficiency	Increased	Increased	Normal	Normal	Malabsorption, GI or liver disease
Sepsis without shock	Increased	Increased	Normal	Normal	Fever

DIC, disseminated intravascular coagulation; GI, gastrointestinal.

TABLE 38.10   Commonly Used Hemostatic Agents*

Component	Contents	Usual Dose	Comments/Disadvantages
FFP (unit)	1 U/mL of each clotting factor	10–15 mL/kg	Large volume Infectious risk
Cryoprecipitate (1 bag)	100 units factor 8/bag 150 mg fibrinogen/bag Factor 13, fibronectin	0.2 bag/kg	Infectious risk
Platelets (unit)	$5.0–7.0 \times 10^{10}$ platelets in 30–60 mL of plasma	½ – 1 single donor apheresis unit	Infectious risk
Factor concentrates (unit)	Units as labeled	Factor 8, 20–50 U/kg Factor 9, 30–130 U/kg	Recombinant
Desmopressin	4 µg/mL	0.3 µg/kg/dose	Increases factor 8 and VWF Improve platelet function Also used in uremia, liver disease Risk for hyponatremia (rare if fluid restriction observed)
AT concentrate	Units as labeled	(Desired AT − baseline AT) × weight (kg)/1.4	Plasma derived or recombinant available

treatment of purpura fulminans, acute promyelocytic leukemia, and thromboses that develop in conjunction with DIC. Most patients with DIC have a coagulopathy that consumes procoagulant proteins and causes clinical oozing or bleeding; in a small percentage of patients, however, thrombosis develops. In these patients, anticoagulant therapy may decrease morbidity and should be administered in a manner similar to that for those patients who have major vascular thrombosis (Table 38.11). Deficient clotting factors and platelets should be transfused to prevent further development of thrombosis or bleeding during anticoagulation.

Neonatal Purpura Fulminans

The differential diagnosis of a neonate who presents with multiple purpuric lesions over the buttocks, trunk, extremities, and face (nose, ears) that change from dark red to purple and black over a few minutes in association with abnormal neurologic findings or an abdominal mass includes sepsis with DIC and a generalized viral infection. A key finding in such a neonate for a homozygous protein C deficiency is the presence of painful petechiae and purpura (purpura fulminans). After viral and bacterial cultures, diagnostic studies should include a CBC and coagulation screening for DIC, as well as measurements of protein C, protein S, AT3, and plasminogen.

To confirm this diagnosis, the clinician must differentiate DIC from congenital protein C deficiency. DIC is characterized by the consumption of clotting factors, anticoagulant proteins, and platelets. Although protein C levels fall in DIC, patients with congenital protein C deficiency have strikingly low levels of protein C. Anticoagulant proteins are routinely consumed in situations of widespread activation of the clotting mechanism. Therefore, mildly depressed levels of protein S, AT3, and plasminogen would be expected when there is generalized intravascular coagulation. In congenital protein C deficiency, the protein C level is strikingly lower than that of the other anticoagulant proteins, which increases the likelihood that the deficiency of protein C represents the primary cause of the coagulopathy. To determine whether the deficiency is hereditary, the next step is to obtain blood samples from the parents to measure levels of the deficient protein or proteins. In homozygous deficiencies, the levels of both parents should be reduced. Deficiency of protein C, protein S, or AT usually manifests as venous thromboembolic

disease in adulthood and is inherited as a co-dominant trait. Congenital severe, symptomatic protein C deficiency is usually inherited in an autosomal recessive manner from asymptomatic parents.

Therapy must be instituted promptly to replace the deficient anticoagulant protein with fresh-frozen plasma. Fresh-frozen plasma contains all of the clotting factors in an unconcentrated form. Protein C has a short half-life and may need to be infused every 6-12 hours to maintain measurable levels. This, unfortunately, leads to problems with fluid and protein overload if repeated doses of plasma are necessary. *Protein C concentrate* is now available as specific therapy for patients with protein C deficiency. The patient should also undergo anticoagulation with heparin to limit further thromboses. A striking improvement after administration of protein C, either as plasma or as concentrate, is strong evidence of the diagnosis. Warfarin therapy has been effective in managing such patients on a chronic basis.

Other Causes of Generalized Bleeding

A coagulopathy is a common complication of severe liver disease, resulting from deficient production of multiple clotting factors and anticoagulant proteins in association with increased D-dimer formed as a result of hyperfibrinolysis. This may contribute to inhibition of platelet function.

Uremia results in a diffuse bleeding diathesis, with mucosal bleeding (epistaxis, gastrointestinal bleeding) as a major manifestation. The major underlying mechanism in uremic bleeding appears to be increased nitric oxide generation, leading to abnormal platelet function. Many patients with bleeding caused by uremia or liver disease respond to DDAVP.

Vitamin K deficiency manifests as generalized bleeding into the skin, gastrointestinal tract, and central nervous system. Children at highest risk are breast-fed neonates, malnourished individuals, those receiving broad-spectrum antibiotics, those with cholestatic liver disease and subsequent vitamin K malabsorption, and those who have ingested rat poison (warfarin). The treatment of patients with vitamin K deficiency is parenteral vitamin K. The response is usually rapid, but in emergency situations, transfusion of fresh-frozen plasma corrects the coagulopathy faster. Differentiation of some of these syndromes from DIC is presented in Table 38.9.

THROMBOSIS

Thromboembolic disease in pediatrics has a bimodal age distribution. Venous and arterial thrombi are common in newborns, especially in premature neonates, because of the combination of low levels of anticoagulant proteins, decreased blood flow, elevated blood viscosity because of high hematocrit, and, in particular, because of the placement of intravascular catheters for monitoring and nutrition. The second peak of thromboembolic disease, usually venous in character, is in adolescence, when patients with primary deficiencies of anticoagulant proteins typically present and when secondary disorders (e.g., vasculitis, pregnancy, malignancy, surgery, major trauma, inflammatory bowel disease, and infection) induce a higher frequency of venous thrombosis.

Venous Thromboembolic Disease
Diagnostic Approach
Venous thromboembolic disease classically manifests with a warm, swollen, tender extremity or affected organ. The differential diagnosis in such cases includes trauma, infection, stasis without thrombosis, lymphedema, edema, and neoplasm. In children and adolescents, thrombi may develop within major internal organs with distinctive clinical manifestations, including sagittal sinus thrombosis with resultant increased intracranial pressure; hepatic vein thrombosis with the **Budd-Chiari syndrome**; portal vein thrombosis associated with splenomegaly and varices; and **renal vein thrombosis** with a resultant abdominal mass, hematuria, and proteinuria. Long-term central venous access is associated with a significant risk for asymptomatic venous thrombosis. **Pulmonary emboli** may manifest as "atypical" pneumonia resulting in shortness of breath and hypoxemia in the absence of fever. The hypoxemia may occur in the presence of minimal findings on routine chest radiographs.

The clinician should obtain a careful history for antecedent trauma, infection, or other predisposing causes of thromboembolic disease (Table 38.12). The abdomen and extremities should be carefully examined for mass lesions leading to venous stasis. The presence of a bruit or hemihypertrophy of the affected limb is a clue to an arteriovenous malformation. In addition, masses within the bone, abdominal tumors, and lymphatic obstruction should be considered. Initial laboratory studies should include a CBC, platelet count, and evaluation for DIC, as well as cultures of the blood if the patient is febrile. During the process of a localized thrombosis, there may be consumption of clotting factors, but rarely is the consumption significant enough in older children and adults to induce abnormal results on routine coagulation screening tests (platelets, PT, PTT, fibrinogen). Tests for fibrin breakdown (D-dimer) may be positive. Unfortunately, these tests are nonspecific and not necessarily diagnostic of vascular thrombosis. Studies in adults have indicated that a negative assay for D-dimer has a strong negative predictive value for pulmonary embolus, especially when combined with an algorithm for risk assignment. The diagnostic approach to a patient with suspected venous thrombosis is presented in Fig. 38.9.

Specific Diagnostic Studies
Compression ultrasonography is generally used to assess for the presence of a lower extremity thrombosis and many episodes of upper extremity thrombosis. While ultrasound with Doppler flow studies to look at flow of red blood cells through arteries or veins may be sufficient for diagnosis of renal or hepatic thrombosis as well, consideration should be given to other modalities, including computed tomography (CT) scan, echocardiogram, and venography. Magnetic resonance imaging and magnetic resonance venography can be useful in diagnosis of venous dural sinus thrombosis.

Modified from Schafer A. The hypercoagulable states. *Ann Intern Med.* 1985;102:814; and from Behrman RE, Kliegman RM, eds. *Nelson Essentials of Pediatrics.* 2nd ed. Philadelphia: WB Saunders; 1994:56.

If pulmonary embolism is suspected, a spiral CT scan is the diagnostic study of choice. CT scan is indicated in any patient with a venous thrombosis, cardiac and/or respiratory symptoms, including tachycardia, tachypnea, and hypoxia. Pulmonary embolism may be present without significant respiratory distress, and should be considered in patients with chest pain or hemoptysis, particularly following surgery and immobilization.

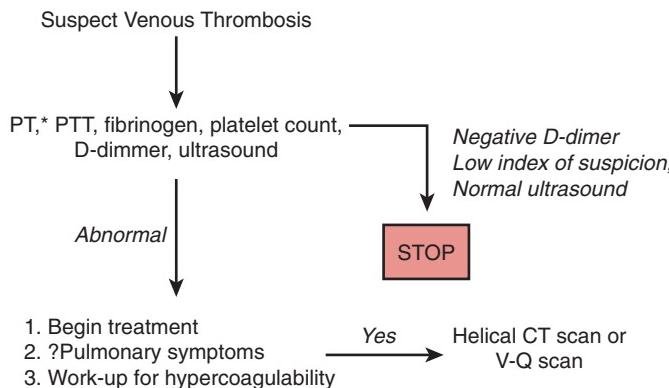
Thrombophilia Testing
In children, the diagnosis of venous thrombosis in the setting of risk factors, such as surgery, immobilization, or catheter placement, does not generally warrant any additional work-up. Adult guidelines specifically recommend against thrombophilia testing in thrombosis in the setting of major transient risk factors. *An unprovoked thrombosis merits work-up for a congenital or acquired thrombophilic condition.*


FIGURE 38.9 Flow diagram for the approach to a patient with venous thromboembolic disease. *See Table 38.12. The INR corrects the PT for institutional differences in reagents and instruments. When a patient is taking a stable warfarin dosage, the INR is calculated by a ratio of the patient's PT to the control PT raised to a correction factor (the International Sensitivity Index) that allows for comparison of different PT reagents and machines in different laboratories. For all patients receiving chronic warfarin therapy, their anticoagulant therapy should be measured as the INR. The INR level should be maintained between 2.0 and 3.0 for effective, safe anticoagulant therapy. An INR exceeding 3.0 has been associated with increased risk for bleeding without improved therapeutic effects for patients with venous thromboembolic disease. CT, computed tomography; PT, prothrombin time; PTT, partial thromboplastin time; V-Q, ventilation-perfusion.

The most severe inherited thrombophilias are deficiencies of anticoagulant proteins C, S, and AT. Although rare, these are associated with a higher relative risk for thrombosis than the more common thrombophilias. Levels of protein C, AT3, and plasminogen may be depleted after development of deep vein thrombosis, pulmonary emboli, or both; low levels do not necessarily imply a congenital deficiency. If low levels are found, studies should be performed on the parents to establish the inheritance of the deficiency because all these are inherited as autosomal co-dominant traits. The patient's levels should be re-evaluated several months after the acute event; the clinician should remember that warfarin reduces functional levels of all the vitamin K-dependent proteins, including proteins C and S.

Less severe, but more common, thrombophilias include **factor 5 Leiden and the prothrombin gene mutation**. These occur in up to 5% of the US population and have a lower relative risk for thrombosis. Testing of asymptomatic family members is not generally required, although affected females should be counseled to avoid estrogen-containing oral contraceptives due to a higher risk for thrombosis.

The **lupus anticoagulant** causes a prolonged PTT that fails to correct on mixing with normal plasma because of the presence of an antibody that reacts with the phospholipid reagent in the PTT. The lupus anticoagulant does not bind in vivo to the platelet membrane; thus, the whole blood clotting time is normal. Paradoxically, the lupus anticoagulant is associated with venous and arterial thromboembolic disease and spontaneous abortions but is usually not a cause of clinical bleeding. If these study findings are negative, the thrombin time should be measured or a comparison of functional and antigenic levels of fibrinogen should be done to detect a dysfibrinogenemia.

Arterial Thrombosis

Arterial thrombi are rare in older children and adolescents and are frequently a manifestation of a systemic disorder resulting in vascular damage or embolic disease such as sickle cell anemia, Kawasaki disease, bacterial endocarditis, periarteritis nodosa, homocystinuria, or cocaine ingestion. The presence of an intraarterial catheter is an obvious nidus for thrombosis. Neck trauma that is often mild can cause carotid or vertebral artery dissection or aneurysms. These dissections or aneurysms can result in emboli to the brain. A history of neck trauma should be sought in older children who present with arterial stroke.

Anticoagulant Therapy
Heparin
Heparin is the most commonly used agent for the initial treatment of venous or arterial thrombosis. Heparin functions as an anticoagulant by binding to AT3 and accelerating the AT3-dependent inactivation of thrombin and factor 10a, as well as of factors 9a and 11a. Although most studies of heparin pharmacokinetics have been performed in adults, there are important differences in the pharmacologic features of heparin in children and especially neonates. Thirty-nine percent of children achieve a prolongation of the PTT within the target range after a bolus dose of 50 U/kg. Children younger than 1 year require an average of 28 U/kg/hr to maintain a therapeutic level of the PTT. In contrast, most children older than 1 year are satisfactorily maintained on 20 U/kg/hr of heparin. One protocol recommends an initial bolus of 50 U/kg of heparin, with 20-25 U/kg/hr for a minimum of 5 days to maintain a PTT of approximately 2-2.5 times the control value. The heparin dose should be adjusted every 4-6 hours until a satisfactory level is attained. Reports in adults suggest that the heparin level is superior for monitoring heparin therapy. Studies have documented an increased risk for recurrent thrombi in patients who failed to achieve adequate anticoagulant levels promptly. Heparin levels are especially useful in premature and full-term newborns who may have a "normal" prolonged PTT. A therapeutic range of 0.3-0.6 U/dL appears to be effective.

Low-molecular-weight (LMW) heparin provides an alternative to standard heparin therapy. Pediatric experience with LMW heparin given subcutaneously is similar to that in adults. LMW heparin given to infants and children with thromboses appears to be as effective as standard heparin, with a similar or reduced risk for bleeding. LMW heparin requires much less laboratory monitoring. The therapeutic dose of the LMW heparin enoxaparin in pediatrics is 1.5 mg/kg for neonates and 1.0 mg/kg every 12 hours for older children.

For long-term anticoagulant therapy, warfarin can be started after the institution of heparin therapy. Total length of therapy for provoked clots should not exceed 3 months, while therapy for unprovoked clots may extend to 6-12 months or indefinitely, depending on the presence of other prothrombotic conditions.

Fibrinolytic Therapy
Fibrinolytic therapy is indicated for serious and potentially life-threatening thrombosis because it provides a more rapid lysis of clots than standard anticoagulant treatment with heparin and is clinically effective in both arterial and venous clots. Because bleeding complications are many times higher than those with heparin in older individuals, the clinical severity of the clot must justify the use of lytic therapy. For smaller thrombi or those in nonvital locations, heparin is safe and effective. Lytic therapy is best used early in the evolution of the thrombus. If the clot has been long-standing, it is unlikely that fibrinolytic therapy will be efficacious.

The presence of any intracranial process, recent major surgery, or recent significant bleeding is an absolute contraindication to fibrinolytic therapy and a relative contraindication to heparin treatment. In patients with a normal cranial sonogram (or CT) and complete occlusion of the aorta or evidence of compromise of major organ function, fibrinolytic therapy has been safely and successfully administered with very careful monitoring. Table 38.11 outlines dose and monitoring studies for 2 commonly used fibrinolytic agents: recombinant TPA and

urokinase. Fibrinolytic therapy appears to result in a more rapid return of pulmonary artery flow after pulmonary emboli and may decrease the likelihood of postphlebitic syndrome after deep vein thrombosis.

Warfarin

Warfarin remains the anticoagulant of choice for long-term oral therapy. Newer oral agents available are less well studied in children. Warfarin acts by blocking the vitamin K–dependent post-translational modification of factors 2, 7, 9, and 10 and of protein C and protein S. The usual dose is 0.1-0.2 mg/kg/day. Younger children appear to require higher doses to achieve a therapeutic level of the international normalized ratio (INR). If warfarin therapy is started early in the course of heparin therapy for thrombotic disease, effective oral anti-coagulant effect is often achieved by day 5, at which time levels of all the vitamin K–dependent factors should be depressed by warfarin. Early in the course of treatment with warfarin, the PT is affected first because factor 7 has the shortest half-life of the vitamin K–dependent procoagulants and factor 7 levels fall briskly after warfarin treatment. The aim of warfarin therapy for venous thromboembolic disease is to achieve a stable INR of 2.0-3.0.

For prevention of embolization from prosthetic valves, a higher INR may be preferable. Patients with protein C or protein S deficiency are at risk for warfarin-induced skin necrosis when warfarin therapy is initiated, particularly if high doses are used. These individuals should be given heparin before warfarin is started, and they should not receive a loading/high dose of warfarin.

Warfarin may be reversed by administration of either intravenously (IV) or oral vitamin K. Although IV vitamin K may work slightly faster, response rates at 24 hours are identical and IV vitamin K carries the associated risk for over-correction and prolonged subtherapeutic INRs. Therefore oral administration is preferable for non–life-threatening bleeding.

SUMMARY AND RED FLAGS

Bleeding and thrombotic problems are often familial but may be acquired. A family history and personal history that quantitate bleeding episodes are of utmost help in planning an evaluation. Red flags include anemia; signs of end-organ bleeding or vascular occlusion, particularly the central nervous system; signs of a systemic disorder (pancytopenia, hypotension, rash, weight loss, chronic fever, liver-renal-pulmonary system involvement); and signs of hemorrhagic shock.

Fever

Patricia S. Lye and Emily M. Densmore

Two-thirds of all children visit a physician for fever before they reach the age of 2 years. Fever in the pediatric population is usually grouped into 4 categories:

- Fever in the neonate
- Fever with localizing signs
- Fever without source (FWS)
- Fever of unknown origin (FUO)

PATHOPHYSIOLOGY OF FEVER

Temperature is controlled by the thermoregulatory center, located in the preoptic area of the anterior hypothalamus. The thermoregulatory center receives input from peripheral receptors and the temperature of the blood bathing the hypothalamus and acts on autonomic, endocrine, and behavioral mechanisms to maintain the body temperature at a particular set point. The hypothalamic set point normally maintains body temperature around 37°C, but there can be significant variation among individuals. Normal temperatures range from 36-37.8°C, depending on the time of day, with the peak in the afternoon (5-7 P.M.) and the trough in the early morning (2-6 A.M.). Although the circadian rhythm is not well established in infancy, it becomes more reliable by the 2nd year of life.

The febrile response not only produces an elevation in body temperature but also causes physiologic changes that enhance the individual's ability to eliminate infection. Production of acute-phase reactants and alterations in metabolism and endocrine function are examples of these changes. **Acute-phase reactants**—proteins that are produced in response to infection or injury—include ceruloplasmin, C-reactive protein, haptoglobin, amyloid A, complement, and fibrinogen. Hormones and cytokines, some of which are endogenous pyrogens, regulate the production of acute-phase proteins. Exogenous pyrogens, such as bacteria or endotoxins, generate the production of endogenous pyrogens, which play a vital role in prostaglandin-related set point elevation and regulation of acute-phase responses.

Fever results when the thermoregulatory set point is elevated above the normal set point; the hypothalamus then generates physiologic changes involving endocrine, metabolic, autonomic, and behavioral processes. Diversion of blood from peripheral vessels to central vessels causes coolness of the extremities but helps increase core temperature. Shivering increases metabolic activity and heat production. The affected patient may feel cold and seek a warmer environment or add clothing to feel warmer and prevent heat loss. Once these processes have resulted in increasing the core temperature to match the elevated set point, the thermoregulatory center works to maintain the temperature as it does during normothermia. The thermoregulatory point returns to normal once the infection is resolved. The hypothalamus then produces physiologic changes to decrease the core temperature; these include sweating, dilation of cutaneous blood vessels, and the sensation of feeling hot, which may lead to behaviors such as removing clothing or seeking a cooler environment.

Fever has both positive and negative effects. High body temperatures may impair the reproduction and survival of some invading microorganisms by decreasing required nutrients, such as free iron, or by increasing immunologic responses such as phagocytosis. However, at extremely high temperatures, immunologic responses may be impaired. Fever increases the basal metabolic rate by 10-12% for each degree Celsius elevation of temperature. This increases oxygen consumption, carbon dioxide production, and fluid and caloric needs. Fluid requirements increase 100 mL/m^2/day for each 1°C rise in temperature above 37.8°C.

Heat illness must be distinguished from fever as a cause for elevated body temperature. In heat illness, there is an unregulated rise in body temperature, despite the fact that the hypothalamic set point is normal. It can result from excessive heat production or inadequate heat dissipation. Temperatures may reach extreme heights and can result in multiorgan dysfunction and death. Restoration of normal body temperature in heat illness is mandatory (Table 39.1).

FEVER WITHOUT SOURCE

A child with fever of recent onset with no obvious historical or physical explanation for the fever is said to have fever without source (FWS). Bacterial pathogens account for a small but clinically significant number of cases. The risk of bacterial infection decreases with increasing age and is highest for infants less than 3 months of age, compared to infants and toddlers 3-36 months of age, and even lower for children over the age of 36 months. Most of the patients in all age groups have a self-limited viral illness. The challenge is to identify which children have fever caused by bacterial pathogens, or other pathogens requiring treatment, in order to avoid the morbidity and mortality associated with delayed treatment, balanced against the risks of testing or treatment when neither is needed. Bacterial infection must be considered in immunocompromised patients or those with central lines or shunts. Studies in adults suggest that patients with high fever (>105ºF) and rigors have a higher risk of bacterial infection; exceptions to this include influenza and adenoviral infections.

TABLE 39.1   Causes of Hyperthermia

Excessive Heat Production
Exertion
Heat stroke (exertion)
Malignant hyperthermia (anesthesia induced)
Neuroleptic malignant syndrome
Catatonia
Tetanus
Status epilepticus
Delirium
Endocrine disorders (hyperthyroidism, pheochromocytoma)
Drugs (cocaine, amphetamines, ephedrine, phencyclidine, tricyclic antidepressants, LSD, lithium, thyroid hormone, salicylates)

Diminished Heat Dissipation
Heat stroke
Occlusive dressings
Dehydration
Extensive burns (including severe sunburn)
Anhidrotic ectodermal dysplasias
Anticholinergic-like drugs (atropine, antihistamines, phenothiazines, tricyclic antidepressants)
Autonomic neuropathy
Spinal cord level paralysis (spinal crisis)
Possible overbundling (especially in a warm environment)
Therapeutic hyperthermia

Hypothalamic Dysfunction*
Stroke
Encephalitis
Granulomatous processes (sarcoid, tuberculosis, eosinophilic)
Trauma
Central: idiopathic
Phenothiazines
Hemorrhage

*Usually associated with hypothermia.
LSD, lysergic acid diethylamide.

◆ History

A detailed history may reveal a potential source for infection. A complete history addresses several important issues: (1) onset and duration of fever; (2) degree of temperature; (3) by what method and in which anatomic site the temperature was taken; (4) medications given, including antipyretics, antibiotics, or home remedies; (5) environmental exposures; (6) associated symptoms; (7) ill contacts; (8) recent immunizations, and (9) recent travel. Inquiry into the child's medical history may reveal important information such as recurrent febrile illnesses, primary or acquired immunodeficiency, or medications such as chemotherapy that alter host defenses.

Fever: Temperature Measurement

Rectal temperature measurement is considered to be the gold standard for children 3 years of age or younger. The most widely accepted definition of fever is rectal temperature of 38°C (100.4°F) or higher. It is important to consider that infants, especially those younger than 2 months of age, may have a blunted febrile (or hypothermic) response to infection. Hence, lack of fever should not be used as a criterion for ruling out infection in infants. Although rectal temperature measurement is the gold standard, it should be avoided in neutropenic immunocompromised patients, in whom rectal manipulation may seed the blood with bacteria.

Oral thermometry can be considered for cooperative patients who are older than 4-5 years of age. **Axillary temperatures** are commonly done and tympanic membrane and temporal artery temperatures are newer modalities with some studies examining their reliability. Axillary temperatures are less precise than rectal temperatures. There is a correlation between axillary and rectal temperature measurements; the axillary temperature is usually 0.5-0.85°C *lower*. **Tympanic membrane thermometers** are often inaccurate in children. **Temporal artery temperature** measurement correlates well with rectal temperature in some studies, but has been shown to be inferior when patients are febrile. It can be considered in settings when children are not likely to be febrile and are over 3 months of age. *When detection of fever is critical for diagnosis and management, rectal temperatures should be used in the child 3 years of age and younger.*

◆ Physical Examination

Many children will have a source for fever identified on their history and/or physical examination. If no focus of infection is found on the physical examination, the clinician must rely on history and observation to determine the appropriate next steps. The child may appear ill or well. Ill-appearing children are typically lethargic or irritable. They may show signs of shock, including weak peripheral pulses, tachycardia, poor perfusion, respiratory distress, mottling, cyanosis, or decreased mental status (Table 39.2). After thorough clinical and laboratory evaluation, ill-appearing children should be admitted to the hospital, and will likely need empiric antibiotic treatment.

Observational Scales

Infants and children with fever without source who do not appear ill create important decision processes in terms of evaluation and management. The physician's ability to make a hypothesis about the child's degree of illness, on the basis of observation, is critical in the evaluation. An objective scoring measure may be used in an effort to assess serious illness in young febrile children. The Acute Illness Observation Scale (AIOS) (Table 39.3), also known as the Yale Observation Score, is a 6-item predictive model graded on a scale of 1-5. Use of the AIOS in conjunction with the history and physical examination has a higher sensitivity for identifying serious illness than history and physical examination alone. The AIOS is most useful in patients younger than 24-36 months; *it has not been shown to provide sufficient data to identify serious illness in 4- to 8-week-old infants, and has not been evaluated in infants less than 4 weeks old.*

◆ Differential Diagnosis

Most children who present with fever without source (FWS) are subsequently determined to have a self-limited benign viral infection. In 1 study in 2-36 month old children who presented with FWS, 76% had 1 or more known pathogenic viruses found; 57% had adenovirus, human herpesvirus 6 (HHV-6: roseola), enterovirus, or parechovirus detected. Other identifiable viruses include respiratory syncytial virus, parainfluenza viruses, influenza viruses, varicella (chickenpox), human metapneumovirus and parvovirus (fifth disease/erythema infectiosum). Measles, mumps, and rubella are uncommon in developed countries but have been reported in epidemics following imported cases or in underimmunized communities. Although rapid testing for viral pathogens is often readily available, a detailed investigation to identify a viral pathogen is not necessary unless the confirmation of a viral infection will change the acute diagnostic plan; treatment with antivirals is an option (HSV, influenza) if the fever is prolonged and evolves into FUO or if there is end-organ involvement, as in hepatitis, myocarditis, encephalitis, or meningitis.

Most viral infections do not have simultaneous co-infection with a bacterial pathogen. Exceptions include croup due to parainfluenza

TABLE 39.2 International Consensus Definitions for Pediatric Sepsis

Infection	Suspected or Proven Infection or a Clinical Syndrome Associated with High Probability of Infection
SIRS	Two of 4 criteria, 1 of which must be abnormal temperature or abnormal leukocyte count: 1. Core temperature >38.5°C (101.3°F) or <36°C (96.8°F) (rectal, bladder, oral, or central catheter) 2. Tachycardia: Mean heart rate >2 SD above normal for age in absence of external stimuli, chronic drugs or painful stimuli *or* Unexplained persistent elevation over 0.5–4 hr or In children <1 yr old, persistent bradycardia over 0.5 hr (mean heart rate <10th percentile for age in absence of vagal stimuli, β-blocker drugs, or congenital heart disease) 3. Respiratory rate >2 SD above normal for age or acute need for mechanical ventilation not related to neuromuscular disease or general anesthesia 4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy) or >10% immature neutrophils

Sepsis	SIRS Plus a Suspected or Proven Infection
Severe sepsis	Sepsis plus 1 of the following: 1. Cardiovascular organ dysfunction, defined as: Despite >40 mL/kg of isotonic intravenous fluid in 1 hr: • Hypotension <5th percentile for age or systolic blood pressure <2 SD below normal for age *or* • Need for vasoactive drug to maintain blood pressure or • 2 of the following: • Unexplained metabolic acidosis: base deficit >5 mEq/L • Increased arterial lactate: >2 times upper limit of normal • Oliguria: urine output <0.5 mL/kg/hr • Prolonged capillary refill: >5 sec • Core to peripheral temperature gap >3°C (5.4°F) 2. ARDS as defined by the presence of a PaO_2/FiO_2 ratio ≤300 mm Hg, bilateral infiltrates on chest radiograph, and no evidence of left heart failure *or* Sepsis plus 2 or more organ dysfunctions (respiratory, renal, neurologic, hematologic, or hepatic)
Septic shock	Sepsis plus cardiovascular organ dysfunction as defined above
MODS	Presence of altered organ function such that homeostasis cannot be maintained without medical intervention

ARDS, acute respiratory distress syndrome; FiO_2, fraction of inspired oxygen; MODS, multiple organ dysfunction syndrome; PaO_2, partial pressure arterial oxygen; SIRS, systemic inflammatory response syndrome.

From Turner DA, Cheifetz IM. Shock. In: Kliegman RM, Stanton BF, St Geme JW III, et al, eds. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016:522, Table 70.7.

virus, which may predispose to bacterial tracheitis and influenza, which may predispose to bacterial pneumonia. The sequence may be biphasic with viral symptoms followed by improvement, followed by worsening symptoms of the bacterial superinfection, or both phases may not be apparent as the child demonstrates no improvement or deterioration. Respiratory syncytial virus (RSV) may predispose patients to otitis media.

Noninfectious conditions manifesting with FWS are extremely rare. Historical clues (recurrences, chronicity) or systemic signs usually indicate malignancy or rheumatic disorders. If the history and physical examination are not suggestive, these diagnoses need not be pursued. Heat-related illness or drug ingestion may be considered if supported by the history. Fever caused by immunizations may not be accompanied by other signs or symptoms, but the history should suggest immunization as the cause.

Urinary Tract Infections (UTIs)

UTIs are the most common serious bacterial infection in children less than 36 months of age who present with FWS. UTIs are almost always occult in children younger than 24 months because the symptoms, except for fever, are nonspecific or nonexistent. UTI occurs in 7% of febrile children younger than 2 years. The prevalence of UTI varies by height of the fever, duration of the fever, age, gender, race, and circumcision status. Children with fever greater than 39°C are at a higher risk of UTIs. Boys with fever for more than 2 days and girls with fever for more than 1 day are more likely to have a UTI. Higher rates of UTIs are found in girls, especially those younger than 12 months of age. For febrile boys younger than 3 months of age, 20.1% of those who are uncircumcised have a UTI; for circumcised boys the rate is 2.4%. UTI rates are higher among white infants than among black infants and among children with abnormal genitourinary tract anatomy or neurogenic bladder.

Urine specimens should be obtained from the following children with FWS: those with a history of UTI, those with a history of urinary tract anomalies or vesicoureteral reflux, all infants younger than 2 months, girls younger than 12-24 months, uncircumcised boys younger than 12 months, and circumcised boys younger than 6 months. There is an age-associated risk of bacteremia with UTIs, particularly in infants. The incidence of bacteremia in patients younger than 2 months with UTI is 10%. The incidence of bacteremia in patients younger than 2 months with UTI ranges from 4-15% depending on the setting. Opinions regarding when to obtain blood cultures in infants with UTI differ, but a reasonable approach would be to obtain blood cultures in children younger than 2-6 months with suspected UTI, and in older infants with UTI if they are ill-appearing (urosepsis).

Bacteremia

Occult bacteremia is defined by the presence of a positive blood culture for pathogenic bacteria in a febrile patient who does not appear extremely ill and who has no focus of infection, excluding otitis media. Following the introduction of the 7-valent pneumococcal vaccine in 2007, invasive pneumococcal disease decreased dramatically. Pneumococcal bacteremia decreased from 80% of the cases of bacteremia to 30%. *Most cases of bacteremia in children were not occult.* Bacteremic children were either ill or had a focus of infection, such as a UTI. In 1 study, the rate of occult bacteremia after 2007 was 0.25%. After the 13-valent pneumococcal vaccine was introduced in 2010, the incidence of invasive pneumococcal disease in children less than 5 years old decreased again with 1 state-based population study showing incidence rates dropping from 46/100,000 to 23/100,000 with the age group most involved being children 2-23 months of age. *Escherichia coli* is the most common cause of bacteremia in children aged less than 12 months, all due to UTIs. Other less common causes of bacteremia in young

TABLE 39.3 **Acute Illness Observation Scale**

Observation Item	1 Normal	3 Moderate Impairment	5 Severe Impairment
Quality of cry	Strong with normal tone or Content and not crying	Whimpering or Sobbing	Weak or Moaning or High-pitched
Reaction to parent stimulation	Cries briefly, then stops or Content and not crying	Cries off and on	Continual cry or Hardly responds
State variation	If awake → stays awake or If asleep and stimulated → wakes up quickly	Eyes close briefly → awakens or Awakes with prolonged stimulation	Falls asleep or Will not rouse
Color	Pink	Pale extremities or Acrocyanosis	Pale or Cyanotic or Mottled or Ashen
Hydration	Skin normal, eyes normal and Mucous membranes moist	Skin, eyes normal and Mouth slightly dry	Skin doughy or Skin tented and Dry mucous membranes and/or Sunken eyes
Response (talk, smile) to social overtures	Smiles or Alert (≤2 mo)	Brief smile or Alert briefly (≤2 mo)	No smile; face anxious, dull, expressionless or No alertness (≤2 mo)

From McCarthy PL, Sharpe MR, Spiesel SZ, et al. Observation scales to identify serious illness in febrile children. *Pediatrics.* 1982;70:802.

children are *N. meningitidis*, nontyphoidal *Salmonella*, *Staphylococcus aureus*, and group A streptococcus. *Neisseria meningitidis* bacteremia is frequently associated with serious sequelae. Children with *N. meningitidis* bacteremia are much more likely to progress to meningitis than are those with *S. pneumoniae* bacteremia. Nontyphoidal *Salmonella* bacteremia is often accompanied or preceded by enteritis. In some instances, particularly in young infants, the diarrhea is mild or even absent. The prevalence of *Salmonella* bacteremia among patients with *Salmonella enteritis* has been reported to be between 2% and 45%; fever is not always present. *Salmonella* infection seldom causes serious complications in patients with normal host defenses and resolves spontaneously. *Infants younger than 3 months, malnourished, and immunocompromised individuals are exceptions.*

◆ Role of Diagnostic Testing in Patients with Fever Without Source

Evaluation is usually divided into 4 different age ranges: younger than 1 month, 1-3 months, 3-36 months, and older than 36 months. Testing for each individual age group is based on risks for diseases and prevalence of pathogens.

Complete Blood Count and Other Markers of Inflammation

The white blood cell (WBC) count is the most commonly used test in young children with FWS. Complete blood count (CBC) is less useful

as a marker for invasive disease caused by *E. coli* than by *S. pneumoniae*, thus its utility has declined with the reduction of the incidence of invasive pneumococcal disease. Similarly, band counts are less commonly used, except in the 29-60 day old infant as part of identifying a low-risk cohort. A WBC count of 5,000-15,000 is generally considered normal for children over 1 month of age. A WBC count less than 15,000/mm³ or even leukopenia may be found in children with *N. meningitidis* bacteremia. A minority of children with occult nontyphoidal *Salmonella* bacteremia have been found to have a WBC count exceeding 15,000/mm³. C-reactive protein (CRP) and procalcitonin combined with a urine dipstick (the lab score) can be used to screen for bacterial infection. This combination of tests has been validated for children 7 days to 36 months of age.

Polymerase Chain Reaction (PCR)

PCR is useful in identifying the cause of fever for common viruses such as respiratory syncytial virus, influenza viruses, parainfluenza viruses, enteroviruses, parechovirus, adenoviruses, or herpes simplex virus.

Additional methods available or in development that may be helpful to identify serious bacterial infections and distinguish bacterial from viral infections utilize molecular microbiology methods. **Gene expression profiles** of the patient's peripheral blood leukocytes demonstrate different biosignatures of RNA production that may differentiate bacterial from viral infections. This method does not identify the

specific pathogen. **Rapid multiplex PCR** combined with standard blood culture methods may identify a specific pathogen much sooner (~20 hours) than standard blood culture techniques. Specific bacteria may be identified using **16S ribosomal RNA** bacterial gene detection. This method does not require bacterial growth. 16S rRNA detection may be helpful when antibiotics were administered before the sample was obtained, and in patients with ventilator-associated pneumonia or bacteria that grow poorly or are present in effusions or tissues (heart valves).

Blood Cultures

Blood cultures are the gold standard for determination of bacteremia. Although blood cultures do not provide immediate results, methods allow for continuous and more rapid detection of bacterial growth. Blood cultures are easy to perform and provide essential information in the diagnosis and management of patients with possible bacteremia. Preliminary blood culture results are typically available within 24 hours, with positive identification of most organisms within 48 hours.

False-negative blood culture results may be due to prior treatment with antibiotics, missing an episode of bacteremia if it is intermittent, and inoculation of too little blood into the culture media. Alternatively, too much blood inoculated into the blood culture bottle may yield a false-negative result because of ongoing killing of bacteria by neutrophils. Three to 5 mL of blood should be added to each blood culture bottle. False-positive results may be due to inadequate skin preparation, leading to contamination with skin flora.

Urinalysis and Urine Culture

A positive urine culture was once considered the gold standard; current recommendations include a urinalysis that has pyuria (defined as >5 WBCs/high-power field [hpf] on the microscopic examination or a positive leukocyte esterase on dipstick) and a positive urine culture for a uropathogen in an appropriately collected specimen. Fifty to 100,000 colonies of a single organism is considered positive (see Chapter 18). Children should have a catheterized urine specimen obtained, unless they are toilet-trained and can supply a clean voided specimen. Suprapubic aspiration is acceptable but requires technical expertise, and parents often perceive it as unsuitably invasive; it may be the only alternative for boys with severe phimosis. The use of plastic receptacles attached to the perineum should be discouraged because contamination from skin and fecal flora commonly occurs.

Lumbar Puncture

Lumbar puncture is indicated if the patient is younger than 28 days or if a diagnosis of sepsis, meningitis, or encephalitis is considered, regardless of the child's age. Normal cerebrospinal fluid (CSF) findings, including chemistry, cell count with differential, Gram stain, PCR, and culture, help exclude the diagnosis of meningitis. Less than 1% of children with normal preliminary CSF results have a positive culture; in most of these, the pathogen is *N. meningitidis*. Thus, even in the presence of normal preliminary CSF results, close follow-up is essential.

Chest Radiographs

Chest radiographs are usually normal in children who have FWS. Respiratory signs or symptoms, such as tachypnea, retractions, crackles, wheezing, rhonchi, nasal flaring, grunting, cough, or hypoxia, may predict chest radiograph findings consistent with pneumonia. In practice, pneumonia can often be diagnosed solely on the basis of the clinical findings of fever, tachypnea, and crackles; chest radiographs are not always necessary. However, chest radiographs may be useful in evaluating for the presence of pleural effusion or other complications of pneumonia.

Stool Cultures

Most acute diarrhea and fever is caused by viral pathogens in developed countries. Obtaining a stool culture is indicated if bacterial enteritis is indicated by the presence of risk factors in the history, such as blood in the stool or certain exposures (petting zoos) (see Chapter 11).

◆ Evaluation and Management
Children Younger Than 3 Months

Febrile infants younger than 3 months have a higher incidence of serious bacterial infections than older infants. The relatively high incidence of bacterial disease probably results from a combination of factors unique to this age group: decreased opsonin activity; decreased macrophage function; decreased neutrophil function; poor immunoglobulin G antibody response to encapsulated bacteria; and susceptibility to bacterial pathogens such as group B streptococci (GBS), gram-negative enteric organisms, and *Listeria monocytogenes*. The incidence of early-onset group B streptococcal infections has decreased with routine screening and the intrapartum treatment of GBS-positive pregnant women; the incidence of late-onset GBS (>1 week) has not decreased. *E. coli* is the most common organism causing bacterial infections in neonates and young infants.

In very young infants, clinical evaluation alone is inadequate for excluding serious bacterial infections. Management of febrile infants **younger than 28 days** includes a sepsis evaluation and hospitalization for parenteral antimicrobial therapy pending culture results. The reasoning for this conservative approach lies in the difficulty in evaluating the behavioral state of neonates, the rapid clinical deterioration of infants with bacterial infections, the immature neonatal immune system, and the possibility of life-threatening viral infections caused by herpes simplex viruses (HSV) or enteroviruses. Sepsis evaluation should include culture of the CSF, blood, and urine; a complete blood cell count with differential; examination of the CSF for cells, protein, and glucose; and urinalysis. A chest radiograph should be considered if the patient has signs or symptoms of a respiratory infection. Testing (blood and CSF PCR for HSV) and treatment for possible HSV infection should be considered in ill-appearing infants, those with a seizure prior to presentation, and those with a vesicular rash consistent with HSV.

A combination of clinical evaluation and laboratory studies can be used to define a specific population of infants **aged 29-60 days** who do not appear ill and are at low risk for bacterial infections. Infants at low risk for bacterial infections are those who are previously healthy with no focus of bacterial infection on physical examination and who have negative laboratory screening results. A number of prospective studies have contributed to the development of specific low-risk screening criteria (Table 39.4). The age groups included vary by study, ranging from 0-90 days to 29-56 days. Because there are differences in study criteria used to define infants at low risk for bacterial infections the most conservative values have been used in the guidelines presented in this chapter. Negative laboratory screening results consist of a WBC count of 5000-15,000/mm^3; fewer than 1500 bands/mm^3 or a band-to-neutrophil ratio of less than 0.2; fewer than 10 WBCs/hpf and no organisms on urinalysis; and fewer than 8 WBCs/hpf and no organisms on CSF Gram stain. Some experts also include a negative chest radiograph and, when diarrhea is present, a stool examination with fewer than 5 WBCs/hpf.

Most experts suggest that febrile infants 29-60 days old who meet the low-risk criteria and have access to close follow-up can be managed as outpatients. Blood, urine, and CSF cultures should be obtained before empirical antibiotic treatment so that viral and bacterial causes

may be distinguished. An alternative strategy is to manage such infants as outpatients, without empirical antibiotic therapy, after blood, CSF, and urine cultures are obtained. Although most of the original studies on outpatient management of febrile infants included infants aged 2-3 months, many experts agree that infants aged 2-3 months can be managed safely according to the guidelines for infants and children aged 3-36 months (Table 39.4).

Regardless of whether the clinician chooses to treat the patient with empiric antibiotics, all low-risk infants should be re-evaluated within 24 hours. Those who appear ill or who have positive culture results should be admitted for parenteral antibiotics. If a child appears well and all culture results are negative, close follow-up should be continued and a 2nd return visit made in 24 hours.

Children Aged 3 to 36 Months

The risk of bacteremia for children with FWS in this age group has decreased with the routine use of pneumococcal vaccines. The most common occult bacterial infection in this age group is UTI. For children in this age group who appear ill, a full sepsis evaluation should be undertaken (Table 39.5).

TABLE 39.4 Low-Risk Criteria in a Child 1–3 Mo Old with Fever

Boston Criteria

Infants are at low risk if they appear well, have a normal physical examination, and have a caretaker reachable by telephone, and if laboratory tests are as follows:
- CBC: <20,000 WBC/μL
- Urine: negative leukocyte esterase
- CSF: leukocyte count less than 10×10^6/L

Philadelphia Protocol

Infants are at low risk if they appear well and have a normal physical examination, and if laboratory tests are as follows:
- CBC: <15,000 WBC/μL; band: total neutrophil ratio <0.2
- Urine: <10 WBC/hpf; no bacteria on Gram stain
- CSF: <8 WBC/μL; no bacteria on Gram stain
- Chest radiograph: no infiltrate
- Stool: no RBC; few to no WBC

Pittsburgh Guidelines

Infants are at low risk if they appear well and have a normal physical examination, and if laboratory tests are as follows:
- CBC: 5,000–15,000 WBC/μL; peripheral absolute band count <1,500/μL
- Urine (enhanced urinalysis): 9 WBC/μL and no bacteria on Gram stain
- CSF: 5 WBC/μL and negative Gram stain; if bloody tap, then WBC:RBC ≤1:500
- Chest radiograph: no infiltrate
- Stool: 5 WBC/hpf with diarrhea

Rochester Criteria

Infants are at low risk if they appear well and have a normal physical examination, and if laboratory findings are as follows:
- CBC: 5,000–15,000 WBC/μL; absolute band count ≤1,500/μL
- Urine: <10 WBC/hpf at ×40
- Stool: <5 WBC/hpf if diarrhea

CBC, complete blood count; CSF, cerebrospinal fluid; hpf, high-powered field; RBC, red blood cell; WBC, white blood cell.
From Nield LS, Kamat D. Fever without a focus. In: Kliegman RM, Stanton BF, St Geme JW III, et al, eds. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016:1281, Table 177.2.

Screening urinalysis (UA) for UTI should be considered in children with a history of UTI, children with a history of urinary tract anomalies or vesicoureteral reflux, girls younger than 12-24 months, especially when the temperature is greater than 39.0°C, uncircumcised boys younger than 12 months, and circumcised boys younger than 6 months. Blood cultures are recommended for children with probable UTIs who are less than 6 months of age. A febrile child with moderate leukocyte esterase on urine dipstick testing or pyuria on an appropriately collected specimen should be treated presumptively for a UTI. Urine cultures should be obtained for any patient with a suspected UTI. The choice of antibiotics should be guided by knowledge of the common pathogens that cause UTIs and by patterns of antibiotic sensitivity in the community. Hospitalization should be considered for the child who is vomiting, is dehydrated, or appears ill; for those in whom compliance is likely to be poor; and for any patient with underlying renal or urologic anomalies.

Examination and culture of the CSF are the only tests to exclude the diagnosis of meningitis and encephalitis. They should be considered in any child in whom the diagnosis of sepsis, meningitis or encephalitis is suspected on the basis of the history, observation, and physical examination findings. Outpatient management of children with FWS is acceptable for those with a low probability of meningitis, good follow-up, and reliable caregivers. Blood cultures should be obtained for all children in whom sepsis or meningitis is suspected. Empiric treatment with antibiotics should be considered in those suspected of sepsis or meningitis after appropriate cultures are obtained.

In summary, management of children aged 3-36 months with fever is based on clinical experience and numerous study results:
- Child who appears ill on initial evaluation or on follow-up: Admit to the hospital for parenteral antibiotics after appropriate laboratory evaluation.
- Well-appearing children with FWS should be screened for UTIs, based on their number of risk factors. Risk factors for girls are: age <12 months, white race, temperature greater than 39°C, and fever for 2 or more days. Girls 2-24 months of age with 1 or more of these risk factors have a greater than 1% probability of having a UTI, and should be screened for a UTI.

    For boys, the risk factors are uncircumcised status, nonblack race, temperature greater than 39°C, and fever for over 24 hours. All uncircumcised boys less than 12 months old, even if they don't have other risk factors, should be screened for a UTI. For boys who are circumcised, 2 or more of the other risk factors increases the risk to over 1% and they should be screened.
- Child with positive blood culture: Reevaluation should occur in any child whose blood culture is presumptively positive. If the blood is found to contain *N. meningitidis* or *Haemophilus influenzae* (which has been rare since the advent of *H. influenzae b* immunization), a CSF sample and a repeat blood culture should be obtained, and the child should be admitted to the hospital for parenteral antibiotics, pending the results of the cultures. The child with occult pneumococcal bacteremia who appears well and is afebrile when returning for a follow-up may be managed as an outpatient with parenteral ceftriaxone followed by oral antibiotics according to the sensitivity of the organism. Because of the concern of pneumococcal resistance to penicillin, a 2nd dose of intramuscular ceftriaxone may be given until sensitivity results are available. If the culture is positive for nontyphoidal *Salmonella* organisms and the child is younger than 3 months, full sepsis evaluation and intravenous antibiotics are recommended. Oral antibiotics and close follow-up are recommended for older children with *Salmonella* bacteremia.
- Child with positive urine culture: If the child is afebrile and appears well, treatment with oral antibiotics is recommended, according to the sensitivity of the organism.

TABLE 39.5   Management of Fever Without Source

Group	Management
Any toxic-appearing child 0–36 mo and temperature ≥38°C (100.4°F)	Hospitalize, broad cultures plus other tests,* parenteral antibiotics
Child <1 mo and temperature ≥38°C (100.4°F)	Hospitalize, broad cultures plus other tests,* parenteral antibiotics

Child 1–3 mo and temperature ≥38°C (100.4°F)	**Two-Step Process**
	1. Determine risk based on history, physical examination, and laboratory studies.
	  Low risk:
	  • Uncomplicated medical history
	  • Normal physical examination
	  • Normal laboratory studies
	  • Urine: negative leukocyte esterase, nitrite and <10 WBC/hpf
	  • Peripheral blood: 5,000–15,000 WBC/mm³; <1,500 bands or band: total neutrophil ratio <0.2
	  • Stool studies if diarrhea (no RBC and <5 WBC/hpf)
	  • CSF cell count (<8 WBC/µL) and negative Gram stain
	  • Chest radiograph without infiltrate
	2. If child fulfills all low-risk criteria, administer no antibiotics, ensure follow-up in 24 hr and access to emergency care if child deteriorates. Daily follow-up should occur until blood, urine, and CSF cultures are final. If any cultures are positive, child returns for further evaluation and treatment. If child does not fulfill all low-risk criteria, hospitalize and administer parenteral antibiotics until all cultures are final and definitive diagnosis determined and treated

Child 3–36 mo and temperature 38–39°C (100.4–102.2°F)	Reassurance that diagnosis is likely self-limited viral infection, but advise return with persistence of fever, temperatures >39°C (102.2°F), and/or new signs and symptoms
Child 3–36 mo and temperature >39°C (102.2°F)	**Two-Step Process** 1. Determine immunization status 2. If received conjugate pneumococcal and *Haemophilus influenzae* type b vaccines, obtain urine studies (urine WBC, leukocyte esterase, nitrite, and culture) for all girls, all boys <6 mo old, all uncircumcised boys <2 yr, all children with recurrent urinary tract infections If did not receive conjugate pneumococcal and *H. influenzae* type b vaccines, manage according to the 1993 Guidelines (see Baraff et al. *Ann Emerg Med.* 1993;22:1198-1210.)

*Other tests may include chest radiograph, stool studies, herpes simplex virus polymerase chain reaction.
CSF, cerebrospinal fluid; hpf, high-powered field; RBC, red blood cell; WBC, white blood cell.
From Nield LS, Kamat D. Fever without a focus. In: Kliegman RM, Stanton BF, St Geme JW III, et al, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2016: Table 177.3.)

Children Older Than 36 Months

Evaluation and management of ill-appearing children older than 36 months with fever without source are similar to those of younger children. For children in this age group who do not appear ill, no screening diagnostic tests are indicated. Close attention should be paid to environmental exposures and ill contacts because of the high likelihood of increased contacts in this school-aged cohort.

CENTRAL NERVOUS SYSTEM INFECTIONS

Bacterial Meningitis

Bacterial meningitis is usually a disease of infants and young children. The attack rate is highest between the ages of 3 and 8 months; 66% of cases occur in children younger than 5 years of age. Bacterial meningitis is seen during all seasons; however, there may be a seasonal correlation between the presence of preceding respiratory pathogens in the upper respiratory tract and the subsequent development of bacterial meningitis. Bacterial meningitis usually occurs sporadically. Clusters of cases have been noted in day care centers, colleges, and other closed communities. Bacterial meningitis occurs more frequently in children with traumatic fractures of the cribriform plate or paranasal sinuses or with a cochlear implant (pneumococci); in children who have undergone neurosurgical procedures such as ventricular shunts (*S. aureus*, *S. epidermidis*, *Corynebacterium* species); in children with

congenital or acquired immunodeficiencies (pneumococci, *L. monocytogenes*, meningococci); in children with anatomic or functional asplenia (pneumococci, meningococci); and in children with sickle hemoglobinopathies (pneumococci). There may be a genetic predisposition in some groups to the development of meningitis, inasmuch as there is an increased incidence of *H. influenzae* type b meningitis in Navahos and Eskimos.

Bacterial meningitis manifests in 2 patterns. In the 1st, the symptoms develop slowly over several days, the initial symptoms being those of a nonspecific illness. The signs and symptoms of meningitis develop subsequently. In the 2nd pattern, the disease develops suddenly and quickly, the 1st indications of illness being the signs and symptoms of meningitis and/or sepsis.

The manifestations of meningitis depend on the child's age. In infants, the findings are usually nonspecific and may be subtle; they include vomiting, diarrhea, irritability, lethargy, poor appetite, respiratory distress, seizures, hypothermia, and jaundice. Only 50% of affected infants have fever; some present only with fever. It is uncommon for affected young infants to have a stiff neck; only 30% have a bulging fontanel.

Older children present with more specific meningeal signs. They complain of a headache that is described as being severe, generalized, deep-seated, and constant. They complain about neck stiffness, caused by inflammation of the cervical dura and reflex spasm of the extensor muscles of the neck. There is pain and limitation of motion on flexion

of the neck, but lateral movement of the neck may be normal and pain-free. They also complain of nausea, vomiting, anorexia, and photophobia.

On examination, they demonstrate irritability, mental confusion or altered consciousness, nuchal rigidity, and, occasionally, hyperesthesia and ataxia. The clinician demonstrates nuchal rigidity by feeling resistance and observing a painful response while flexing the patient's neck. The stiffness may not be recognized until the end of flexion. The neck usually can be rotated without symptoms. In the child who is crying and tensing the muscles, nuchal rigidity may be demonstrated if the examiner places 1 hand under the occiput of the supine patient and lifts the child. If the neck does not flex, it is stiff. Alternatively, a sitting child may be observed following an object as it falls to the floor. The child who flexes the neck to look at the object does not have nuchal rigidity. In the presence of meningitis, flexion of the neck causes spontaneous flexion of the legs at the hips and knees, the **Brudzinski sign** (Fig. 39.1). The **Kernig sign** is elicited when the patient lies supine and, with the knee flexed, the leg is flexed at the hip. The knee is then extended. A positive sign is present if this movement is limited by contraction of the hamstrings and causes pain. Absence of nuchal rigidity is found in 1.5% of older children with meningitis; it may be absent in children who have overwhelming infections, are deeply comatose, or who have focal or global neurologic impairment.

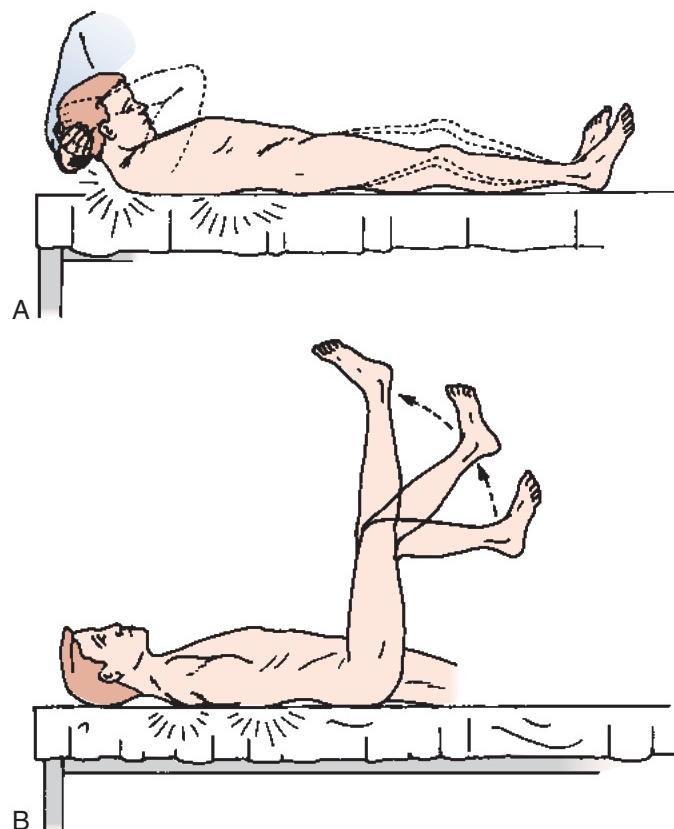
As many as 15% of children with bacterial meningitis initially present in a **comatose** or semicomatose state (see Chapter 31). Because


FIGURE 39.1 *A*, Brudzinski sign. The patient lies supine, and the head is passively elevated from the table by the examiner. The patient complains of neck and low back discomfort and attempts to relieve the meningeal irritation by involuntary flexion of the knees and hips. *B*, Kernig sign. The patient lies supine, with the hips and knees flexed. The knees are then gradually extended. Complaints of pain in the lower back, neck, and/or head are suggestive of meningeal irritation. (From Reilly BM. *Practical Strategies in Outpatient Medicine*. 2nd ed. Philadelphia: WB Saunders; 1991:95.)

of the short duration and inconsistent development of increased intracranial pressure, **papilledema** is usually not seen at presentation. When it is present, venous sinus thrombosis, subdural effusion, or an intracranial abscess must be considered. **Seizures** occur before hospital admission in up to 20% of affected patients.

Children with meningitis may also present with cutaneous findings. Although commonly associated with meningococcal disease, purpura, petechiae, or a diffuse nonspecific maculopapular rash may be present in meningitis caused by any of the common bacterial pathogens (see Chapter 40).

Septic arthritis may be seen simultaneously with bacterial meningitis. This has been assumed to be caused by simultaneous localizing infection after a primary bacteremia. Reactive arthritis caused by immune complex deposition is also seen with bacterial meningitis. This arthritis affects 1 large joint and appears 5-7 days after treatment for meningitis has started. In general, arthritis occurring acutely with meningitis should be assumed to be infectious (see Chapter 33).

Various eye disorders have also been described with acute bacterial meningitis, including transient cataracts, paralysis of the extraocular muscles, pupillary dysfunction, dendritic ulcers, endophthalmitis, cortical blindness, and conjunctivitis.

Recurrent episodes of bacterial meningitis rarely occur. Potential etiologies include congenital CSF fistulas (inner ear, dermal sinus, neuroenteric cysts, lumbosacral sinus tracts), traumatic or surgical CSF fistula (skull fracture, postoperative nasal surgery, cochlear implant), immunodeficiency states and parameningeal infections (mastoiditis, sinusitis, craniofacial osteomyelitis).

◆ Diagnostic Studies
Lumbar Puncture and Cerebrospinal Fluid Analysis

The definitive diagnosis of meningitis is based on examination of the cerebrospinal fluid (CSF). The CSF is usually obtained via a lumbar puncture (spinal tap). The lumbar puncture is performed by introducing a small-bore, short-beveled, spinal needle with a stylet into the subarachnoid space at the L3-L4 or L4-L5 level (Figs. 39.2 to 39.4). A needle with a stylet is used to minimize the risk of introducing a nest of epidermal cells into the subarachnoid space that may later grow into a cord-compressing epidermoid tumor. Approximately 3 mL of fluid is removed for analysis.

There are a few **contraindications** for the performance of a lumbar puncture. The 1st is cardiorespiratory compromise. Performance of the lumbar puncture requires that the child be held in flexion to open the intervertebral spaces. In seriously ill children or children with significant underlying cardiac or pulmonary disease, this positioning may be enough to cause respiratory compromise. The lumbar puncture may need to be postponed, be performed cautiously with continuous oxygen saturation monitoring, or performed with the patient in the sitting position.

Second, children with **increased intracranial pressure** from a focal central nervous system (CNS) lesion, such as brain abscess or tumor, or from illnesses associated with cerebral edema have a high risk of cerebral herniation after a lumbar puncture. If signs or symptoms of increased intracranial pressure are present, the lumbar puncture should be postponed until the increased pressure is lowered with appropriate treatment. *If a lumbar puncture is delayed, appropriate antibiotic therapy should be initiated without further delay.* Third, a lumbar puncture should not be done if the spinal needle must pass through an area of infection on its way to the subarachnoid space. To do so might introduce pathogens into the CNS that could cause meningitis.

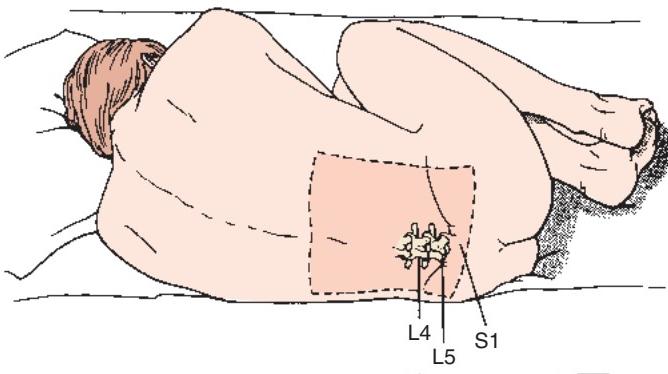
Epidural hematomas causing lower limb paralysis may be a complication of lumbar punctures in children with bleeding disorders. Therefore, in children with hemophilia, disseminated intravascular


FIGURE 39.2 Lateral decubitus position for a lumbar puncture. L4-L5 position is determined by a vertical line drawn between the superior iliac crests. (From Davidson RI. Lumbar puncture. In: Vander Salm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures.* 2nd ed. Boston: Little, Brown; 1992:443.)

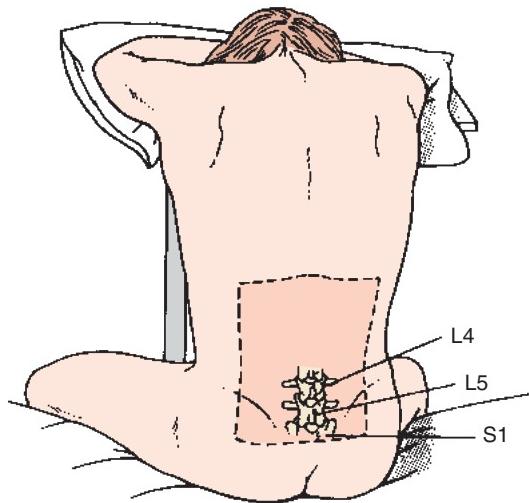

FIGURE 39.3 Sitting position for a lumbar puncture. (From Davidson RI. Lumbar puncture. In: Vander Salm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures.* 2nd ed. Boston: Little, Brown; 1992:443.)

FIGURE 39.4 The needle and stylet are advanced into the subarachnoid space. On penetration into the space, the examiner often feels a give or pop after moving through the dura. After the needle enters into the subarachnoid space, the clinician removes the stylet and collects the cerebrospinal fluid. (From Davidson RI. Lumbar puncture. In: Vander Salm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures.* Boston: Little, Brown; 1992:447.)

coagulopathy, or thrombocytopenia, lumbar puncture should be postponed until the bleeding disorder is corrected, and extra care should be taken to avoid a traumatic lumbar puncture. Such children should be monitored after the procedure for the development of neurologic deficits. *Empirical therapy may be started while the coagulopathy is corrected.*

Other, rarer complications of lumbar puncture include cortical blindness from compression of the posterior cerebral artery against the tentorium cerebelli, causing ischemic infarction of the occipital lobes. Cervical spinal cord infarction, with respiratory arrest and flaccid tetraplegia, may occur if intracranial hypertension causes herniation of the cerebellar tonsils through the foramen magnum with resulting compression of the anterior spinal artery or its penetrating branches. Post–lumbar puncture headache may occur in up to 10% of older children and adults; it is presumably caused by persistent CSF leakage at the lumbar puncture site.

The CSF is examined for red blood cells (RBCs), white blood cells (WBCs) and differential, glucose, protein, and the presence (by culture, by Gram stain or other stain, or by antigen or DNA-PCR testing for specific agents) of pathogenic organisms. Opening pressure measurements are obtained with the head of the bed flat and with the child relaxed and in the lateral decubitus position with the back no longer tightly flexed. The upper limit of normal value in children 1-18 years of age is less than 25 cm of water. Opening pressure is less than 5 cm H_2O in premature infants and less than 10 cm H_2O in normal newborns. Opening pressure measurements are elevated if the lumbar puncture is performed with the patient in the sitting position and if the patient is combative or performing the Valsalva maneuver. Obstructive hydrocephalus, hyperventilation, or removal of fluid can all lead to lowering of the measurement. Children with bacterial meningitis usually have a mean opening pressure of 18 ± 7 cm H_2O.

Normal CSF is clear and colorless (Table 39.6). Blood in the CSF indicates a traumatic lumbar puncture or a CNS hemorrhage. Obtaining a RBC count on tubes 1 and 3 may differentiate the 2 conditions because the count is unchanged in CNS hemorrhage but may decline in traumatic taps. Centrifugation of the CSF sample may also help differentiate between a traumatic tap and a CNS hemorrhage. When blood has been present in the CSF for several hours, the CSF is xanthochromic after centrifugation. However, if the blood was recently mixed with CSF, as in the case of a traumatic tap, the supernatant is clear. Xanthochromic CSF can also be caused by icterus or an elevated CSF protein concentration.

The normal values for WBCs in the CSF are shown in Table 39.6. Most children with bacterial meningitis have a WBC count of at least 1000/mm^3 in their CSF, but, in general, more than 6/mm^3 in children after the neonatal period is considered abnormal. Normal values for neonates are 0-18 (mean: 6) WBCs in the CSF.

An absolute neutrophil count exceeding 3/mm^3 (neutrophils may be as high as 35%) is also considered abnormal and evidence of a

TABLE 39.6		Cerebrospinal Fluid Findings in Central Nervous System Disorders			
Condition	Pressure (mm H$_2$O)	Leukocytes (mm^3)	Protein (mg/dL)	Glucose (mg/dL)	Comments
Normal	50–80	<5, ≥75% Lymphocytes	20–45	>50 (or 75% serum glucose)	
Common Forms of Meningitis					
Acute bacterial meningitis	May be elevated (100–300)	100–10,000 or more; usually 300–2,000; PMNs predominate	Usually 100–500	Decreased, usually <40 (or <50% serum glucose)	Organisms usually seen on Gram stain and recovered by culture
Partially treated bacterial meningitis	Normal or elevated	5–10,000; PMNs usual but mononuclear cells may predominate if pretreated for extended period of time	Usually 100–500	Normal or decreased	Organisms may be seen on Gram stain. Pretreatment may render CSF sterile. Organism detected by antigen or PCR tests
Viral meningitis or meningoencephalitis	Normal or slightly elevated (80–150)	Rarely >1,000 cells. Eastern equine encephalitis and lymphocytic choriomeningitis may have cell counts of several thousand. PMNs early but mononuclear cells predominate through most of the course	Usually 50–200	Generally normal; may be decreased to <40 in some viral diseases, particularly mumps (15–20% of cases)	HSV encephalitis is suggested by focal seizures or by focal findings on CT or MRI scans or EEG. HSV and enteroviruses may be detected by PCR of CSF
Uncommon Forms of Meningitis					
Tuberculous meningitis	Usually elevated	10–500; PMNs early, but lymphocytes predominate through most of the course	100–3,000; may be higher in presence of CSF block	<50 in most cases; decreases with time if treatment is not provided	Acid-fast organisms almost never seen on smear. Organisms may be recovered in culture of large volumes of CSF. *Mycobacterium tuberculosis* may be detected by PCR of CSF; elevated ADA and gamma interferon
Fungal meningitis	Usually elevated	5–500; PMNs early but mononuclear cells predominate through most of the course. Cryptococcal meningitis may have no cellular inflammatory response	25–500	<50; decreases with time if treatment is not provided	Budding yeast may be seen. Organisms may be recovered in culture. Cryptococcal antigen (CSF and serum) may be positive in cryptococcal infection
Syphilis (acute) and leptospirosis	Usually elevated	50–500; lymphocytes predominate	50–200	Usually normal	Positive CSF serology. Spirochetes not demonstrable by usual techniques of smear or culture; dark-field examination may be positive
Amebic (*Naegleria*) meningoencephalitis	Elevated	1,000–10,000 or more; PMNs predominate	50–500	Normal or slightly decreased	Mobile amebas may be seen by hanging-drop examination of CSF at room temperature

TABLE 39.6 Cerebrospinal Fluid Findings in Central Nervous System Disorders—cont'd

Condition	Pressure (mm H_2O)	Leukocytes (mm^3)	Protein (mg/dL)	Glucose (mg/dL)	Comments
Brain Abscesses and Parameningeal Focus					
Brain abscess	Usually elevated	5–200; CSF rarely acellular; lymphocytes predominate; if abscess ruptures into ventricle, PMNs predominate and cell count may reach >100,000	75–500	Normal unless abscess ruptures into ventricular system	No organisms on smear or culture unless abscess ruptures into ventricular system
Subdural empyema	Usually elevated	100–5,000; PMNs predominate	100–500	Normal	No organisms on smear or culture of CSF unless meningitis also present; organisms found on tap of subdural fluid
Cerebral epidural abscess	Normal to slightly elevated	10–500; lymphocytes predominate	50–200	Normal	No organisms on smear or culture of CSF
Spinal epidural abscess	Usually low, with CSF block	10–100; lymphocytes predominate	50–400	Normal	No organisms on smear or culture of CSF
Chemical (drugs, dermoid cysts, myelography dye)	Usually elevated	100–1,000 or more; PMNs predominate	50–100	Normal or slightly decreased	Epithelial cells may be seen within CSF by use of polarized light in some children with dermoids
Noninfectious Causes					
Sarcoidosis	Normal or elevated slightly	0–100; mononuclear	40–100	Normal	No specific findings
Systemic lupus erythematosus with CNS involvement	Slightly elevated	0–500; PMNs usually predominate; lymphocytes may be present	100	Normal or slightly decreased	No organisms on smear or culture. Positive neuronal and ribosomal P protein antibodies in CSF
Tumor, leukemia	Slightly elevated to very high	0–100 or more; mononuclear or blast cells	50–1,000	Normal to decreased (20–40)	Cytology may be positive
Acute disseminated encephalomyelitis	Normal or elevated	~100 lymphocytes	Normal to elevated	Normal	MRI adds to diagnosis
Autoimmune encephalitis	Normal	~100 lymphocytes	Normal to elevated	Normal	Anti-NMDAR antibody positive

CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; HSV, herpes simplex virus; MRI, magnetic resonance imaging; NMDAR, N-methyl-D-aspartate receptor; PCR, polymerase chain reaction; PMN, polymorphonuclear neutrophils; ADA, adenosine deaminase.
From Prober CG, Srinivas NS, Mathew R. CNS infections. In: Kliegman RM, Stanton BF, St Geme JW III, et al, eds. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016, Table 603.1.

bacterial infection. Although there are case reports of children with proven, usually rapidly fulminant meningococcal bacterial meningitis who do not have CSF pleocytosis, the CSF of 98% of children with meningitis has pleocytosis and more than 50% neutrophils. It takes 200-400 WBCs/mm^3 to turn CSF turbid.

On occasion, the spinal needle is advanced too far and passes through the subarachnoid space and penetrates the richly vascularized ventral epidural space. Blood is thereby introduced into the subarachnoid space, and the CSF appears bloody. This occurrence is often called a traumatic tap. It is then difficult to know whether the WBCs seen on examination of the CSF are caused by CSF pleocytosis or are peripheral blood WBCs contaminating the CSF. To aid in this determination, the ratio of WBCs to RBCs in the CSF is compared with the ratio of WBCs to RBCs in the patient's peripheral blood. A higher ratio in the CSF indicates the presence of CSF pleocytosis. When the CSF ratio is at least 10 times higher than the blood ratio, bacterial meningitis is indicated,

with a sensitivity of 88% and a specificity of 90%. Conversely, the negative predictive value for the presence of bacterial meningitis of a less than 10-fold difference between the ratios is 99%. Traumatic taps usually do not alter the CSF glucose, Gram stain, or culture findings, which are often abnormal with bacterial meningitis. When there is doubt about the validity of the cell count after a bloody tap, the lumbar puncture should be repeated after several hours by introducing the spinal needle 1 intervertebral space above the original tap site.

In normal CSF, the glucose concentration is two-thirds that of serum glucose concentration. The CSF glucose concentration is low in most infected infants and younger children and in 45% of school-aged children with bacterial meningitis. In children older than 2 months of age, a CSF/serum glucose ratio of less than 0.4 is 80% sensitive and 98% specific for the presence of bacterial meningitis. The presence of RBCs in a CSF sample that is promptly analyzed does not affect the glucose concentration.

The normal CSF protein concentration is less than 45 mg/dL in children older than 2 months. The mean CSF protein concentration is 90 (range, 20-170) in full-term infants and 115 (range, 65-150) in preterm infants.

The CSF protein concentration is elevated in more than 90% of younger children with bacterial meningitis but in only 60% of infected school-aged children. Every 1000 RBCs in the CSF (from a traumatic tap) increases the protein concentration by approximately 1 mg/dL.

The presence of bacterial pathogens in the CSF should be investigated. Microscopic examination of a Gram-stained sample of the fluid is performed first. The sensitivity of this test is directly related to the number of organisms in the CSF and is inversely related to the age of the patient. The Gram stain identification of certain organisms, such as *H. influenzae*, may be problematic. A decision whether to treat a child for bacterial meningitis should not be based on the Gram stain alone; the definitive diagnosis is based on the CSF culture. Rapid diagnostic tests for bacterial antigens in CSF, including countercurrent immunoelectrophoresis and latex particle agglutination, suffer from variations in sensitivity and specificity that limit their value in clinical practice.

Some patients will have been treated with antibiotics before the lumbar puncture is performed. When the CSF from such a child is examined, organisms may not be seen on Gram stain or recovered on culture. However, abnormalities of CSF cell count (including elevated leukocytes), protein concentration, and glucose concentration usually continue to suggest the diagnosis of bacterial meningitis. In this setting, presumptive treatment for bacterial meningitis is initiated. If an organism is identified by culture or antigen detection, definitive antibiotic treatment is administered. If no organism is identified, the decision to continue treatment depends on the clinical suspicion of bacterial meningitis and the exclusion of other causes of aseptic meningitis (Tables 39.7 and 39.8). Newer laboratory techniques that utilize PCR to detect bacterial pathogens are being developed and may be useful in the diagnosis of bacterial meningitis in patients who have been treated with antibiotics before lumbar puncture.

Computed Tomography

Routine computed tomography (CT) of the head is not indicated in children with suspected meningitis. Even though children with bacterial meningitis have increased intracranial pressure, most CT scans are normal. In addition, most lumbar punctures do not result in cerebral herniation in patients with meningitis. CT should be reserved for children who show clinical signs of herniation or cerebral edema and for those who may have an intracranial mass causing signs and symptoms similar to meningitis.

Other Laboratory Tests

Usually, the peripheral blood WBC and platelet counts are elevated with bacterial meningitis. A low WBC count and thrombocytopenia may also be seen; these are associated with overwhelming infection and a poor outcome. The sensitivity (70%), specificity (54%), and negative predictive value (81%) of the differential WBC count are too low to render the differential WBC examination useful in making the diagnosis of bacterial meningitis.

Blood cultures may be useful in identifying the bacterial pathogen of meningitis. However, a negative blood culture may be found in up to 33% of children with meningococcal meningitis, 20% of children with pneumococcal cases, and 10% of patients with *H. influenzae* type b meningitis. These numbers increase with prior antibiotic therapy. In addition, there is a negative correlation between the length of illness before diagnosis and the rate of positive blood cultures. A bacterial meningitis score has been developed to attempt to distinguish between bacterial and aseptic (nonbacterial) meningitis in patients with CSF pleocytosis. The risk of bacterial meningitis is low if *none* of the following criteria are present: history of a seizure with the illness, blood neutrophil count $\geq 10 \times 10^9$ cells/L, positive CSF Gram stain, CSF protein ≥ 80 mg/dL, or CSF neutrophil count $\geq 1 \times 10^9$ cells/L. This diagnostic tool is 99% sensitive and 62% specific for bacterial meningitis. It should only be applied to non–ill-appearing children older than 2 months without petechiae, purpura, or other concerning findings on examination who have not been pretreated with antibiotics.

Aseptic Meningitis

Aseptic meningitis is an inflammatory process of the meninges, most often characterized by acute signs and symptoms of meningeal irritation; CSF pleocytosis, usually with a predominance of mononuclear cells; a normal or, less frequently, elevated CSF protein concentration; normal or, less often, low CSF glucose concentration; and no organisms demonstrable by Gram stain or bacterial cultures. There are many causes of aseptic meningitis (see Table 39.7). The most common cause is viral infection; up to 90% of cases are caused by enteroviruses and arbovirus. The definitive diagnosis is made by identifying the organism in the CSF. However, this is not always possible, and other causes must be excluded by history, presence or absence of associated symptoms, and appropriate laboratory tests (Tables 39.7 and 39.8).

Viral Meningitis

Enteroviral meningitis occurs most often during the summer and early fall months. Transmission is via the fecal-oral route, and young children exhibit increased transmission of the viruses and more severe disease in comparison with other age groups. Initially, patients may have a respiratory tract infection, a nonspecific febrile illness, or vomiting and diarrhea. Viral infection of the meninges occurs 7-10 days after initial exposure. The clinical course may be biphasic. Virus from the oropharynx can be cultured only during the 1st 5-7 days of the illness but may be excreted in stool for 6-8 weeks.

Children with viral meningitis present with fever, nuchal rigidity, irritability, headache, and vomiting. Less common symptoms are anorexia, drowsiness, photophobia, myalgia, and malaise. As in bacterial meningitis, affected young infants often lack meningeal signs. In addition, children may have an altered sensorium, but focal neurologic signs are rare. Seizures are more common in infants.

The number of WBCs in the CSF varies from zero to several thousand (Table 39.6). Up to 75% of *initial (early in the illness)* CSF specimens contain a predominance of polymorphonuclear cells. Mononuclear cells predominate by 2 days after the onset of symptoms. Of children with enteroviral meningitis, 18% may have decreased CSF glucose concentrations, whereas 12% may have elevated CSF protein. Treatment of enteroviral meningitis is supportive. Admission to the hospital may be required while bacterial meningitis is being ruled out and for intravenous hydration. Analgesics and antipyretics may also be indicated. The lumbar puncture performed to diagnose viral meningitis is often helpful in ameliorating the acute symptoms. The mechanism for this is not clear.

The outcome is quite good for patients in whom common viral pathogens cause aseptic meningitis. Sequelae in older children are rare. Adverse outcomes are more common (but unusual) in children who have viral meningitis during the 1st year of life. Speech and language development may be affected. Treatment and outcome for the other types of aseptic meningitis depend on the underlying cause.

Tuberculous Meningitis

Tuberculous meningitis is an important treatable cause of aseptic meningitis. During the primary pulmonary tuberculous infection and

Philadelphia: WB Saunders; 1998:450; and from Davis LE. Aseptic and viral meningitis. In: Long SS, Pickering LK, Prober CG, eds. *Principles and Practice of Pediatric Infectious Disease*. New York: Churchill Livingstone; 1997:329.

subsequent lymphohematogenous spread to extrapulmonary sites, tubercle bacilli produce local microscopic granulomas in the CNS and meninges. If this primary CNS infection is not contained by host defense mechanisms (T lymphocytes, monocytes), or if host defense mechanisms fail at a later period, tuberculous meningitis may result. Meningitis occurs weeks to months after the primary pulmonary process.

The symptoms of tuberculous meningitis are insidious and subacute (weeks to months). Stage 1 is a prodrome with nonspecific manifestations (apathy, poor school function, irritability, weight loss, fever, night sweats, nausea); stage 2 is heralded by the onset of neurologic signs (headache, cranial neuropathy, nuchal rigidity, signs of increased intracranial pressure); and stage 3 manifests with altered levels of consciousness (lethargy, stupor, coma). Meningismus is not present in all patients.

The diagnosis is supported by a history of contacts with adults with known active tuberculosis, a chronic cough, or human immunodeficiency virus (HIV) disease or by a history of immigration, poverty, or homelessness. In addition, the patient's chest radiograph is consistent with active or, more often, quiescent tuberculosis (parenchymal-hilar node calcifications, infiltrates, hilar adenopathy, and, in rare cases, endobronchial or cavitary lesions), and the patient's tuberculin skin test yields a positive result (see Chapter 2). Cranial CT or magnetic resonance imaging (MRI) may show the most intense meningeal inflammation around the base of the brain or inflammatory mass lesions (tuberculomas). The CSF results (Table 39.6) include profound hypoglycorrhachia, a high CSF protein, lymphocyte- or monocyte-predominant cells (usually 500 cells/mm^3), increased opening pressure, and, on occasion, tubercle organisms on acid-fast staining. PCR amplification of *Mycobacterium tuberculosis* DNA aids in making a more rapid diagnosis than does culture of CSF, sputum, or gastric aspirates, which traditionally requires 2-6 weeks. The differential diagnosis depends on the stage of the illness.

Encephalitis

Encephalitis is inflammation of the brain parenchyma, whereas meningoencephalitis is inflammation of the brain accompanied by inflammation of the meninges. Meningoencephalitis is distinguished from aseptic meningitis by evidence of brain parenchymal involvement, including behavior or personality changes; altered level of consciousness (including agitation or coma); generalized seizures; focal neurologic signs, including focal seizures and focal motor defects (hemiparesis or ataxia); or movement disorders.

Enteroviruses and arboviruses cause most cases of infectious encephalitis in children. Enterovirus encephalitis, uncommon without meningeal involvement, is suggested by epidemic occurrence and presence of typical prodrome or associated findings (Table 39.8); prompt diagnosis is by PCR for enterovirus in CSF, blood, throat, or stool specimens. A CSF or blood specimen is preferred because PCR may identify enterovirus in throat and especially stool for weeks after the primary infection has resolved. Arbovirus encephalitis is suggested by mosquito or tick exposure and epidemic occurrence and is diagnosed by findings of arbovirus immunoglobulin M in CSF or blood or by paired serologic findings for immunoglobulin G.

Infections with herpes simplex virus (HSV) occur throughout the year. In neonates, HSV encephalitis usually occurs between 7 and 21 days of age; may produce focal or generalized CNS disease; and may occur with or without conjunctivitis, oral mucosal involvement, vesicles on skin, or disseminated disease (hepatitis, pneumonia, septic appearance). After the neonatal period, HSV encephalitis is usually isolated to the CNS and classically produces necrotizing encephalitis with a focus in the temporal lobe. Symptoms in persons with HSV encephalitis range broadly from those suggesting mild aseptic meningitis to the presence of status epilepticus and coma and then death. In addition to neutrophils and monocytes, CSF examination may show increased numbers of erythrocytes and elevated protein. CT, MRI, and an electroencephalogram (EEG) may suggest a temporal lobe focus. Specific diagnosis is by PCR of CSF for herpes simplex DNA. CSF culture is usually negative. In the appropriate clinical setting, presumptive therapy with intravenous acyclovir, 60 mg/kg/day given every 8 hours, is indicated while the results of PCR of CSF for HSV are awaited.

Autoimmune encephalitis. Anti-D-methyl-D-aspartate receptor (anti-NMDAR) encephalitis is a novel and relatively common form of encephalitis. Data from the California Encephalitis Project showed that anti-NMDAR encephalitis was the most common identifiable cause of encephalitis in their cohort, which included patients from 6 months to 30 years. Most of the cases occurred in children and adolescents. Patients present with similar features as viral encephalitis, but seizures, language dysfunction, psychosis, autonomic dysfunction, movement disorders, and EEG abnormalities are more common in these patients.

FEVER OF UNKNOWN ORIGIN

In adults, FUO is defined as an illness lasting more than 3 weeks, a fever higher than 38.3°C (101°F) on several occasions, and uncertainty

TABLE 39.8 Characteristics of the Most Common Causes of Aseptic Meningitis Syndrome

Organism	Age Group Serology	Season	Prodrome	Clinical Characteristics	Epidemiologic Characteristics	Agent Identification	Serologic Diagnosis
Common							
Enteroviruses	Infants, young children	Summer, fall	None, or mild GI or pharyngitis syndrome for 1–3 days	Exanthem, myopericarditis, conjunctivitis, pleurodynia, hand–foot–mouth disease, herpangina, myositis, hepatitis	Epidemic	Culture or PCR of CSF, blood, throat, stool	Enterovirus serologic study
Arboviruses	Children, elderly	Summer, early fall	Fever, rash, malaise for 1–5 days	Encephalitis or aseptic meningitis	Geographic area, contact with insect vector, encephalitis in community or animals	PCR of CSF	IgM, paired IgG
Herpes simplex type 2	Young adults	Year round	Genital vesicles for 1–7 days	Associated primary herpes lesions	Sexual exposure	Culture of genital lesions; PCR of CSF	IgM, paired IgG
Borrelia burgdorferi (Lyme disease)	Children, adults	Spring–late fall	Erythema migrans; secondary symptoms weeks to months later	Facial palsy or other cranial nerve palsy; radiculitis; heart block	Endemic area, deer tick exposure (often unrecognized)	PCR of CSF	IgG, IgM: EIA with Western blot confirmation
Less Common							
Mumps	5- to 9-year-olds	Late winter–spring	Parotitis, orchitis: 2–10 days	Parotitis, orchitis, oophoritis, pancreatitis	Exposure to mumps or vaccination	PCR of CSF, throat	IgM, paired IgG
HIV	Young adults	Year round	Fever, arthralgias, maculopapular rash, pharyngitis, adenopathy	Same as prodrome; meningitis may occur 1–5 days into the illness	2–6 wk after sexual or blood exposure	Blood PCR for HIV, RNA, or DNA	IgG (EIA) negative at this stage
Lymphocytic choriomeningitis virus	Older children, young adults	Fall, early winter	Fever and flulike syndrome, 5–21 days	Orchitis, alopecia	Exposure to mice, hamsters	PCR of CSF, blood	IgG
Mycobacterium tuberculosis	Infants (primary infection), young adults (reactivation)	Year round	Fever	Pneumonia, basilar inflammation with cranial nerve palsy and intracranial hypertension	History of tuberculosis or exposure, HIV risk factors	Culture, PCR of CSF for mycobacteria	None
Leptospira	Young adults	Late summer, early fall	Hepatitis and hematuria, 1–7 days	Conjunctivitis, splenomegaly, jaundice, nephritis, rash	Exposure to animals, water contaminated with animal urine	Culture of blood, CSF, urine	Paired IgG
Fungal	Premature infant, young adult	Year round	Fever	Basilar inflammation on CT or MRI, cranial nerve findings	Endemic area (blastomycosis, histoplasmosis) Immunodeficiency (cryptococcosis) Prematurity (candidal disease)	Culture of CSF for fungus, meningeal biopsy	Specific IgG
Mycoplasma organisms	Children, young adults	Fall, winter	Fever, malaise, sore throat, cough	Cough, rash, hemolytic anemia	Family or community epidemic	PCR of CSF, nasopharyngeal secretions	IgM

CSF, cerebral spinal fluid; CT, computed tomography; EIA, enzyme immunoassay; GI, gastrointestinal; HIV, human immunodeficiency virus; IgG and IgM, immunoglobulins G and M; MRI, magnetic resonance imaging; PCR, polymerase chain reaction.

of diagnosis after a 1-week study in the hospital (Table 39.9). In pediatrics, the defined duration of fever is variable, from 8 days to 3 weeks (average, 2 weeks). This may be dependent on the age of the patient, with shorter periods of fever in young infants and more traditional adult standards in adolescent patients. FUO is defined as a temperature higher than 38°C (100.4°F) daily for at least 8-14 days and no diagnosis after an initial evaluation. The initial evaluation recommended varies but always includes a noncontributory history and physical examination, and nondiagnostic initial laboratory and radiologic tests. In accordance with this definition, the differential diagnosis for FUO in children is large (Table 39.10).

Most children with FUO have an infectious disease; in a systematic review of studies of children with FUO, 51% of children had an infectious cause, 9% had a collagen vascular cause and 6% had a malignancy. There were 11% identified as otherwise miscellaneous which included Kawasaki disease and inflammatory bowel disease; 23% were without a formal diagnosis. Infections identified included urinary tract infections (UTI) and tuberculosis in all children; and osteomyelitis and bartonellosis in developed countries and brucellosis and typhoid in developing countries. Often patients with an FUO have atypical manifestations of common childhood bacterial or viral diseases rather than unusual or uncommon disorders.

◆ Evaluation

The evaluation of a child with FUO centers on a detailed history and physical examination. Taking the history should be repeated because parents often remember important details after the initial interview. The physical examination findings may also change during the course of the investigation revealing important clues (Fig. 39.5, Table 39.11).

◆ History

The history should include the time of day of the fever, who measured the temperature, and the instrument that was used to measure the temperature. Increased temperatures after exercise and in the afternoon often represent normal variations. The appearance of the

child while febrile is also important. Increased temperature without sweating might be seen in a child with ectodermal dysplasia or factitious fever.

The pattern of fever should be noted (Fig. 39.6). Sustained fever, intermittent fever, and relapsing fever have been associated with different disease states. Sustained or remittent fever remains elevated with little variation during the day and has been associated with enteric (typhoid) fever, tularemia, and rickettsial diseases such as typhus and Rocky Mountain spotted fever. Intermittent fever normalizes at least once a day and is associated with tuberculosis, abscesses, lymphomas, juvenile idiopathic arthritis (JIA), and some forms of malaria. Children with relapsing fever have afebrile days between febrile episodes. Relapsing fever has been associated with rat bite fever, *Borrelia* species infection, malaria, brucellosis, subacute bacterial endocarditis, African trypanosomiasis, lymphomas, and Lyme disease. Saddle-back or double-hump fever lasts a few days, is followed by an afebrile day or 2, and then returns. It has been associated with some viruses and dengue fever. Double quotidian fever (2 fever spikes each day) occurs in kala-azar, malaria, and gonococcal endocarditis. Periodic fevers occur as acute febrile episodes separated by prolonged afebrile, healthy periods. Diseases to consider include cyclic neutropenia, familial Mediterranean fever, and the syndrome of periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA). Periodic fever syndromes have different prevalence patterns in different ethnic groups and different inheritance patterns. A detailed family history is particularly important when these diagnoses are considered (see Chapter 41).

Unfortunately, neither the fever pattern nor the duration is specific for a particular cause. Fevers lasting for more than 1 year are not usually infectious; factitious fever, rheumatic or granulomatous disorders, familial diseases, or malignancies need to be considered in these patients.

A history of rash is important for diagnosing Lyme disease, JIA, and acute rheumatic fever (see Chapter 40). A history of pica is associated with visceral larva migrans and toxoplasmosis. Exposure to domestic and wild animals should be identified to exclude zoonoses (see Chapter 40). The food history should be detailed and should include water sources, use of game meats, cooking practices, and consumption of unpasteurized, raw milk, or soft cheese.

Travel history is critically important in the establishment of a differential diagnosis. Areas visited, accommodations, activities,

prophylactic treatments, animal and insect exposures, and water and food sources should be reviewed. Coccidioidomycosis, histoplasmosis, malaria, Lyme disease, and Rocky Mountain spotted fever have regional distributions. Children who have traveled to or have emigrated from developing countries are at increased risk for endemic diseases and *M. tuberculosis* (Table 39.12).

Previous medical records should be reviewed. Weight loss is important for diagnosing many chronic diseases such as lymphoma, tuberculosis, and inflammatory bowel disease. Poor weight gain and growth, with or without gastrointestinal symptoms, may be the only historical clue to inflammatory bowel disease (see Chapter 11). HIV risk factors in the parents and child should be reviewed. Past and current medications should also be reviewed. The review of systems may reveal heat intolerance, palpitations, tremors, and declining quality of schoolwork in a child with hyperthyroidism. A history of severe head trauma may be associated with hypothalamic dysfunction and central fevers.

◆ Physical Examination

Whenever possible, the patient should be examined during a febrile episode. A high fever in the absence of an increased pulse may be present in a patient with factitious fever. To verify this diagnosis, the temperature of freshly voided urine may be recorded. Tremor, tachycardia, palpitations, exophthalmos, lid lag, eyelid retraction, and smooth, flushed skin with diaphoresis are suggestive of hyperthyroidism.

Eyes

The ophthalmologic examination should include assessment of visual acuity, extraocular motion, visual field integrity, and gaze, as well as inspection of external structures and ophthalmoscopic examination (see Chapter 32). Conjunctivitis, iritis-uveitis-scleritis, or both may be seen in a variety of infectious conditions, including Epstein–Barr virus (EBV) infection, leptospirosis, rickettsial infection, and cat-scratch disease. Conjunctivitis, uveitis, or both occur with Kawasaki disease, systemic lupus erythematosus (SLE), polyarteritis nodosa, and JIA. Sarcoidosis may be associated with conjunctival and uveal tract nodules. A thorough ophthalmoscopic evaluation (and, if needed, slit-lamp examination) should be performed. Sarcoidosis may be accompanied by vascular occlusions, hemorrhages, vascular sheathing, and preretinal inflammatory exudates. Cytomegalovirus (CMV) produces chorioretinitis associated with white infiltrates near vessels and confluent depigmented areas. Histoplasmosis causes small atrophic spots and, in rare cases, focal granulomas of the retina and choroid. *Toxoplasma gondii* is a common cause of recurrent retinochoroiditis. Retinal changes also occur with bacterial endocarditis. Tuberculosis can cause formation of choroidal tubercles and also ulcerative palpebral conjunctival lesions. Slit-lamp examination may also reveal iridocyclitis in JIA, Behçet syndrome, and inflammatory bowel disease.

Ears, Nose, and Throat

The frontal and maxillary sinuses should be palpated for tenderness. The nares should be inspected for inflamed mucosa and purulent discharge. Tympanic membranes should be viewed and insufflated (see Chapter 4). The mouth should be checked for lesions, inflammation, and tooth tenderness. Behçet syndrome may manifest with oral aphthous lesions. Inspection of teeth and gums may reveal a dental abscess. Exudative and nonexudative pharyngitis is associated with EBV infection, tularemia, leptospirosis, and CMV. PFAPA syndrome is characterized by periodic fever, aphthous stomatitis, pharyngitis, and cervical adenopathy. *Candida* infection in the mouths of children older than 2 years may result from immunodeficiency such as HIV or from the use of inhaled steroids.

Neck

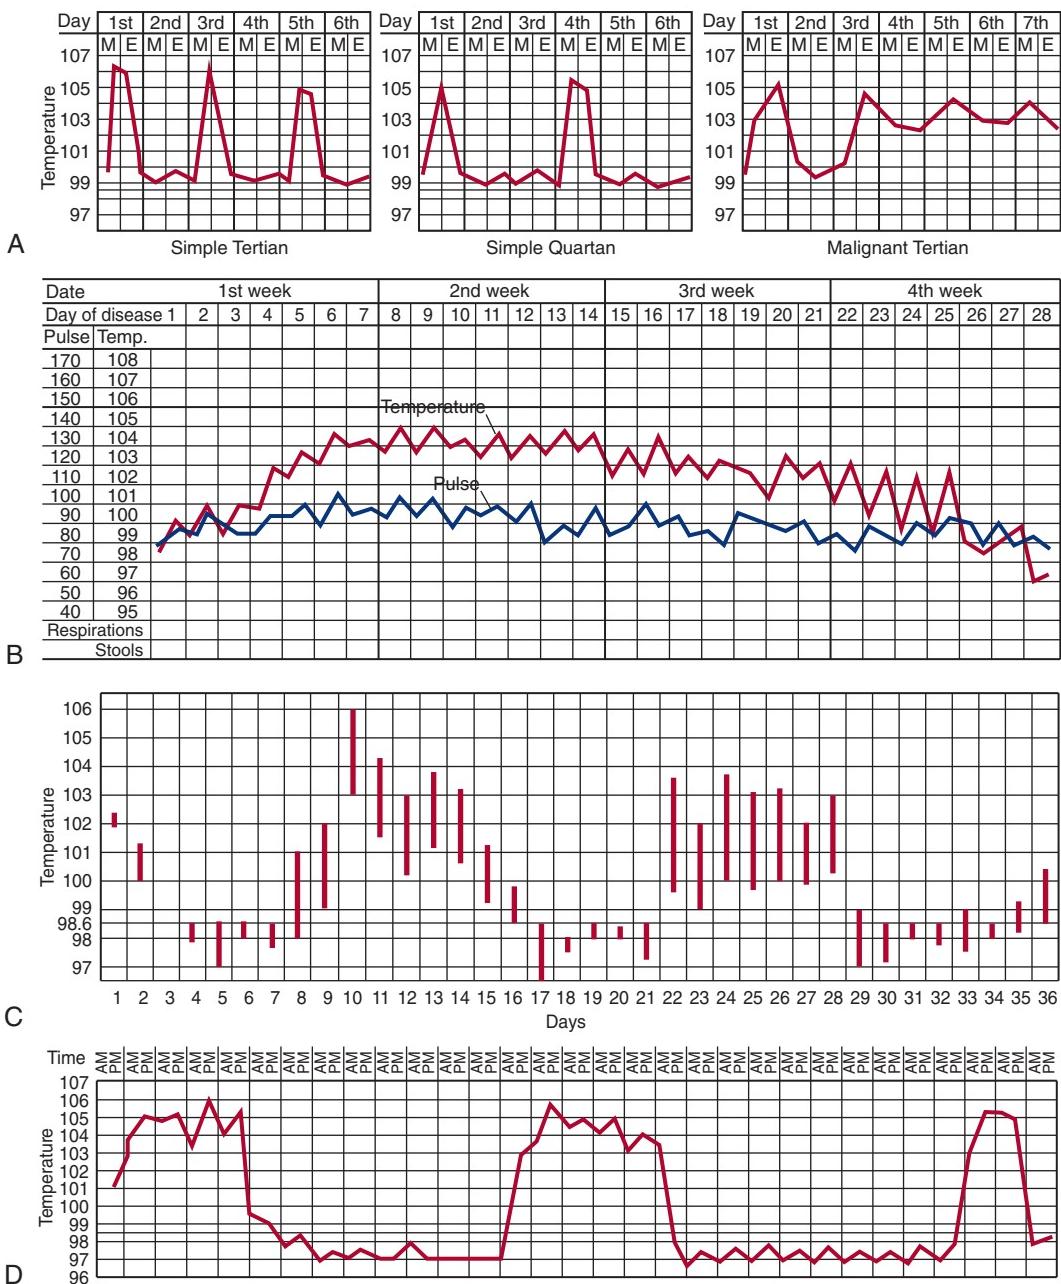
The neck should be examined for adenopathy or thyroid enlargement (see Chapter 36). The rest of the lymphatic system should be carefully examined. A single tender node may be seen with cat-scratch disease. Generalized adenopathy can be seen in CMV infection, EBV infection, and systemic JIA (see Chapter 33).


FIGURE 39.6 Distinctive Fever Patterns. *A,* Malaria. *B,* Typhoid fever (demonstrating relative bradycardia). *C,* Hodgkin disease (Perl-Ebstein pattern). *D,* Borreliosis (relapsing fever pattern). (Data from Woodward TE. The fever pattern as a clinical diagnostic aid. In: Mackowiak PA, ed. *Fever: Basic Mechanisms and Management.* 2nd ed. Philadelphia: Lippencott-Raven; 1997:215-236.)

Heart, Lungs, and Abdomen

Careful auscultation of the heart and lungs is essential. A mitral or aortic regurgitant murmur may be the initial finding of endocarditis or of carditis in children with acute rheumatic fever. A pericardial friction rub may also suggest JIA, SLE, rheumatic fever, malignancy, or viral pericarditis. The abdomen must be carefully palpated for evidence of masses or hepatosplenomegaly (see Chapters 14 and 17). Abdominal tenderness may be present with abdominal abscesses, hepatosplenomegaly, and inflammatory bowel disease. A rectal examination should be performed, and stool should be tested for occult blood. Sexually active girls should have a pelvic examination. Pain on movement of the uterus during the pelvic examination may indicate pelvic inflammatory disease.

Musculoskeletal Evaluation

The musculoskeletal examination should include assessments of strength and of active and passive range of motion and evaluation for warmth, tenderness, or swelling of joints. Irritability and pain on palpation over a bone or disuse pseudoparalysis may be the 1st clue to osteomyelitis. Bone pain may also result from neoplastic infiltration of the bone marrow or sickle cell anemia. Unexplained fever, arthralgias, and arthritis may be present with acute rheumatic fever, JIA, Lyme disease, Kawasaki disease, SLE, polyarteritis nodosa, and Behçet syndrome (see Chapter 33). Myalgias occur commonly with viral diseases such as influenza, and may be present with rickettsial diseases, polyarteritis nodosa, Takayasu arteritis, and dermatomyositis.

TABLE 39.12 Causes of Fever in the Returned Traveler

Diagnosis	%
Malaria	30–40
Hepatitis	3–6
Respiratory infection*	2–11
Urinary tract infection/pyelonephritis	2–4
Dysentery	4–5
Dengue fever	2–6
Enteric fever	1–2
Tuberculosis	1–2
Rickettsial infection	~1
Acute HIV infection	<1
Amebic liver abscess	<1
Other miscellaneous infections	4–9
Miscellaneous noninfectious causes	1–6
Undiagnosed	~25

*Includes upper respiratory tract infection, pneumonia, and bronchitis.
HIV, human immunodeficiency virus.
Modified from Suh KN, Kozavsky PE, Keystone JS. Evaluation of fever in the returned traveler. *Travel Med.* 1999;83:997-1017.

Skin

The skin must be inspected for evidence of rashes and other lesions (see Chapter 40). JIA may manifest with an evanescent, salmon-colored macular rash over the trunk and joints that may appear and disappear rapidly and be evident only during febrile periods. Dermatomyositis is characterized by a heliotropic rash of the upper eyelids and an erythematous eruption (vasculitis) over the extensor surfaces (Gottron sign). SLE may manifest with a butterfly rash over the nose and malar regions, signs of photosensitivity in sun-exposed areas, or vasculitis. The rash of Kawasaki disease is erythematous and may manifest in many forms; it is most commonly a diffuse maculopapular rash. In Rocky Mountain spotted fever, there are macular erythematous spots on the wrists, ankles, or forearms that may become maculopapular and expand centripetally to the proximal extremities and torso; palms and soles may be involved and petechiae may develop later in the course of the illness. Endocarditis may be associated with splinter hemorrhages or Janeway lesions (painless, small, erythematous or hemorrhagic lesions on the palms and soles). Lyme disease usually manifests with erythema migrans. This rash begins at the site of the tick bite and is erythematous with a pale center. The rash radiates out from the bite in a circular manner and persists for weeks; satellite secondary lesions may also appear.

Tularemia, salmonellosis, listeriosis, and EBV infections may feature generalized maculopapular rashes.

◆ Diagnostic Studies

Laboratory evaluation should proceed in a stepwise, focused manner with emphasis on identifying serious illnesses with defined interventions (see Fig. 39.5). Initial studies should include a complete blood cell count with differential, erythrocyte sedimentation rate (ESR) measurement, CRP, blood cultures, urinalysis, urine culture, tuberculin skin tests with controls (anergy panel) or gamma interferon release assay, and chest radiograph. Because EBV infection is common in childhood, viral-specific antibody titers may also be obtained at the initial evaluation (see Chapter 36). Further studies should be directed by information obtained from detailed histories and physical examinations.

Specific serologic studies aid in the diagnosis of CMV, toxoplasmosis, brucellosis, tularemia, hepatitis A, B, and C, and leptospirosis. Biopsies of lymph nodes, the skin, the liver, or bone marrow may be indicated. Radiologic studies that may be of benefit if directed by the history, physical examination findings, and initial laboratory study results include sinus CT, abdominal imaging, or total body MRI (to evaluate for occult osteomyelitis, malignancy, histiocytic disorders).

The complete blood cell count with differential is neither specific nor diagnostic, except in rare circumstances, such as seeing lymphoblasts on the blood smear. Approximately 30% of patients have abnormal white blood cell counts; 46% may have a left shift, lymphocytosis, atypical lymphocytes, or blasts. An elevated ESR or CRP indicates inflammation. The ESR is usually (70-90% of the time) high in children with FUO caused by infectious pathogens, malignancies, and rheumatic diseases. Of patients with an ESR less than 10 mm/hr, 90% have a self-limited viral disease.

Urinalysis and urine culture identify occult infections, particularly in young girls. The urinalysis may also be abnormal in patients with endocarditis and rheumatic and other inflammatory disorders.

Unexpected consolidations, calcifications, interstitial changes, perihilar adenopathy, or cardiomegaly (heart failure, pericarditis) may be found on chest radiographs. Chest films are abnormal in 10-15% of patients with FUO. CT of the chest may reveal abnormalities not detected by a chest x-ray.

Specialized radiologic studies performed without specific diagnostic clues from the history, physical examination findings, or initial laboratory evaluation results have a low yield. Whole body MRI is another technique that may be useful in children with FUO. It is helpful in identifying abnormal areas in bones, such as with occult osteomyelitis.

Cause
Infections
A wide variety of infections have been identified in children with FUO including subacute bacterial endocarditis, urinary tract infections (UTI), sinusitis, abscesses, osteomyelitis, and rheumatic fever.

Bacterial endocarditis. Bacterial endocarditis is rare in children; incidence increases with advancing age and history of preexisting heart disease (see Chapter 8). A new murmur or a change in the characteristic of an existing murmur may not be initially evident. Vegetations also may not be visible initially by transthoracic echocardiography; a transesophageal approach is much more sensitive. Serial blood cultures with anaerobic and aerobic media are necessary for definitive diagnosis.

Urinary tract infection. Both upper and lower urinary tract infections may be asymptomatic, and leukocytes may not always be present in urine (see Chapter 18). Sterile pyuria may be present with tuberculosis, nongonococcal urethritis, viral cystitis, Kawasaki disease, reactive arthritis, interstitial nephritis, and other rheumatic diseases. Renal ultrasonography may show areas of decreased echogenicity, enlarged echogenic kidneys, and renal or perinephric abscesses. Kidneys may be enlarged with acute pyelonephritis. A CT scan with contrast may show infected parenchyma as a nonenhancing lucency. Nuclear medicine renal scans also identify active areas of infection and old scars.

Sinusitis. Factors that decrease the size and patency of the ostium, or impair the mucociliary transport system predispose a child to sinusitis. Ethmoid and maxillary sinuses are present at birth. The frontal sinuses usually appear near 5 or 6 years of age but may be asymmetric or absent. Sphenoid sinuses may be seen radiographically by 9 years of age. Prolonged nasal congestion, headache, purulent nasal discharge, sore throat, daytime cough, tender teeth, and halitosis may be present

in children with sinusitis. CT studies may be helpful. Rhinoscopy may show purulent material at the ostium of an infected sinus. Infectious complications of sinusitis include dural space empyema or brain abscesses.

Abscesses. Hepatic, renal, perinephric, pelvic, and subphrenic abscesses may present with FUO. Internal jugular thrombophlebitis may manifest with prolonged fever and severe neck pain. Liver abscess may manifest with right upper quadrant tenderness and hepatomegaly. Blood cultures and liver function study results are often normal. The diagnosis may be made with MRI, CT with contrast, or ultrasonography. The diagnosis of perinephric abscesses is made with CT with contrast or ultrasonography. CT or ultrasound guidance may be used to direct percutaneous drainage of many abscesses. Pelvic abscesses should be suspected in children with FUO who have abdominal, rectal, or pelvic tenderness.

Osteomyelitis. Osteomyelitis usually follows bacteremia, but it sometimes follows penetrating injury. Tenderness to palpation over the infected site is common. Abnormalities in plain films appear late (2 weeks). MRI is the imaging modality of choice. The blood or bone culture is often positive, and the ESR is often elevated. Suppurative myositis may mimic osteomyelitis and manifest as an FUO.

Rheumatic fever. Acute rheumatic fever may cause FUO; the diagnosis is made by fulfillment of the Jones criteria, updated in 2015 (see Chapter 8). Initially, a child may present with polyarthralgia and an increased ESR. Elbows, wrists, knees, and ankles are frequently involved. The later migratory nature of the true arthritis differentiates rheumatic fever from JIA.

Bacterial Syndromes

Bacterial syndromes that cause FUO in children include agents of the following:
- Lyme disease
- Cat-scratch disease
- Q fever
- Rat bite fever
- Tularemia
- Brucellosis
- Leptospirosis

Lyme disease. Lyme disease is caused by the spirochete *Borrelia burgdorferi* and is transmitted by the *Ixodes dammini* and *I. pacificus* ticks. The usual manifestation of early Lyme disease is with erythema migrans, an erythematous, annular, expanding rash with central clearing. The rash resolves 1-30 days (usually 2 weeks) after exposure. Patients may exhibit fever, chills, fatigue, headaches, malaise, myalgias, arthralgias, and lymphadenopathy. Early disseminated Lyme disease follows 2-8 weeks after exposure; facial nerve palsy, peripheral neuropathy, cardiac conduction defects, myocarditis, and aseptic meningitis may occur. Diagnosis is made clinically in early localized Lyme disease because serology lacks sensitivity and specificity during early infection and because erythema migrans is so specific for Lyme disease. Diagnosis of early disseminated Lyme disease requires a typical clinical illness, exposure to ticks known to carry *B. burgdorferi* and serologic evidence of infection with a 2-tier testing strategy. The initial test is an enzyme-linked immunosorbent assay (ELISA) or immunofluorescent (IFA) test. If this result is equivocal or positive, a Western immunoblot is performed. Western blot should not be performed if the ELISA is negative or has not been performed because it lacks specificity in this setting.

Cat-scratch disease. Cat-scratch disease is a febrile illness associated with cats (usually kittens) and, more rarely, dogs. *Bartonella henselae*, which may be transmitted by the cat flea and by cat saliva, is the etiologic agent. After a scratch or bite, a papule forms and may persist from days to months. Regional lymphadenopathy with 1 or more nodes occurs proximal to the skin site 1-9 weeks after inoculation. The node or nodes become enlarged and tender and may have overlying erythema. The lymphadenopathy usually resolves after 2 months but may last up to 3 years. Affected children may have adenopathy with fever, headache, malaise, anorexia, sore throat, and conjunctivitis (see Chapter 36).

Q fever. Q fever is caused by *Coxiella burnetii*, formerly classified as a rickettsia. It manifests with headache, fever, chills, malaise, and, on occasion, respiratory symptoms. Hepatic, cardiac, and CNS involvement may occur. Rash is usually not seen. Domestic farm animals, cats, rodents, and marsupials may be infected. Pasteurization destroys the organism in milk. Diagnosis is made by serologic testing.

Rat bite fever. Rat bite fever is a relapsing fever caused by *Streptobacillus moniliformis* or *Spirillum minus*. *S. moniliformis* is a pleomorphic gram-negative bacillus transmitted by rat bite or by contaminated food or water. In 1-10 days after exposure, patients may exhibit fever, chills, malaise, and muscle aches. A rash may form on the extremities; arthralgias and arthritis may occur. Complications include abscesses, pneumonia, endocarditis, myocarditis, and meningitis. Diagnosis is made by blood culture or culture of other infected fluid, such as abscess aspiration.

Tularemia. *Francisella tularensis* is the causative agent of tularemia. The disease is spread by contact with wild animals, such as rabbits and squirrels, and by insects that bite these animals, such as mosquitoes, ticks, and deer flies, as well as by contaminated water. A maculopapular nodule forms at the portal of entry and later becomes ulcerated. The child may present with fever, chills, and headache. Lymphadenopathy, pharyngitis, conjunctivitis, hepatosplenomegaly, and pneumonia may also occur. Diagnosis is made by serologic study.

Brucellosis. Brucellosis is caused by gram-negative coccobacilli: *Brucella abortus*, *B. melitensis*, *B. suis*, or *B. canis*. The microorganisms are found in sheep, goats, cattle, swine, and dogs. Infection may occur by airborne spread or by ingestion of meat or milk. The child may present with fever, chills, malaise, headache, arthralgias, or myalgias. Pneumonia, cardiac involvement, and CNS involvement occur in rare cases. Diagnosis is made by special culture techniques and serologic study.

Leptospirosis. Leptospirosis is caused by members of the spirochete genus *Leptospira*. Infection is spread by contact with the urine of wild or domestic animals. In 1-2 weeks after exposure, patients experience the abrupt onset of fever, chills, nausea, vomiting, headache, and occasionally conjunctival suffusion and rash. Liver, renal, and CNS involvement may also occur. Diagnosis is made by special culture techniques and serologic testing.

Fungal Infections

Fungal causes of FUO include:
- Blastomycosis
- Histoplasmosis
- Coccidioidomycosis
- Cryptococcoses

Blastomyces dermatitidis is a saprophytic fungus with both yeast and mycelial forms; it is found in the soil all over the world but is common in the Americas. It is endemic in the Southeast and Midwest regions of North America. Infections with this fungus may be disseminated or pulmonary. The diagnosis is made by visualization of single-budding yeast in clinical material, culture on Sabouraud agar, or serologic tests.

Histoplasma capsulatum is a yeast found in soil in the Ohio River valley and other locations in the United States that causes pulmonary and disseminated disease. Diagnosis is made by the demonstration of the microorganism in biopsy specimens or by complement-fixing antibody.

Coccidioides immitis is found in soil in the southwestern United States. Infections in humans are associated with a febrile pulmonary disease characterized by cough, rash, and chest pain. Diagnosis is usually made serologically.

Cryptococcus neoformans is often found in pigeon droppings and can cause a variety of diseases. The diagnosis is made by culture or by identification of encapsulated yeast in collected specimens.

Chlamydial Infection

Psittacosis and lymphogranuloma venereum are chlamydial causes of FUO. *Chlamydia psittaci* may be transmitted by infected birds and produces respiratory illness with fever. Cardiac, liver, CNS, and thyroid involvement are rare. Diagnosis is made serologically. *C. trachomatis* is a sexually transmitted organism that causes urogenital infections, perihepatitis, invasive lymphadenopathy (lymphogranuloma venereum), neonatal conjunctivitis, and neonatal pneumonia. Diagnosis is by cell culture and rapid antigen tests.

Rickettsial Infections

Rocky mountain spotted fever. Rocky Mountain spotted fever manifests with fever, headache, intense myalgias, and abdominal symptoms. A characteristic rash is usually present by the 6th day of illness. The rash covers the palms, wrists, soles, and ankles and progresses from macular to petechial. The disease can last up to 3 weeks. Many end organs, including the heart, kidneys, and CNS, can be involved. Transmission of the causative agent, *Rickettsia rickettsii*, occurs by tick bite. Diagnosis is made by PCR testing of blood.

Ehrlichiosis and Anaplasmosis. These infections are caused by *Ehrlichia chaffeensis*, *Anaplasma phagocytophila*, and *E. ewingii* and are transmitted by the Lone Star tick. Anaplasmosis is caused by Anaplasma phagocytophilia and is transmitted by the black legged deer tick. These illnesses are usually seen in the southeastern and upper Midwestern United States, respectively, and have manifestations similar to that of Rocky Mountain spotted fever. The patient presents with headache, myalgias, fever, chills, nausea, vomiting, weight loss, thrombocytopenia, and leukopenia. Rash is inconsistent but may be seen after 1 week. Pulmonary and renal complications can occur. Mental status changes are less frequent. Diagnosis is confirmed by PCR.

Viral Infections

Cytomegalovirus infection. CMV may cause a mononucleosis-like syndrome in children. Generalized or cervical adenopathy may be seen along with fatigue, malaise, fever, hepatosplenomegaly, and abdominal pain (see Chapter 36). A morbilliform rash may also be present. Retinitis, hepatitis, colitis, and pneumonia may occur in children with impaired immune systems. The virus is transmitted by contact with secretions. Infection is diagnosed by culture (nasopharyngeal, blood, urine) or by the detection of specific immunoglobulin G and immunoglobulin M antibodies.

Infectious mononucleosis. Infectious mononucleosis is typically caused by EBV and may manifest with fever, exudative pharyngitis, malaise, and fatigue (see Chapter 36). The appearance of rash is sometimes preceded by amoxicillin therapy, but rash may occur without antibiotic administration. Tender lymphadenopathy and hepatosplenomegaly may occur. The diagnosis may be made by nonspecific tests (heterophile antibody or Monospot) in older patients, but these studies are unreliable for young children. Specific antibody tests against viral capsid antigen, early antigen, and nuclear antigen are recommended in younger children. Treatment is supportive.

Human immunodeficiency virus infection. Infection with HIV or associated opportunistic infections or associated malignancies is another cause of FUO in children.

Parasites

FUO in children may be caused by parasitic infections, including (1) babesiosis, (2) toxoplasmosis, and (3) toxocariasis.

Babesiosis is caused by *Babesia microtia* and is a parasite of rodents transmitted to humans by tick bite. Infection may result in fever, chills, nausea, vomiting, night sweats, myalgias, and arthralgias. Identification of the organism in a thick smear of red blood cells is diagnostic.

T. gondii is a protozoan parasite. Children become infected from eating contaminated, undercooked meat or from exposure to the feces of domestic cats. Most infections acquired postnatally are asymptomatic but children may develop a mononucleosis-like illness (see Chapter 36).

Toxocariasis (previously visceral larva migrans) results from ingestion of larvae of *Toxocara canis* or from *T. cati* shed in dog and cat feces, respectively. Infection results in fever, intense eosinophilia, hepatomegaly, and hypergammaglobulinemia. Lung, heart, and CNS involvement is rare. The eye may become infected. Diagnosis is presumed with increased eosinophils and hypergammaglobulinemia, and elevated titers of isohemagglutinin to A and B blood group antigens.

Infections in Children Who Live in or Have Traveled to Developing Countries

In a child who has traveled to or lives in a developing country, consideration must be given to the area, water sources, and activities. Some causes of FUO to consider include malaria, hepatitis, typhoid fever, tuberculosis, and amebic liver abscess (Table 39.12).

Malaria

Malaria is transmitted by the bite of an infected mosquito carrying 1 of the 5 species of the *Plasmodium* genus that cause disease in humans. The patient experiences chills, rigors, high fever, diaphoresis, and headaches. The incubation period varies among species, from 1 week to several months. Demonstration of the parasite on thick peripheral blood smear is diagnostic. Risk for malaria can be checked for areas of the world on www.cdc.gov/malaria.

Hepatitis

Hepatitis A may be contracted by ingestion of contaminated food or water. Hepatitis B and C viruses are transmitted through blood products or sexual contact. Diagnosis is by serologic testing. Symptoms can include fever, malaise, jaundice, hepatomegaly, nausea, and anorexia. Hepatitis B and C can become chronic (see Chapter 15).

Typhoid Fever (Enteric Fever)

Enteric fever is caused by infection with 3 serovars of *S. enterica*, which includes *S. typhi*. After ingestion of contaminated water or food, incubation lasts from 1-6 weeks. Persistent fever, headache, malaise, anorexia, and rose spots are clinical hallmarks of enteric fever. Diagnosis is by blood culture.

Tuberculosis

Tuberculosis may manifest as FUO in children (see Chapters 2 and 36). Affected children may have pulmonary or extrapulmonary disease. The signs and symptoms of pulmonary disease may vary greatly from weight loss, tuberculin skin test conversion, and low-grade fever to mass effect from mediastinal lymphadenopathy and fulminant disseminated pulmonary involvement with miliary infiltrates or, in rare cases, cavitation. Nonpulmonary tuberculosis more commonly manifests as FUO, inasmuch as positive chest radiograph findings and pulmonary signs may initiate an early work-up for tuberculosis. Hematogenous spread may cause liver, heart, or renal involvement. Ingested bacilli may result in gastrointestinal tuberculosis. The diagnosis requires demonstration of

acid-fast bacilli from sputum, gastric aspirate, or the affected organ. Skin testing may yield negative results even with positive controls.

Amebiasis

Intestinal infection with *Entamoeba histolytica* may produce invasion of the mucosal lining and spread to other organs such as the liver. Amebic liver abscess may manifest with fever, weight loss, right upper quadrant pain, and anorexia. The patient may have painful hepatomegaly without splenomegaly. The abscess may be localized with abdominal ultrasonography or CT. Diagnosis is by serologic study.

Rheumatic Causes of Fever of Unknown Origin

Rheumatic diseases as a cause of FUO are the 2nd most common identified cause of FUO after infections. In a systematic review, the most common causes were JIA and SLE (see Chapter 33).

Juvenile Idiopathic Arthritis

JIA is a diagnosis that requires time to identify all of its manifestations and to exclude other entities. JIA is defined by arthritis of unknown origin that begins in a child younger than 16 years and persists for a minimum of 6 weeks. JIA is divided into 3 subtypes: systemic, polyarticular, and oligoarticular. The systemic form often manifests with prolonged high fever. Affected children often have a daily fever and may have a fine macular rash, arthralgias, arthritis, hepatosplenomegaly, or pericardial involvement. Polyarticular JIA may manifest with arthritis, low-grade fever, morning stiffness, anorexia, and weight loss.

Polyarteritis

Polyarteritis is a necrotizing vasculitis that may manifest with myalgia, arthralgia, fever, vasculitic skin lesions, and abdominal pain. Cardiac, CNS, and renal involvement may also occur. The ESR usually is markedly elevated. Biopsy and the presence of antibodies to proteinase 3 and myeloperoxidase (antineutrophil cytoplasmic antibodies) are helpful.

Systemic Lupus Erythematosus

SLE may manifest with fever, photosensitivity, mouth sores, weight loss, rash, myalgias, malaise, and hepatosplenomegaly. Patients may also have serositis and renal involvement. Laboratory tests that are helpful include lupus erythematosus cell preparation and those for antinuclear antibody, anti-Smith antibody, anti-ribonuclear protein antibody, anti-Ro (Sjögren syndrome type A) antibody, and anti-La (Sjögren syndrome type B) antibody.

Behçet Syndrome

Behçet syndrome is very rare in children but may manifest with FUO. Patients may have aphthous stomatitis, arthritis, genital ulcers, uveitis, and erythema nodosum.

Neoplasms

Hodgkin disease, lymphoma, neuroblastoma, and leukemia may all manifest as FUO. In young children, leukemia, neuroblastoma, and lymphoma should be suspected, whereas in adolescents, Hodgkin disease and Ewing sarcoma are more common as causes of FUO.

Hodgkin Disease

Hodgkin disease may manifest with firm, nontender adenopathy, fever, night sweats, and weight loss. Diagnosis is made through biopsy.

Lymphoma

Non-Hodgkin lymphoma may manifest as painless adenopathy, cough or dyspnea from a mediastinal mass, abdominal mass, nerve compression, bone pain, fever, and weight loss. Diagnosis is by biopsy.

Neuroblastoma

Neuroblastoma may manifest as abdominal, thoracic, or pelvic masses; spinal cord compression; bone pain; hypertension; hepatomegaly; diarrhea; and fever (see Chapter 17). Diagnosis is aided by radiologic studies and urinary catecholamine measurements and is confirmed by biopsy.

Leukemia

Both acute lymphocytic leukemia and acute nonlymphocytic leukemia may manifest with lethargy, pallor, bleeding, fever, bone pain, lymphadenopathy, and arthralgias. Diagnosis is made by blood smear and bone marrow biopsy.

Pheochromocytoma

Pheochromocytomas are rare catecholamine-secreting tumors; 10% occur in children. These tumors manifest with paroxysmal or sustained hypertension, headache, excessive sweating, fever, hyperglycemia, and palpitations. The tumors are usually in the adrenal medulla, but 35% of those occurring in children are multiple or extraadrenal. Diagnosis is made by measuring urinary or plasma metanephrine or catecholamine levels. Localization of tumor is by CT, MRI, or iodine 131-metaiodobenzylguanidine scanning.

Miscellaneous Causes of Fever of Unknown Origin
Genetic Diseases (See Chapter 41)

Familial Mediterranean fever is an autosomal recessive trait seen in Sephardic Jews and people of Middle Eastern descent. The fever may be accompanied by joint, abdominal, and chest pain. Anhidrotic ectodermal dysplasia is an X-linked recessive disorder associated with decreased ability to sweat, dental abnormalities, and sparse hair. Eyebrows and eyelashes may be absent. Fever may result from the inability of the body to cool itself. Diagnosis is made by skin biopsy that shows an absence of eccrine glands.

Drug Fever

Drug fever is a diagnosis of exclusion. Some drugs are more likely than others to cause drug fever (α-methyldopa, quinidine, penicillins). There is no characteristic fever pattern. There is a highly variable lag time between the initiation of the drug and the onset of fever, and there is an infrequent association with rash or eosinophilia. Some drugs may cause fever by virtue of physiologic side effects. Anticholinergic drugs may decrease sweating and diminish the body's ability to cool itself. Chronic salicylate intoxication can cause increased heat production by uncoupling oxidative phosphorylation.

Kawasaki Disease

Kawasaki disease may manifest with a variety of signs, including rash; lymphadenopathy; conjunctival hyperemia; strawberry tongue; erythematous lips; swelling of hands and feet; arthralgia; arthritis; myocarditis; late desquamation of hands, feet, and perineal area; and sterile pyuria. Fever may be high and spiking. Diagnosis is by fulfillment of clinical criteria (see Chapter 40).

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD; ulcerative colitis, Crohn disease) may manifest with FUO. Ulcerative colitis may manifest with bloody diarrhea, fever, fecal urgency, and straining (see Chapter 11). Pyoderma gangrenosum, arthritis, and erythema nodosum can also be seen. Crohn disease (regional enteritis) may manifest with abdominal pain, fever, anorexia, and growth failure. Diarrhea may develop later. Arthritis, erythema nodosum, and finger clubbing may also occur. Diagnosis of IBD is by endoscopy and histology.

Thyrotoxicosis

Hyperthyroid states may manifest with FUO. Children usually have multiple symptoms, such as irritability, tremor, eyelid lag, and exophthalmos. Diagnosis is made from thyroid function studies.

Factitious Disorders

Factitious fever may be a form of factitious disorder imposed on self (formerly Munchausen syndrome) or medical child abuse (formerly Munchausen syndrome by proxy) (see Chapter 26). A variety of techniques have been used to falsely elevate a recorded temperature. A mercury thermometer may be rubbed between hands or placed near a light bulb. Hot liquids may be placed in the mouth before an oral temperature is taken. Hot rectal douches have also been reported to raise a rectally taken temperature. Even with pathologic fevers, there is some circadian rhythm to the temperature curve; with factitious fever there is no rhythm. In addition, there is usually no vasoconstriction, sweating, tachypnea, or tachycardia. If factitious fever is suspected, the temperature should be obtained while the patient is observed. The temperature of freshly voided urine can also be recorded.

Other patients may produce actual diseases that cause true fevers, such as by injecting infected pyogenic material subcutaneously or intravenously or by taking toxic levels of thyroid hormone. Once the diagnosis is documented, psychiatric care is indicated.

Patients in Whom No Diagnosis Is Made

If no diagnosis is made, most patients are clinically well and asymptomatic on follow-up. Some may be determined to be healthy from the start; most are in good health at follow-up, whereas few have symptoms at the end of evaluation. Some may have relapses of fever for a few months. JIA, inflammatory bowel disease, and PFAPA syndrome may not be immediately diagnosed but usually manifest typical symptoms and signs within 2 years of the onset of the FUO.

SUMMARY AND RED FLAGS

Many children with fever will have a source identified on their initial history and physical examination. Red flags include patients with symptoms or signs of sepsis (tachycardia, hypotension) or meningitis or encephalitis (fever, headache, irritability, altered mental status and for the older child, meningismus). Affected infants with meningitis are more likely than older children to have subtle and nonspecific symptoms.

A child with fever of recent onset with no adequate historical or physical explanation for the fever is said to have fever without source (FWS). Because of the high volume of children with FWS, it is important to have a reliable system for individual patient evaluation and management. Although the majority of patients with FWS have a self-limited viral illness, 5-10% have an invasive bacterial infection, with young infants at highest risk. Because of the potential for morbidity and mortality from the organisms that cause invasive disease, identification of patients at high risk is essential. Although there is no single, timely series of tests that correctly categorizes all patients, the combination of careful clinical evaluation and appropriate laboratory screening criteria can help identify a level of risk in children of different ages. The reduction of bacteremia due to vaccine-serotype pneumococcus has led to a careful reduction in diagnostic testing, especially in the 3-36 month old child with FWS. Red flags include a history of immunodeficiency or other chronic medical illness, no prior immunizations, toxic appearance, signs of shock, petechiae or purpura, poor responsiveness, and other signs of altered mental status.

Some children, who are initially thought to have FWS, develop into patients with FUO. Definitions of FUO in children vary. A practical definition balancing different recommendations is FUO is a temperature higher than 38°C (100.4°F) daily for at least 8-14 days and no diagnosis after an initial evaluation. Work-up of the patient with FUO should proceed in a stepwise manner. It should be kept in mind that many patients with FUO have unusual, atypical, or complicated manifestations of common childhood illness, mainly infections. Red flags include weight loss, night sweats, signs of organ system dysfunction or failure, or unstable vital signs suggestive of sepsis. Only in this last category should a rapid diagnostic approach be performed and empirical antibiotic therapy initiated.

Fever and Rash

Emily M. Densmore and Patricia S. Lye

The coexistence of fever and rash suggests a relatively wide spectrum of pathologic entities for diagnostic consideration. This spectrum includes local or systemic infection with a wide range of microbial pathogens; toxin-mediated disorders, including those associated with bacterial superantigen production; inflammatory conditions, including vasculitides and rheumatologic diseases; and hypersensitivity disorders. While most conditions causing fever and rash are benign and self-limited, a thorough clinical evaluation is crucial to identify those caused by life-threatening diseases or those requiring specific treatment. The essential elements for accurate diagnosis include a detailed history and a thorough physical examination including a careful systematic observation of the patient for evidence of toxicity. Because this approach lacks perfect sensitivity, the laboratory may play an important role in the diagnostic process.

FEVER AND RASH

◆ History

Information about the features of the rash includes when it occurred in relation to the fever, its evolution or progression, its anatomic distribution, and whether it is pruritic or painful (Table 40.1). Degree of illness should be evaluated, especially in the infant and toddler, by assessing oral intake, activity level, and urine output. A description of the fever pattern can be useful (see Chapter 39) and immunization status will help prioritize the differential diagnosis. Essential information from the epidemiologic and social history should include season of the year; geographic location of the patient's residence; exposure to known ill contacts; recent travel or exposure to individuals from different geographic areas; exposure to pets, wildlife, or insects; recent immunizations; a detailed list of medications; previous blood transfusion; and for the adolescent patient, intravenous drug use and sexual activity.

The medical and family history should be used to assess the overall health of the patient over time, as well as that of family members, to determine the possibility of underlying primary or acquired immunodeficiency or diseases associated with autoimmunity or chronic inflammation. A history of increased susceptibility to infection, as manifested by chronic or recurrent infectious illnesses after infancy, such as pneumonia, sinusitis, bronchitis, otitis media, diarrhea, and bacteremia, is an important indicator of underlying immunodeficiency disease (see Chapter 41). In addition, the occurrence of an unusually severe infection or an infection with a pathogen of low virulence (e.g., *Pneumocystis jiroveci*) should raise a suspicion of an immunodeficiency state. A history of hemolytic anemia, leukopenia, thrombocytopenia, or arthritis suggests an autoimmune disorder or malignancy, which may also be associated with impairment in immune function (see Chapter 33).

In a thorough systems review, the clinician should assess the probability of a subacute or chronic underlying infectious, inflammatory, or malignant disease by inquiring about anorexia, nausea, vomiting, weight loss or failure to thrive, night sweats, fatigue, cough, and exercise intolerance. The clinician should seek symptoms suggesting multisystem disease, such as myalgias, arthralgias, headache, precordial pain or pain with inspiration, abdominal pain, jaundice, skin photosensitivity, peripheral edema, alopecia, Raynaud phenomenon, and hematuria. In patients with symptoms that indicate the presence of multisystem disease, a thorough survey of the functional status of the central, peripheral, and autonomic nervous systems is clinically relevant. Specific inquiries into visual disturbances, photophobia, disordered mentation, neck stiffness, paresthesia, weakness, or seizure activity are essential and may reveal potentially life-threatening infection within the central nervous system or a systemic vasculitis involving the nervous system, such as systemic lupus erythematosus (SLE) or polyarteritis nodosa.

◆ Examination

The physical examination is used to refine the probability of underlying serious illness, to identify rashes typical of a specific diagnosis, to look for noncutaneous disease manifestations, and to identify if further testing or treatment is indicated (Table 40.2; also see Chapters 39 and 48).

A critical 1st step is an assessment of the patient's vital signs and degree of toxicity. Lethargy, irritability, altered mental status, decreased activity, poor perfusion, pallor, or cyanosis indicate serious illness; resuscitation and treatment directed at the most likely diagnoses should be initiated without delay. The importance of the height of fever in predicting the risk of serious illness is unclear. Underlying chronic illness and degree of toxicity are more useful for risk assessment than fever height. The presence of tachycardia and tachypnea in any patient with fever and rash suggests the possibility of sepsis. Tachycardia may also be seen in endocarditis or in myocarditis secondary to certain viruses, Kawasaki disease (KD), or acute rheumatic fever. Evidence of alteration in mental status suggests either sepsis associated with decreased organ perfusion or primary meningoencephalitis. The presence of hypotension usually indicates septic shock, but other disorders such as toxic shock syndrome (TSS), dengue hemorrhagic shock syndrome, hemorrhagic fever with renal syndrome caused by Hantavirus, and the hemorrhagic shock and encephalopathy syndrome must also be considered in this context. Hypertension may be noted in association with vasculitic disorders involving small- to medium-sized arteries, such as polyarteritis and SLE.

The clinical characteristics of the rash are often helpful in establishing an etiologic diagnosis. A morphologic nomenclature of cutaneous manifestations helps the clinician with differential diagnosis,

TABLE 40.1 Essential Elements of the History in the Clinical Assessment of Fever and Rash

Demographic Data
Age
Sex
Ethnicity
Season
Geographic area
Exposures
Ill contacts (home, daycare, school, workplace)
Sexual contacts
Travel outside area of residence
Pets, wildlife, insects (especially ticks)
Medications and drugs
Transfusions
Immunizations
Occupational

Features of Rash
Temporal associations (onset relative to fever)
Progression and evolution
Location and distribution
Pain or pruritus
Timing and pattern of desquamation

Associated Symptoms
Focal (suggesting organ-specific illness)
Systemic (suggesting generalized or multisystem illness)

Prior Health Status
Medical and surgical history
Growth and development
Recurrent infectious illnesses

Family History

TABLE 40.2 Essential Elements of the Physical Examination in the Clinical Assessment of Fever and Rash

Degree of Toxicity
Vital Signs
Fever pattern
Tachycardia or bradycardia
Tachypnea
Hypotension or hypertension

Characteristics of Rash
Macular
Papular
Maculopapular
Petechiae or purpura
Diffuse erythroderma
Accentuation in flexural creases
Desquamation with stroking (Nikolsky sign) or spontaneous
Localized erythroderma
Expansile
Painful
Urticaria
Vesicles, pustules, bullae
Nodules
Ulcers

Distribution and Localization of Rash
Generalized or localized
Symmetric or asymmetric
Centripetal or centrifugal

Musculoskeletal
Neurologic
Lymphadenopathy
Hepatosplenomegaly
Arthritis

documentation, and communication (see Chapter 48). An **exanthem** is defined as a skin eruption occurring as a sign of a generalized disease. An **enanthem** is an eruption on the mucous membranes that occurs in the context of generalized disease. Exanthems and enanthems may be macular, maculopapular, vesicular, urticarial, petechial, or diffusely erythematous. Rashes are usually classified according to their most typical lesion morphology. However, morphology may vary as rashes evolve; the rash of Rocky Mountain spotted fever is classically described as petechial, but it may initially be maculopapular. Because a wide variety of infectious agents, including viruses, bacteria, and the rickettsiae, as well as drugs and inflammatory conditions can cause exanthems and enanthems, few of these eruptions are pathognomonic (Tables 40.3, 40.4, and 40.5).

Specific Skin Lesions
Maculopapular Eruptions
Macules are flat, nonpalpable circumscribed lesions, while **papules** are <1 cm, circumscribed palpable lesions. Maculopapular lesions may coalesce into a more confluent morbilliform (measles-like) eruption. A rash with multiple small papules that feels like sandpaper is described as **scarlatiniform**. Maculopapular rashes are usually seen in viral

illnesses, drug eruptions, and immune complex-mediated disorders. The classic childhood exanthems such as measles, rubella, erythema infectiosum (fifth disease, caused by parvovirus B19), and roseola (exanthem subitum, caused by human herpesvirus types 6 and 7) produce a maculopapular rash and are usually clinically recognizable (Figs. 40.1 and 40.2; see Table 40.5). Other organisms that commonly cause a maculopapular rash include enteroviruses, Epstein–Barr virus

TABLE 40.3	**Differential Diagnosis of Fever and Rash**			
Lesion	**Pathogen or Associated Factor**		**Lesion**	**Pathogen or Associated Factor**
Maculopapular or Macular Rash	***Viruses*** Measles (confluent), rubella (discrete), roseola (human herpesvirus 6),* fifth disease (parvovirus),* EBV,* enteroviruses,* hepatitis B virus (papular acrodermatitis or Gianotti–Crosti syndrome), HIV, dengue virus, adenovirus ***Bacteria*** Rheumatic fever (group A streptococcus), scarlet fever, erysipelas, *Arcanobacterium haemolyticum,* secondary syphilis, leptospirosis, *Pseudomonas,* meningococcal infection (early), *Salmonella* (typhoid rose spots), Lyme disease, *Mycoplasma pneumoniae,* *Listeria monocytogenes, Brucella melitensis* ***Rickettsiae*** Early Rocky Mountain spotted fever, typhus (scrub, endemic), ehrlichiosis (monocytic) ***Other*** Kawasaki disease,* *Coccidioides immitis*, drug reactions, SJIA, hereditary fever syndromes, HLH		**Petechial-Purpuric**	***Viruses*** Atypical measles, congenital rubella, cytomegalovirus, enterovirus, HIV, hemorrhagic fever viruses, hemorrhagic varicella, EBV, hepatitis B, adenovirus, yellow fever ***Bacteria*** Sepsis (meningococcal,* gonococcal, pneumococcal,* *S. aureus,*), endocarditis, rat-bite fever (*Spirillum minus* or *Streptobacillus moniliformis*), *Pseudomonas aeruginosa*, group A streptococcus rickettsiae, *Capnocytophaga canimorsus* ***Rickettsiae*** Rocky Mountain spotted fever,* epidemic typhus, ehrlichiosis ***Other*** Vasculitis, thrombocytopenia, Henoch–Schönlein purpura,* malaria
Diffuse Erythroderma	***Bacteria*** Scarlet fever (group A streptococcus),* other streptococci, toxic shock syndrome (*Staphylococcus aureus* and group A streptococcus),* staphylococcal scarlet fever, ehrlichiosis *(Ehrlichia chaffeensis)* ***Fungi*** *Candida albicans*		**Erythema Nodosum**	***Viruses*** EBV, hepatitis B, C, HSV, HIV ***Bacteria*** Group A streptococcus, tuberculosis, *Yersinia*, cat-scratch disease, brucellosis, Q fever, *M. pneumoniae*, tularemia, syphilis ***Fungi*** Coccidioidomycosis, histoplasmosis, blastomycosis, sporotrichosis, cryptococcosis ***Other*** Sarcoidosis, inflammatory bowel disease, estrogen-containing oral contraceptives, systemic lupus erythematosus, Behçet disease, lymphoma
Urticarial Rash	***Viruses*** EBV, hepatitis B, HIV, enteroviruses ***Bacteria*** *M. pneumoniae*, group A streptococci, *Shigella*, meningococcus, *Yersinia* ***Other*** Various parasites, insect bites, food-drug allergens (usually afebrile)		**Distinctive Rashes** Ecthyma gangrenosum	*P. aeruginosa, Vibrio vulnificus*

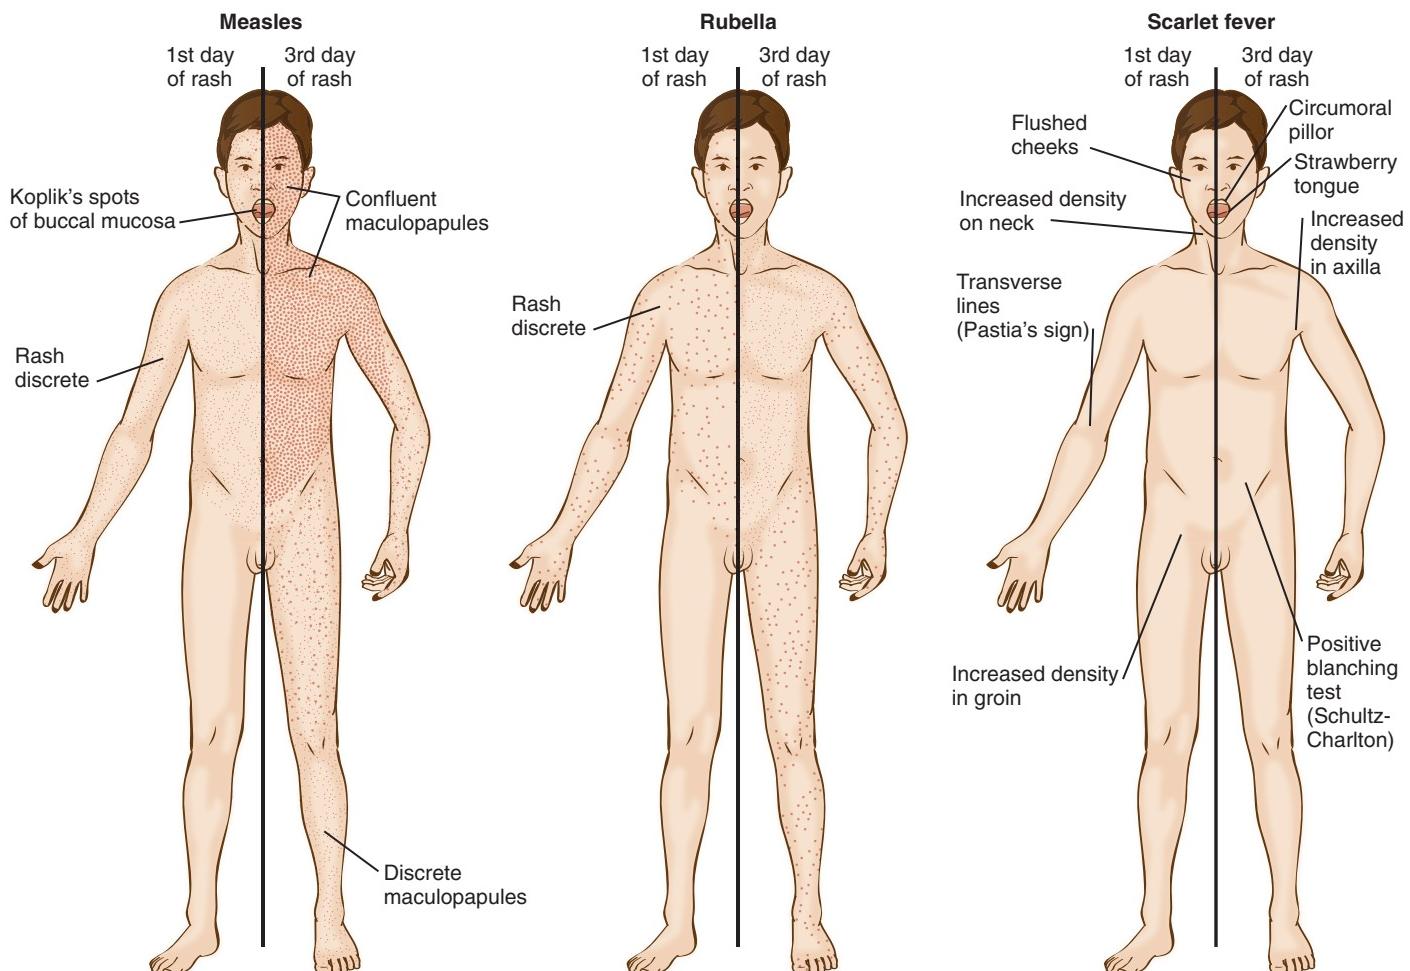

FIGURE 40.2 Schematic drawings illustrating difference in appearance, distribution, and progression of rashes of measles, rubella, and scarlet fever. (From Gershon AA, Hotez PJ, Katz SL, eds. *Krugman's Infectious Diseases of Children*. 11th ed. Philadelphia: Mosby; 2004:928.)

TABLE 40.4 Common Bacterial Exanthems

Disease	Cause	Age	Season	Transmission	Incubation (Days)	Prodrome
Scarlet fever	Group A streptococcus	School age	Fall, winter, spring	Direct contact, droplets	1–4	Sore throat, headache, abdominal pain, cervical lymphadenopathy, fever, 0–2 days, acute onset
Staphylococcal scalded skin syndrome (SSSS)	*Staphylococcus aureus* producing exfoliative toxin	Neonates and infants	Any	Colonization, contact	Unknown	None
Toxic shock syndrome (TSS)	*S. aureus* producing toxic shock syndrome toxin-1 (TSST-1) and staphylococcal enterotoxins (SEs) Group A streptococcus producing *Streptococcus pyogenes* exotoxins (SPEs)	Adolescent girls if menstrual; others variable	Any	Colonization, contact	Variable, often 1–5	Myalgias, fevers, and gastrointestinal symptoms May be secondary to wound infection, trivial mucosal or respiratory infection, or necrotizing fasciitis or myositis
Meningococcemia	*Neisseria meningitidis*	Any (<5 yr and adolescents)	Winter, spring, follows influenza epidemics	Close, prolonged contact	5–15	Fever, malaise, myalgia, 1–10 days
Rocky Mountain spotted fever (RMSF)	*Rickettsia rickettsii*	Any (>5 yr), male > female	Summer	Carrier ticks	3–12	Fever, myalgia, headache, malaise, ill appearance, 2–4 days
Rickettsialpox	*R. akari*	Any	Any	Mouse mite	7–14	Fever, chills, headache, malaise, 4–7 days

Common Bacterial Exanthems, cont.

Features and Rash Structure	Enanthem	Complications	Prevention/Treatment	Comments
Diffuse erythema with "sandpaper" feel: accentuation of erythema in flexural creases (Pastia lines); circumoral pallor, lasts 2–7 days; may exfoliate	Palatal petechiae, strawberry tongue	Peritonsillar abscess, rheumatic fever, glomerulonephritis	Prevent rheumatic fever with penicillin within 10 days of onset of pharyngitis, treat with penicillin	Similar syndrome may be noted with *Arcanobacterium haemolyticum* in adolescents; group A streptococci may also produce toxic shock or true bacteremic shock syndromes in addition to cellulitis, lymphangitis, and erysipelas; *S. aureus* may produce a scarlatiniform rash
Sudden onset, tender erythroderma progressing to diffuse flaccid bullae; significant perioral, perinasal peeling; eventual diffuse exfoliation (positive Nikolsky sign), possibly conjunctivitis, purulent rhinorrhea	Unusual	Shock	Treat with intravenous antibacterial active against *S. aureus*	—
Diffuse sunburn-like erythroderma; hypotension, diarrhea, emesis, mental status changes; late desquamation	Conjunctivitis	Shock, multisystem organ dysfunction/failure	Treat with intravenous antibacterial active against *S. aureus*; penicillin if group A streptococcus suspected; clindamycin; possible intravenous immune globulin; prevent menstrual-associated TSS by frequent changes of tampon	—
Erythematous, nonconfluent, discrete papules (early); petechiae, purpura present on trunk, extremities, palms, soles	Petechiae	Shock, meningitis, pericarditis, arthritis, endophthalmitis, gangrene, disseminated intravascular coagulation	Contacts: rifampin; general: vaccine; treat with ceftriaxone, cefotaxime, penicillin (if sensitive)	*Neisseria gonorrhoeae*, pneumococcus, *Haemophilus influenza* type b, group A streptococcus may produce similar clinical manifestations
Early maculopapular, then petechial or, rarely, purpuric; present on extremities, then trunk, palms, and soles	Petechiae variable	Shock, myocarditis, encephalitis, pneumonia	Remove ticks as soon as possible; use tick repellants; treat with doxycycline	*Ehrlichia chaffeensis* and other rickettsiae may produce similar illnesses with or without a rash
At primary bite site, eschar; secondary papulovesicles in same stage throughout illness; fewer vesicles than in chickenpox (5–30); present on trunk and proximal extremities	Unknown	Usually none	Treat with doxycycline	Often confused with chickenpox; may be more common than expected, especially in crowded urban settings with poor housing

TABLE 40.5 Common Viral Exanthems

Disease	Cause	Age	Season	Transmission	Incubation (Days)	Prodrome
Measles (rubeola)	Measles virus	Infants, adolescents	Winter, spring	Respiratory droplet	10–12	High fever, cough, coryza, conjunctivitis, 2–4 days
Rubella (German measles)	Rubella virus	Infants, young adults	Winter, spring	Respiratory droplet	14–21	Malaise, fever <101°F, posterior auricular, cervical, occipital adenopathy, 0–4 days
Roseola (exanthem subitum)	Human herpesvirus type 6 (HHV-6), Human herpesvirus type 7 (HHV-7)	Infants (6 mo–2 yr) for HHV-6, can be older children for HHV-7	Any	Unknown; saliva of asymptomatic carrier?	9–10 (HHV-6); unknown (HHV-7)	Irritability, high fever 3–7 days, cervical, occipital adenopathy;
Fifth disease (erythema infectiosum)	Parvovirus B19	Prepubertal children, schoolteachers	Winter, spring	Respiratory droplets; blood transfusion, placenta	5–15	Headache, malaise, myalgia; often afebrile
Chickenpox (varicella)	Varicella-zoster virus	1–14 yr	Late fall, winter, early spring	Respiratory droplet	12–21	Fever
Enteroviruses	Coxsackievirus, echovirus, and others	Infants, young children	Summer, fall	Fecal-oral	4–6	Variable: irritable, fever, sore throat, myalgias, headache
Mononucleosis	Epstein–Barr virus	Children, adolescents	Any	Close contact, saliva, blood transfusion	28–49	Fever, adenopathy, eyelid edema, sore throat, hepatosplenomegaly, malaise; atypical lymphocytosis
Gianotti–Crosti syndrome (papular acrodermatitis of childhood)	Hepatitis B virus, Epstein–Barr virus, coxsackieviruses, others	1–6 yr	Any	Variable; fecal, sexual, blood products for hepatitis B	Unknown; 50–180 days for hepatitis B	Usually none except for specific viral disease; arthritis-arthralgia for hepatitis B

CNS, central nervous system; HBIG, hepatitis B virus immune globulin; VZIG, varicella-zoster immune globulin.

Common Viral Exanthems, cont.

Features and Rash Structure	Enanthem	Complications	Prevention/ Treatment	Comments
Maculopapular (confluent), begins on face, spreads to trunk; lasts 3–6 days Brown color develops; fine desquamation; toxic, uncomfortable appearance, photophobia; rash may be absent in human immunodeficiency virus infection	Koplik spots on buccal mucosa before rash	Febrile seizures, otitis, pneumonia, encephalitis, laryngotracheitis, thrombocytopenia; delayed subacute sclerosing panencephalitis	General: measles vaccine at 12–15 mo and again at 4–6 yr Exposure: measles vaccine if within 72 hr; immune globulin if within 6 days of exposure (must then wait 5–6 mo to vaccinate) The World Health Organization recommends treatment with vitamin A in all patients with measles	Reportable to public health department; epidemics reported, contagious 3 days before symptoms and to 4 days after rash Increasing incidence as vaccination rates are decreasing
Discrete, nonconfluent, rose-colored macules and papules, begins on face and spreads downward; lasts 1–3 days	Variable erythematous macules on soft palate	Arthritis, thrombocytopenia, encephalopathy; fetal embryopathy	General: rubella vaccine at 12–15 mo and again at 4–6 yr; exposure: possibly immune serum globulin	Reportable to public health department; epidemics reported, contagious 2 days before symptoms and 5–7 days after rash
Discrete macules on trunk, neck; sudden-onset rash with defervescence; lasts 0.5–2 days; some patients have no rash	Variable erythematous macules on soft palate	Single or recurrent febrile seizures; encephalopathy; dissemination (e.g., liver, CNS, lung) in immunosuppressed patients	None	No epidemics
Local erythema of cheeks (slapped cheek appearance); lacy pink red erythema of trunk and extremities, ± pruritus; rash may lag prodrome by 3–7 days; lasts 2–4 days, may recur 2–3 wk later	None	Arthritis, aplastic crisis in patients with chronic hemolytic anemia (e.g., sickle cell), fetal anemic hydrops, vasculitis, Wegner granulomatosis	Isolation of patients with aplastic crisis but not normal host with fifth disease	Epidemics reported; once rash is present, the normal host is not contagious; patients with aplastic crisis often have no rash
Pruritic papules, vesicles in various stages, 2–4 crops and then crusts; distributed on trunk and then face, extremities; lasts 7–10 days; recurs years later in dermatomal distribution (zoster, shingles)	Oral mucosa, tongue	Staphylococcal or streptococcal skin infection, arthritis, cerebellar ataxia, encephalitis, thrombocytopenia, Reye syndrome (with aspirin), myocarditis, nephritis, hepatitis, pneumonia; dissemination in immunocompromised	VZIG for exposed immunosuppressed patients, susceptible pregnant women, preterm neonates, and infants at birth whose mother developed varicella 5 days before and 2 days after birth; active immunization with live attenuated vaccine at 12 mo	Acyclovir therapy for immunosuppressed and possibly normal patients (controversial); contagious 1–2 days after rash (usually no longer contagious when all lesions are crusted and no new lesions appear)
Hand–foot–mouth: vesicles in those locations; others: nonspecific, usually fine nonconfluent, macular or maculopapular rash, rarely petechial, urticarial, or vesicular; lasts 3–7 days	Yes	Aseptic meningitis, hepatitis, myocarditis, paralysis: usually in younger patients	None	Rash may appear with fever or after defervescence; rash may be present in <50% of enteroviral illnesses; epidemics possible, contagious up to 2 wk
Maculopapular or morbilliform on trunk, extremities; may be confluent; often elicited by simultaneous administration of ampicillin or allopurinol; rash in 15% and in 50% with drug-induced form, lasts 2–7 days	Variable	Anemia, thrombocytopenia, aplastic anemia, hepatitis; rarely hemophagocytic lymphohistiocytosis, lymphoproliferative syndrome	None	Cytomegalovirus and toxoplasmosis also produce mononucleosis-like illness; monospot or heterophile tests negative
Papules, papulovesicles, discrete or confluent; face, arms, extremities, often spares trunk; lasts 4–10 days	Variable	As per specific disease	Hepatitis B: HBIG plus vaccine	—

(EBV), cytomegalovirus, adenovirus, and hepatitis B virus. **Erythema migrans,** the distinctive rash of Lyme disease (caused by the tick-borne spirochete *Borrelia burgdorferi*), begins as a papule at the site of a recent tick bite and slowly expands over days to weeks to form an erythematous, annular lesion, sometimes with partial central clearing (Fig. 40.3). **Erythema marginatum,** a rare but major manifestation of acute rheumatic fever, is also distinctive (Fig. 40.4).

Morbilliform drug eruptions are often indistinguishable from viral exanthems and present 7-14 days after exposure to a drug (Fig. 40.5). As with most viral exanthems, the rash starts on the trunk and spreads to the extremities. Examples of causative agents include aminopenicillins, cephalosporins, antiepileptics, and sulfonamides. Morbilliform drug eruptions usually resolve spontaneously after discontinuation of the culprit drug, but sometimes they are the 1st sign of the potentially life-threatening syndrome drug rash with eosinophilia and systemic symptoms (**DRESS**, also known as drug-induced hypersensitivity syndrome, formerly anticonvulsant hypersensitivity syndrome).

Inflammatory diseases can present with fever and maculopapular rash. Systemic juvenile idiopathic arthritis (SJIA, Still's disease) presents with an evanescent, salmon-colored macular rash on the trunk and proximal extremities that coincide with fever spikes (see Chapter 33). Many of the hereditary periodic fever syndromes manifest with maculopapular (or urticarial) rash associated with fever (see Chapter 41).

FIGURE 40.3 Erythema Migrans—Erythematous Target-Like Plaque of Lyme Disease. The primary skin lesion of *B. burgdorferi* infection is noted for centrifugal expansion, sometimes leaving a central clearing. (Courtesy James Gathany; Content Providers CDC/James Gathany—this media comes from the Centers for Disease Control and Prevention's Public Health Image Library [PHIL], with identification number #9875. FIGURE 40.5 Morbilliform drug eruptions. *A,* Fine pink macules and thin papules becoming confluent on the posterior upper arm, which is a dependent area in this hospitalized patient. *B,* More edematous ("urticarial") pink papules; unlike true urticaria, these lesions are not transient. (Courtesy Julie V. Schaffer, MD. From Fever and Rash. In: Bolognia JL, ed. *Dermatology Essentials.* Philadelphia: Elsevier; 2014;3:28-38.)

Petechiae and Purpura

Extravasation of red blood cells from the vasculature into the skin produces petechiae and purpura. These lesions do not blanch with applied pressure. **Petechiae** are pinpoint lesions (<3 mm), and **purpura** are larger lesions, and can be either palpable or nonpalpable. While the majority of patients with fever and petechiae have a benign illness, their presence, especially in a child younger than 24 months, is of particular concern. Between 2% and 20% of affected patients have an underlying bacterial infection, and depending on the clinical setting, 0.5-10% have sepsis caused by *Neisseria meningitidis*. Other potentially serious infections signaled by a petechial rash and fever include bacterial endocarditis and Rocky Mountain spotted fever. Group A streptococcal (GAS) pharyngitis is the most common bacterial cause of fever and petechiae, with up to 20% of patients with fever and petechiae being diagnosed with GAS pharyngitis in some studies. Common viral causes include enterovirus and adenovirus. Febrile children may develop petechiae after coughing or vomiting; petechiae in this setting are almost always located in the superior vena cava distribution above the nipple line. Noninfectious causes of fever and petechiae include drug eruptions and acute leukemia. Not all children with fever and petechiae have thrombocytopenia.

Diffuse purpuric lesions may be noted in a wide variety of disorders. These include infectious diseases associated with organisms with a predilection for vascular endothelium, such as *N. meningitidis* and *R. rickettsii*; virus-associated diseases, such as dengue hemorrhagic fever and the hemorrhagic fever with renal syndrome caused by the Hantavirus; uncommon bacterial diseases, such as Brazilian purpuric fever caused by *Haemophilus aegyptius*; and the hemorrhagic shock–encephalopathy syndrome. Purpura is also associated with disseminated intravascular coagulation (DIC) and profound thrombocytopenia, such as in idiopathic thrombocytopenic purpura (see Chapter 38). Purpura followed by subsequent necrosis of skin is referred to as **purpura fulminans**, which has been reported after relatively benign infections such as varicella or with more serious disorders (meningococcemia). Purpura can occur in the noninfectious vasculitides, such as Henoch–Schönlein purpura (HSP). Discrete, raised purpuric lesions (palpable purpura) distributed predominantly over the buttocks and lower extremities are typical for this disorder. While all febrile patients presenting with diffuse or discrete purpuric lesions must be considered to be at risk for bacteremia (Fig. 40.6), patients with HSP are generally well-appearing but may have significant discomfort from arthritis or abdominal pain.

Vesiculobullous Eruptions

Vesicular rashes (sharply demarcated, raised lesions containing clear fluid), **bullae** (vesicles exceeding 1 cm in diameter), or **pustules** (raised lesions containing cloudy fluid composed of serum and inflammatory cells) may be suggestive of focal or disseminated infection with various pathogens or signal a serious drug reaction. **Localized vesicles** may suggest infection with herpes simplex virus (HSV) type 1 or 2 (especially if the vesicles are grouped on an erythematous base), varicella-zoster virus (especially if grouped vesicles are distributed in a dermatomal pattern) (Fig. 40.7), or infection with nonviral pathogens, such as *Rickettsia akari* (the cause of **rickettsialpox**, a mouse mite-borne rickettsiosis found worldwide but common in New York City). Localized pustules and bullae are usually suggestive of pyodermas caused by *Staphylococcus aureus*, but pustular lesions distributed on the palms and soles in the context of fever may represent infective emboli with microabscess formation (Janeway lesions), which are often caused by *S. aureus* endocarditis.

Vesicles distributed in a more **generalized pattern**, especially with a concentration of lesions over the head and trunk, are suggestive of primary varicella-zoster virus infection (**chickenpox**), whereas a more generalized pattern with a concentration over the extremities is suggestive of enteroviral infection, especially with coxsackievirus A16 (**hand–foot–mouth disease**). Orthopoxviruses such as monkeypox, like smallpox, cause a systemic febrile rash illness with lesions that progress from papules to vesicles to pustules concentrated on the face and extremities. **Acute generalized exanthematous pustulosis (AGEP)** is a rare cutaneous hypersensitivity reaction characterized by numerous sterile pustules beginning on the face and spreading to the trunk and limbs. It typically presents within 24 hours after exposure to an offending drug, usually a β-lactam or macrolide antibiotic. The clinician evaluating the sexually active patient presenting with asymmetric generalized pustules or vesicopustular lesions should also consider disseminated infection with *N. gonorrhoeae.* Diffuse vesiculobullae may be noted in Stevens–Johnson syndrome (SJS) or in toxic epidermal necrolysis (TEN), life-threatening mucocutaneous hypersensitivity diseases usually related to drugs.

FIGURE 40.7 Skin lesions of chickenpox. Note the varying stages of development (macules, papules, and vesicles) present at the same time. (From Paller AS, Mancini AJ. *Hurwitz Clinical Pediatric Dermatology.* 5th ed. Philadelphia: Elsevier; 2016.)

Nodules

Nodules (discrete, raised, firm, well-demarcated lesions without fixation to the overlying skin) may be associated with a number of underlying infectious or inflammatory disorders, such as polyarteritis nodosa and Sweet syndrome (acute febrile neutrophilic dermatosis). Red, pink, or plum-colored nodules distributed in a seemingly random manner over the skin surface may represent leukemic infiltrates. The subcutaneous nodules of acute rheumatic fever are usually located over bony extensor surfaces near tendons and are found in <5% of patients with acute rheumatic fever. They may also be found in patients with polyarticular JIA and dermatomyositis.

Erythema nodosum (erythematous and painful nodules usually distributed over the extremities) may be associated with viral infections including hepatitis B and C; bacterial infectious agents, most commonly group A β-hemolytic streptococcus; *Brucella* species; *Yersinia* species; mycobacterial infections; fungal infections with *Candida* species, *Histoplasma capsulatum*, *Blastomyces dermatitidis*; *Cryptococcus neoformans*, or *Coccidioides immitis*; or drug reactions, especially in response to oral contraceptives and sulfonamides. Other noninfectious causes include SLE, sarcoidosis, and inflammatory bowel disease.

Ulcers

Ulcers are depressed lesions in which the epidermis and some or all of the dermis has been destroyed. In immunocompromised hosts, infection with HSV may manifest with shallow erosive or ulcerative lesions. In immunocompetent hosts, cutaneous ulcerations may be noted in noninfectious disorders associated with vasculitis, such as SLE, polyarteritis nodosa, and HSP.

Pyoderma gangrenosum and **ecthyma gangrenosum** are painful cutaneous ulcerative lesions with an erythematous, raised edge. The lesions usually begin as a papule and break down rapidly with central necrosis. It may be seen in immunocompromised patients with systemic infections with bacterial pathogens, such as *Pseudomonas aeruginosa* and *Stenotrophomonas maltophilia* (ecthyma). In immunocompetent patients, the lesion may manifest in the context of inflammatory bowel disease (pyoderma gangrenosum), PAPA (pyogenic arthritis, pyoderma gangrenosum, acne), or rheumatoid arthritis. Digital ulcerations may be noted in patients with small vessel vasculitis, such as SLE. Oral ulcerations may be noted in those with herpes simplex or coxsackievirus (hand–foot–mouth disease) or as a manifestation of Behçet disease, SLE, PFAPA (periodic fever, aphthous stomatitis, pharyngitis, adenitis), or inflammatory bowel disease.

Erythema

Diffuse erythema (**erythroderma**) is associated with toxin-mediated disorders characterized by superantigen production. Bacterial superantigens cause nonspecific T cell stimulation resulting in several acute

FIGURE 40.8 An infant with staphylococcal scalded skin syndrome. (From Kliegman RM, Stanton BF, St Geme JW III, et al, eds. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016.)

rash-fever disorders, such as the staphylococcal scalded skin syndrome (SSSS; Fig. 40.8), streptococcal scarlet fever, staphylococcal or streptococcal toxic shock syndrome, and possibly KD.

Localized erythema in the context of acute fever is strongly suggestive of cellulitis, erysipelas, or abscess. The presence of warmth, tenderness, and associated lymphangitis is highly indicative. Organisms causing cellulitis or abscess formation are usually inoculated directly into the skin as a result of trauma. However, bacteremic localization is well described among young children with preseptal or facial cellulitis associated with *H. influenzae* type b or *S. pneumoniae*.

Patients with SLE or dermatomyositis may present with an isolated erythematous malar rash (butterfly rash), which is exacerbated by exposure to sunlight. The acute onset of intense "slapped-cheek" erythema of the face suggests erythema infectiosum, a recognizable exanthem caused by parvovirus B19, and should be differentiated easily from the malar rash of SLE, which usually manifests other characteristics, such as chronicity as well as hyperkeratosis and follicular plugging. In addition, patients with erythema infectiosum tend to have a maculopapular, lacelike rash over the arms, which may spread to the buttocks and thighs (Fig. 40.9; see Table 40.5).

Patients with **dermatomyositis** may have localized lilac-colored lesions over the eyelids (heliotrope rash), which may be associated with periorbital edema. Such patients characteristically, but not invariably, have an erythematous, scaly eruption on the face, neck, knees, elbows, and phalanges. When the rash is localized over the knuckles, it resembles dripped wax and has been referred to as Gottron papules.

◆ Other Physical Examination Findings
Joint Manifestations

Pain, swelling, tenderness, and limited range of motion involving 1 joint or multiple joints, or that migrate from joint to joint, or discrete pain at the insertion of tendons, ligaments, or fascia (enthesopathy) indicates a primary infectious illness, a "reactive" (immunologically mediated) disorder, or a systemic inflammatory condition. Primary infectious illnesses associated with this finding include *N. gonorrhoeae*, *B. burgdorferi* (Lyme disease), parvovirus, and rubella, including vaccine-associated strains. Reactive disorders, such as reactive arthritis (arthritis/enthesitis, conjunctivitis, urethritis), may be associated with infection caused by enteric pathogens, such as *Salmonella* and *Shigella*

FIGURE 40.9 Erythema infectiosum. (From Kliegman RM, Stanton BF, St Geme JW III, et al, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2016).

organisms, or genital pathogens, such as *N. gonorrhoeae* or *Chlamydia* species, but may also include diseases of unknown origin, such as inflammatory bowel disease, in which the rash is usually erythema nodosum. A **serum sickness-like reaction** can be seen after treatment with antibiotics. Children with systemic inflammatory conditions including KD, HSP, polyarteritis, SLE, SJIA, acute rheumatic fever, and some of the hereditary periodic fever syndromes may also have joint manifestations (see Chapters 33 and 41).

Cardiac Manifestations

Cardiac manifestations may accompany acute rheumatic fever, bacterial endocarditis, KD, or SJIA (see Chapter 33). The presence of tachycardia out of proportion to the severity of the fever may be indicative of sepsis or the carditis accompanying acute rheumatic fever, KD, or DRESS. A precordial friction rub is suggestive of pericarditis, which is noted frequently in patients with SJIA. The presence of a new murmur or a changing murmur on auscultation is suggestive of bacterial endocarditis, whereas the detection of the apical systolic murmur of mitral regurgitation or the diastolic murmur of aortic insufficiency is suggestive of acute rheumatic fever (see Chapter 8). A gallop rhythm on auscultation indicates underlying myocarditis, which may accompany coxsackievirus infection, rheumatic disease, or KD.

Ocular Manifestations

Isolated ocular manifestations, such as conjunctival injection and frank conjunctivitis, may be suggestive of infection with measles or adenovirus, leptospirosis, KD, SJS, TEN, or reactive arthritis. The skin, eye, mouth form of neonatal HSV can infect the eyes, causing conjunctivitis and keratitis. **Anterior uveitis** (redness with accompanying photophobia or pain or change in vision) may indicate KD, SJIA, sarcoidosis, ulcerative colitis, Behçet syndrome, or uncommonly, an infection such as leptospirosis. Retinal hemorrhages seen on funduscopy may indicate bacterial endocarditis.

Neurologic Manifestations

Neurologic findings accompanying fever and rash may be indicative of specific infectious or immunologically mediated disorders. Mental status findings suggestive of recent-onset psychosis may indicate cerebritis, which can accompany SLE. Significant alteration in mental status accompanied by seizure or focal motor impairment or cerebellar dysfunction may be suggestive of primary infectious encephalitis associated with arbovirus, herpes simplex, measles, varicella-zoster virus, rickettsia, West Nile virus, or *M. pneumoniae* infection. Nuchal rigidity, the Kernig sign, or the Brudzinski sign indicates meningeal irritation, which may accompany infection caused by the enteroviruses; bacteria such as *S. pneumoniae* or *N. meningitidis*; fungi such as *H. capsulatum* and spirochetes such as *B. burgdorferi*; or inflammation caused by underlying SLE, sarcoidosis, or KD. Cranial nerve palsies, ataxia, or peripheral neuropathy may accompany infection with *B. burgdorferi* early in the course of **Lyme disease** (especially Bell's palsy), or it may indicate an underlying vasculitis, such as SLE. Movement abnormalities, particularly chorea, may be suggestive of either SLE or acute rheumatic fever. **Hemophagocytic lymphohistiocytosis (HLH)** is a life-threatening syndrome of excessive immune activation that can have varied neurologic manifestations including seizure, mental status changes, and ataxia. The rash associated with HLH is also variable and can be maculopapular, erythrodermic, petechial, or purpuric. When seen in a patient with SJIA, the syndrome is called macrophage activation syndrome.

Pulmonary Manifestations

The presence of isolated lower respiratory tract findings (decreased breath sounds, rales, expiratory wheezing, respiratory distress, and cyanosis) indicates underlying pulmonary infection with an organism such as measles, respiratory syncytial virus, adenovirus, *Mycoplasma pneumoniae*, or *Legionella pneumophila*. Although sarcoidosis, collagen vascular disease, and systemic vasculitis (granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis, HSP) may involve the lower respiratory tract, isolated pulmonary findings are infrequently indicative of these disorders. The acute respiratory distress syndrome can develop in any patient with a serious systemic inflammatory condition such as sepsis, SJS, TEN, HLH, and DRESS.

Clusters of Findings

Clusters of findings on examination that are of diagnostic importance include the following.

The **mucocutaneous–lymph node** cluster (bilateral conjunctival injection, palmar-plantar erythema/indurative edema of the hands and feet, erythema of the oropharyngeal mucosa/"strawberry" tongue, cervical lymphadenopathy) is suggestive of KD, TSS, SJS, streptococcal scarlet fever, Rocky Mountain spotted fever, dengue, and leptospirosis.

The **reticuloendothelial cell hyperplasia cluster** (hepatosplenomegaly with or without generalized adenopathy) is suggestive of (1) disseminated infectious disease caused by bacteria (*Salmonella typhi* or other enteric fever pathogens), virus (cytomegalovirus, human immunodeficiency virus–1 [HIV-1], EBV), rickettsia (*Orientia tsutsugamushi* in "scrub typhus"), protozoa (malaria), or fungus (*H. capsulatum*, *C. immitis*); (2) disseminated malignancy; (3) sarcoidosis; (4) HLH; or (5) rheumatologic disease.

The **mononucleosis-like syndrome cluster** (exudative pharyngitis and regional adenopathy with or without splenomegaly) is suggestive of infection with group A streptococcus, *Arcanobacterium haemolyticum*, *Francisella tularensis*, EBV, toxoplasmosis, cytomegalovirus, or coxsackievirus or DRESS.

◆ Diagnostic Studies

The history and physical examination together determine the prior probability of a specific disease. In the context of a very high or very low prior probability of a specific disease, laboratory testing adds very

little useful information. Thus, ancillary testing is most useful when the prior probability of specific disease is equivocal.

◆ Laboratory Tests

In an ill-appearing child, basic laboratory testing including complete blood count with smear; chemistries; blood, and possibly cerebral spinal fluid cultures should be obtained. Coagulation studies should be completed in patients with petechiae, purpura, bleeding, or concern for DIC.

A Gram stain of any ulcerative, pustular, petechial, or purpuric lesion can be useful. The identification of bacteria suggests pyogenic infection, which may be localized or disseminated. The presence of only polymorphonuclear white blood cells in the fluid of pustular lesions does not exclude bacterial infection from consideration, especially disseminated infection with *N. gonorrhoeae*. Specimens of these lesions or any fluid from a pustule should also be obtained for bacterial culture.

Vesicular and bullous lesions in a febrile child with an uncertain diagnosis can be unroofed, scraped at the base, and submitted for microscopic examination after Tzanck preparation. The presence of multinucleated giant cells or eosinophilic intranuclear inclusions indicates infection with herpesvirus or varicella-zoster virus. The sensitivity of the Tzanck preparation for cutaneous herpes simplex infection is 64% and the specificity is 86%. Because the sensitivity of the procedure is low, a negative result does not exclude the diagnosis of herpes simplex infection. Thus, to identify the virus, a specimen of the lesion should also be obtained for polymerase chain reaction (PCR), which is more sensitive than culture.

Diagnosing a systemic infectious illness may necessitate the use of specific bacterial, viral, or fungal culture techniques; paired acute- and convalescent-phase serologic study; antigen detection systems; or molecular techniques such as PCR or 16S (bacterial) 28S (fungal) ribosomal DNA. Culture techniques are most specific when normally sterile tissue or body fluids are sampled and inoculated directly into liquid or solid media. Interpretation of bacterial cultures obtained from nonsterile sites, such as the tonsils and nasopharynx, are subject to increased rates of false-positive results because of recovery of organisms that colonize these areas.

Serologic techniques are potentially useful in establishing a diagnosis of a specific infection by demonstrating a 4-fold rise in titer between samples obtained during the acute and convalescent phases of illness. Confirmation of infection with the rickettsiae is probably best accomplished through serologic techniques demonstrating a 4-fold increase in titer because culture systems and PCR testing for rickettsiae are not widely available. Detection of a recent infection with group A streptococci may be accomplished by demonstrating antibodies to streptolysin O (ASO titer) or to deoxyribonuclease B (anti-DNAse B). Alternatively, immunoblot or PCR techniques rather than serologic tests best confirm many specific viral pathogens.

Antigen detection systems are useful for rapid diagnosis. A solid-phase detection system, such as enzyme-linked immunosorbent assay (ELISA), has the advantage of being independent of the need for intact cellular material but is affected by antigen or antibody cross-reactivity in the sample (which limits specificity) and by poor antigen-antibody affinity (which limits sensitivity). Nonetheless, ELISA is the preferred technique for the serologic diagnosis of a wide spectrum of infectious agents, including *B. burgdorferi* (Lyme disease pathogen) (as the 1st part in a 2-tier serologic assay, the 2nd being a Western immunoblot; see Chapter 39) and hepatitis B virus.

Latex particle agglutination is an alternative solid-phase antigen detection system that does not require intact cellular material and whose advantages include rapidity of use and ease of interpretation.

Latex particle agglutination is used for the rapid identification of patients with group A streptococcal pharyngitis or with invasive disease caused by encapsulated bacteria, such as *S. pneumoniae*, *H. influenzae* type b, *N. meningitidis*, group B streptococci, and *Escherichia coli* BK1. Latex particle agglutination is limited by factors similar to those affecting ELISA. Latex agglutination tests for group A streptococci have specificities of more than 90%, which facilitates their use for clinical confirmation of infection, but their sensitivities are only 60-90%, which limits their use in excluding infection.

The identification of patients with noninfectious systemic illness caused by underlying rheumatologic disease, immune complex disease, or vasculitis is best accomplished through serologic techniques combined with other indirect laboratory evidence of active inflammation or tissue injury (see Chapter 33). Diagnoses of autoinflammatory diseases are based on clinical criteria and can be confirmed with genetic testing (see Chapter 41). Cardiovascular biomarkers such as N-terminal pro-B-type natriuretic peptide (NT-proBNP) are increased in the serum of patients with KD and hold promise in supporting the diagnosis of KD.

Histopathology

Punch biopsy for light and electron microscopy and immunohistologic studies should be considered for diagnostic purposes for patients presenting with fever and bullous lesions that are clearly not typical pyodermas; fever and nodular lesions; or lesions suggestive of vasculitis (palpable purpura, livedo reticularis). A punch biopsy with indirect immunofluorescent antibody staining may also be useful for patients with petechial lesions, especially in an acral distribution, for the early diagnosis (at days 4-8 of illness) of infection with *R. rickettsii*. This procedure has a sensitivity of 53% and a specificity of 100%. The low sensitivity of the test may be related to the rickettsiostatic effect of antimicrobial treatment before presentation, but it indicates clearly that decision making in the acute care setting is limited by the high rate of false-negative classifications expected with this procedure.

Other Diagnostic Studies

Echocardiography and electrocardiography (ECG) are part of the diagnosis of some fever and rash syndromes. The 2015 revision of the Jones criteria for diagnosis of acute rheumatic fever adds echocardiography as a way to diagnose cardiac involvement even when it is not clinically evident. Prolonged P-R interval on ECG remains 1 of the minor Jones criteria. In incomplete KD, echocardiography is used to guide diagnosis when patients do not meet all classic criteria.

◆ Diagnosis and Decision Making

Accurate diagnosis depends on careful synthesis of selected data obtained from the clinical assessment. Because most children with acute episodes of fever and rash have a common, self-limited infectious disease, a specific diagnosis can often be established simply by pattern recognition alone (e.g., visual recognition of the common exanthems of childhood or a specific lesion such as erythema migrans) or with minimal use of adjunctive testing (a rash consistent with scarlet fever accompanied by a positive PCR or latex agglutination test for group A streptococcus). Because the spectrum of infectious pathogens is broad, and the presenting complaints or features of the rash may be atypical, and on occasion, the diagnosis may not yield easily to simple pattern recognition. In these situations, empirical use of the laboratory may prove useful to the clinician.

In a series of febrile children presenting for evaluation of generalized erythematous rashes of various patterns that were not indicative of a specific disorder by history or examination, an infectious cause could be established in 65% after a limited set of laboratory tests. The

tests consisted of a throat culture for streptococci (including non–group A streptococci) and serologic studies to detect rubella, measles, hepatitis A and B viruses, EBV, parvovirus B19, and *M. pneumoniae.* This strategy was based on physician knowledge of the age-specific and/or seasonal incidence of infectious pathogens in the population studied. It may be preferable to "watchful waiting" and serial clinical follow-up when the patient is judged to be at risk for a treatable illness associated with significant subsequent morbidity (e.g., streptococcal infection leading to acute rheumatic fever) or when specific information is necessary to advise parents of the risk of contagion to other children, to immunocompromised contacts, or to pregnant women.

Well-appearing patients with fever and petechial rash present a challenge to the clinician. Such patients with cough or emesis and petechiae only above the nipple line, and a positive streptococcal antigen test, or patients with normal leukocyte, absolute neutrophil, and platelet counts and a normal prothrombin time are exceedingly unlikely to have an invasive bacterial illness such as meningococcemia.

The subset of patients with fever and rash who appear toxic, have unstable vital signs, or altered mental status must have a comprehensive evaluation and a diagnosis confirmed as quickly as possible to detect potentially life-threatening underlying infection. Patients with thrombocytopenia and an abnormal coagulation profile should be admitted for further evaluation and treatment of DIC, which may have an underlying infectious or inflammatory cause. Patients with thrombocytopenia and a normal coagulation profile may have infection with tick-borne rickettsial pathogens, *Ehrlichia chaffeensis*, EBV, an autoimmune disease such as SLE, or a primary hematologic-oncologic disorder, such as idiopathic thrombocytopenic purpura or leukemia associated with an intercurrent infection; such patients should be evaluated for these disorders. Patients with eosinophilia and elevated transaminases may have DRESS.

Several serious diseases present with features that resemble benign processes; it is crucial to distinguish these as early in the clinical course as possible so definitive treatment can be given (Table 40.6).

Clinical Syndromes

In certain instances, the diagnostic approach to disorders manifesting with fever and rash is wholly dependent on an aggregation of nonspecific signs, symptoms, and laboratory results. These disorders either have many underlying causes manifesting with overlapping features or have unknown causes for which no confirmatory tests have yet been devised. These diseases are diagnosed by recognizing patterns and sometimes by excluding other diagnoses; some are based on formalized aggregation, termed *syndromic diagnosis*. Although syndromic diagnosis is based on explicit clinical criteria, some of the clusters of signs, symptoms, and laboratory findings were established originally for epidemiologic purposes (case definition) to facilitate exploration of an underlying cause. As such, although they are usually quite specific, these criteria may be less sensitive when they are applied in the acute care setting for the purposes of clinical diagnosis.

Kawasaki Disease

KD is a medium-vessel vasculitis of childhood with a predilection for the coronary arteries. It is the 2nd most common vasculitis of childhood after HSP, and it is the most common cause of acquired heart disease in children in the United States. Etiology is unknown, but epidemiologic studies support an infectious trigger. A genetic role is suspected given the 10- to 20-fold increased incidence in Japan as compared to the United States and United Kingdom. Genetic linkage studies and genome-wide association studies have demonstrated associations between polymorphisms in the *ITPKC* gene, a T cell regulator, and *FCGR2A*, an immunoglobulin (Ig)G receptor, with increased susceptibility to KD. The majority (75-85%) of affected children are less than 5 years old, and infants aged <6 months and children over 5 years old are at the highest risk for coronary artery aneurysms.

The fever of KD is usually high and unremitting; patients are often irritable and ill-appearing. Rash is seen in more than 80% of patients with KD and is polymorphic. It is often morbilliform, but may also be erythema multiforme-like (fixed erythematous target lesions [see Fig. 40.10]), urticarial, scarlatiniform, or pustular. Erythema and early desquamation (within 48 hours) of the perineum is common. Vesiculobullous lesions and petechiae are unusual.

Diagnosis is made on clinical grounds (Table 40.7 and Figs. 40.10 to 40.15). Fewer than 75% of patients meet the classic complete criteria at presentation; diagnosis of incomplete KD may be made with less than 4 criteria with the addition of laboratory and echocardiographic criteria (Fig. 40.16). Application of this algorithm increases sensitivity for KD to 97%. Early diagnosis is crucial to decrease the risk of coronary artery aneurysms, which decreases to less than 5% in promptly treated patients.

Toxic Shock Syndrome

TSS is a life-threatening illness caused by superantigen-producing strains of group A streptococcus and *S. aureus*. The syndrome is defined by fever, diffuse macular erythroderma with convalescent desquamation, hypotension, mucositis, strawberry tongue, and multiorgan dysfunction. While menstrual staphylococcal TSS classically affects menstruating teenage girls secondary to vaginal colonization with toxic shock syndrome toxin 1 (TSST-1) producing strains of *S. aureus*, streptococcal TSS is usually associated with obvious severe cutaneous infection. Diagnostic criteria are slightly different for each syndrome.

Staphylococcal Toxic Shock Syndrome

Laboratory criteria for diagnosis include negative results on the following tests, if obtained: blood or cerebrospinal fluid cultures (blood culture may be positive for *S. aureus*) and serologies for Rocky Mountain spotted fever, leptospirosis, or measles. A probable case meets the laboratory criteria and 4 of 5 clinical criteria and a confirmed case meets the laboratory and all 5 clinical criteria:

Fever: temperature greater than or equal to 102°F (greater than or equal to 38.9°C)

Rash: diffuse macular erythroderma

Desquamation: 1-2 weeks after onset of rash

Hypotension: systolic blood pressure less than or equal to 90 mm Hg for adults or less than 5th percentile by age for children aged less than 16 years

Multisystem involvement (3 or more of the following organ systems):

1. Gastrointestinal: vomiting or diarrhea at the onset of illness
2. Muscular: severe myalgia or creatine phosphokinase level at least twice the upper limit of normal
3. Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia
4. Renal: blood urea nitrogen or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria (greater than or equal to 5 leukocytes/high-power field) in the absence of urinary tract infection
5. Hepatic: total bilirubin, alanine aminotransferase enzyme, or aspartate aminotransferase enzyme levels at least twice the upper limit of normal for laboratory
6. Hematologic: platelets less than 100,000/mm^3
7. Central nervous system: disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent

TABLE 40.6   Potentially Life-Threatening Conditions with Initial Skin Findings That Can Mimic a More Common Benign Disorder

Potentially Life-Threatening Condition	Benign Disorder That Is Mimicked Early in the Course	Clues to the Diagnosis as the Condition Evolves
DRESS/DIHS*	Morbilliform/urticarial drug eruption > viral exanthem	• Facial swelling • High fever • Prominent lymphadenopathy • Marked peripheral blood eosinophilia, atypical lymphocytes • Elevated transaminases, other signs of internal organ involvement
Stevens–Johnson syndrome/ toxic epidermal necrolysis	Morbilliform/urticarial drug eruption > viral exanthem	• Early involvement of palms and soles • Duskiness of blistering (often initially in the center of lesions) • Painful/tender skin • Mucosal erosions (oral, nasal, ocular, genital)
RMSF/other rickettsial spotted fevers	Viral exanthem	• Potential exposure to ticks (e.g., season [spring to late summer for RMSF], geographic location) • High fever, myalgias, headache (often for 2–5 days prior to rash) • Rash begins on wrists/ankles, spreads centripetally (± palms/soles) • Petechiae within erythematous macules/papules
Meningococcemia	Viral exanthem	• Petechiae → retiform purpura • Fever with chills, myalgias • Headache, stiff neck
Kawasaki disease	Viral exanthem, morbilliform/urticarial drug eruption, erythema multiforme, "diaper dermatitis" (for early perineal eruption)	• Early perineal erythema → desquamation • Conjunctival injection • "Chapped" lips, "strawberry" tongue • Acral erythema and edema • Continued high-spiking fever ≥5 days • Prominent unilateral lymphadenopathy
Staphylococcal scalded skin syndrome	Seborrheic dermatitis, viral exanthem	• Painful/tender skin • Periorifacial (around mouth and eyes) edema and (later) radial scale-crusts • Confluent erythema → superficial erosions/peeling, especially in intertriginous sites
Toxic shock syndrome	Scarlatiniform exanthem	• Strawberry tongue • Mucositis • Rapid evolution • Hypotension
Necrotizing fasciitis	Cellulitis	• Tense, "woody" induration • Extreme pain or (later) anesthesia • Rapid evolution • Erythema → dusky gray color • Watery, malodorous discharge

*In general, begins ≥2 wk after the drug is initiated and has a relatively limited set of culprit medications.
DIHS, drug-induced hypersensitivity syndrome; DRESS, drug reaction with eosinophilia and systemic symptoms; RMSF, Rocky Mountain spotted fever.
Modified from Bolognia J, Schaffer JV, Duncan KO, Ko CJ. Fever and rash. In: Bolognia J, Schaffer JV, Duncan KO, Ko CJ, eds. *Dermatology Essentials*. Oxford: Saunders; 2014:35. Table 3.1.

Streptococcal Toxic Shock Syndrome

Confirmed case: isolation of group A streptococci from a normally sterile site (blood, cerebrospinal, pleural, or peritoneal fluid, tissue biopsy, surgical wound); or
Probable case: isolation of group A streptococci from a nonsterile site (throat, sputum, vagina, superficial skin lesion), and
Clinical signs of severity:
1. Hypotension: systolic blood pressure ≤ 90 mm Hg in adults or below 5th percentile for age in children, and
2. Two or more of the following signs:

- Renal impairment: creatinine ≥177 μmol/L (≥2 mg/dL) for adults or ≥2 times the upper limit of normal for age; in patients with preexisting renal disease, a 2-fold or greater elevation over the baseline level
- Coagulopathy: platelets ≤100 × 10⁹/L (≤100,000/mm³) or DIC defined by prolonged clotting times, low fibrinogen level, and the presence of fibrin degradation products
- Liver involvement: serum aspartate aminotransferase, alanine aminotransferase, or total bilirubin levels greater than or equal to 2 times the upper limit of normal for age; in patients with

TABLE 40.7 Clinical and Laboratory Features of Kawasaki Disease

Epidemiologic Case Definition (Classic Clinical Criteria)*

Fever persisting at least 5 days[†] *and*

Presence of at least 4 principal features:

Changes in extremities:
- Acute: Erythema of palms, soles; edema of hands, feet
- Subacute: Periungual peeling of fingers, toes in 2 and 3 wk

Polymorphous exanthem

Bilateral bulbar conjunctival injection without exudate

Changes in lips and oral cavity: erythema, lip cracking, strawberry tongue, diffuse injection of oral and pharyngeal mucosa

Cervical lymphadenopathy (>1.5 cm in diameter), usually unilateral

Exclusion of other diseases with similar findings

Other Clinical and Laboratory Findings

Cardiovascular findings:

Congestive heart failure, myocarditis, pericarditis, valvular regurgitation

Coronary artery abnormalities

Aneurysms of medium-size noncoronary arteries

Raynaud phenomenon

Peripheral gangrene

Musculoskeletal system:

Arthritis, arthralgias

Gastrointestinal tract:

Diarrhea, vomiting, abdominal pain

Hepatic dysfunction

Hydrops of gallbladder

Central nervous system:

Extreme irritability

Aseptic meningitis

Sensorineural hearing loss

Genitourinary system:

Urethritis/meatitis

Other findings:

Erythema, induration at bacille Calmette-Guérin inoculation site

Anterior uveitis (mild)

Desquamating rash in groin

Laboratory Findings in Acute Kawasaki Disease

Leukocytosis with neutrophilia and immature forms

Elevated erythrocyte sedimentation rate

Elevated C-reactive protein

Anemia

Abnormal plasma lipids

Hypoalbuminemia

Hyponatremia

Thrombocytosis after 1 wk[‡]

Sterile pyuria

Elevated serum transaminases

Elevated serum gamma-glutamyl transpeptidase

Pleocytosis of cerebrospinal fluid

Leukocytosis in synovial fluid

*Patients with fever for at least 5 days and <4 principal criteria can be diagnosed with Kawasaki disease when coronary artery abnormalities are detected by 2-dimensional echocardiography or angiography.

[†]In the presence of ≥4 principal criteria, Kawasaki disease diagnosis can be made on day 4 of illness. Experienced clinicians who have treated many patients with Kawasaki disease may establish diagnosis before day 4.

[‡]Some infants present with thrombocytopenia and disseminated intravascular coagulation.

preexisting liver disease, a 2-fold or greater elevation over the baseline level
- Acute respiratory distress syndrome defined by acute onset of diffuse pulmonary infiltrates and hypoxemia in the absence of cardiac failure, or evidence of diffuse capillary leak manifested by acute onset of generalized edema, or pleural or peritoneal effusions with hypoalbuminemia
- A generalized erythematous macular rash that may desquamate
- Soft tissue necrosis, including necrotizing fasciitis or myositis, or gangrene

Erythema Multiforme

Erythema multiforme (EM) is a self-limited immune reaction that occurs in the setting of infection. It is characterized by the abrupt onset of fixed erythematous papules that evolve into target lesions (see Fig. 40.10). It was previously thought to be related to SJS, but it is now clear that EM is a distinct disease. The basic lesions are round macular targets symmetrically distributed especially over the palms, soles, and extensor surfaces of the extremities. EM is typically associated with infection, most often HSV. *M. pneumoniae* has also been associated with EM. Drugs and systemic disease are rare causes of EM.

Stevens–Johnson Syndrome, Toxic Epidermal Necrolysis, and Staphylococcal Scalded Skin Syndrome

SJS and TEN are rare, life-threatening mucocutaneous exfoliative dermatoses that are usually drug related. They are thought to be associated with an immune response to an antigenic complex formed by the reaction of intermediate drug metabolites with host tissues. Several drug-related HLA alleles have been found to increase susceptibility for the development of SJS and TEN. SJS and TEN are characterized by diffuse cutaneous erythema and full-thickness necrosis of the epidermis with detachment of the skin at the dermal-epidermal junction. They differ in the percentage of involved total body surface area (BSA); SJS involves ≤10% BSA, SJS/TEN overlap involves between 10% and 30% BSA, and TEN involves ≥30% BSA. They are usually associated with exposure to drugs and differ histopathologically from SSSS, which also manifests clinically with diffuse erythema and blistering, in its cleavage plane. In SSSS, blistering is produced more superficially by disruption of the epidermal granular cell layer in response to 1 of 2 staphylococcal exfoliative toxins (ET-A or ET-B). This results in easy disruption of skin with firm rubbing (Nikolsky sign). SSSS is usually seen in infants and young children, whereas SJS and TEN are seen in older children. The key feature that distinguishes SJS and TEN is the presence of blistering lesions which may involve the lips, eyes, nasal mucosa, genitalia, or rectum (Figs. 40.17 and 40.18). Extensive ocular involvement, including corneal ulceration, uveitis, and panophthalmitis, may develop. Pulmonary and renal involvement have also been reported. Representative medications frequently associated with SJS and TEN include aminopenicillins, carbamazepine, phenytoin, trimethoprim-sulfamethoxazole, and nonsteroidal antiinflammatory medications. Prognosis is related to the speed with which the culprit medication is withdrawn, so a timely diagnosis is critical.

Evaluation of Suspected Incomplete Kawasaki Disease (KD)[1]

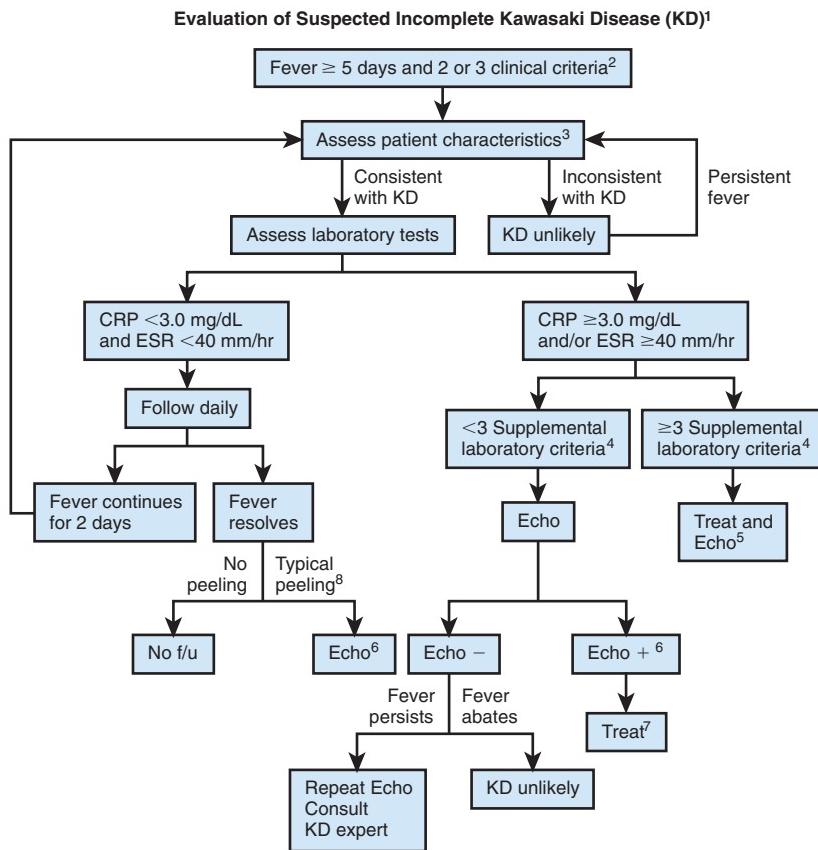

FIGURE 40.16 Algorithm for evaluation of suspected incomplete Kawasaki disease (KD). (1) In the absence of a gold standard for diagnosis, this algorithm cannot be evidence based, but rather represents the informed opinion of an expert committee. Consultation with an expert should be sought anytime assistance is needed. (2) Infants ≤6 months old on day 7 of fever or later without other explanation should undergo laboratory testing and, if evidence of systemic inflammation is found, given an echocardiogram (Echo), even if they have no clinical criteria. (3) Characteristics suggesting disease other than KD include exudative conjunctivitis, exudative pharyngitis, discrete intraoral lesions, bullous or vesicular rash, and generalized adenopathy. Consider alternative diagnoses. (4) Supplemental laboratory criteria include albumin ≤3.0 g/dL, anemia for age, elevation of alanine aminotransferase, platelet count after 7 days ≥450,000/mm^3, white blood cell count ≥15,000/mm^3, and urine white blood cell count ≥10/high-power field. (5) Can treat before performing echocardiogram. (6) Echocardiogram findings are considered positive (Echo+) for purposes of this algorithm if any of 3 conditions are met: z-score of the left anterior descending coronary artery (LAD) or right coronary artery (RCA) ≥2.5; coronary arteries meet Japanese Ministry of Health criteria for aneurysms; ≥3 other suggestive features exist, including perivascular brightness, lack of tapering, decreased left ventricle (LV) function, mitral regurgitation, pericardial effusion, or z-scores in LAD or RCA of 2-2.5. (7) If echocardiogram findings are positive, treatment should be given to children within 10 days of fever onset and to those beyond day 10 with clinical and laboratory signs (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR]) of ongoing inflammation. (8) Typical peeling begins under nail beds of fingers and then toes. Echo–, negative echocardiogram findings; f/u, follow-up. (From Newburger JW, Takahashi M, Gerber MA, et al. Diagnosis, treatment, and long-term management of Kawasaki disease. *Pediatrics.* 2004;114:1708-1733; Son MBF. Kawasaki disease. In: *Nelson Textbook of Pediatrics.* Philadelphia: Elsevier; 2016:1209.e1-1214.e1, Chapter 166.)

Serum Sickness and Serum Sickness-Like Reaction

Serum sickness is a systemic hypersensitivity condition resulting from immune complex deposition in tissue and blood vessels that causes tissue damage through complement activation. It is classically associated with the administration of animal serum proteins, but the availability of alternative therapies, including monoclonal antibodies of human origin, has decreased the incidence of true serum sickness. A serum sickness-like reaction can be triggered by antibiotics or other drugs (particularly cefaclor, penicillins, sulfonamides, phenytoin, carbamazepine) and presents 1-2 weeks after exposure. Symptoms include fever, rash, arthralgia or arthritis, and lymphadenopathy. The rash of serum sickness-like reaction is morbilliform or large fixed serpiginous and cyclic urticarial plaques; it can be confused with other circular rashes such as giant urticaria and EM (Fig. 40.19). Serum sickness-like reactions do not exhibit the hypocomplementemia, vasculitis, circulating immune complexes, and renal lesions that are seen in serum sickness. Critical to making the diagnosis is identification of exposure to a drug in the preceding 1-2 weeks. A watchful waiting approach may support the diagnosis, inasmuch as the syndrome should resolve within approximately 4 weeks if exposure to the purported offending agent has been curtailed. Persistence of findings beyond this period indicates another disorder associated with immune complex–mediated vasculitis.

Henoch-Schonlein Purpura

HSP is usually a self-limited IgA-mediated vasculitis representing the most common vasculitis of childhood. It affects vessels in the skin, joints, gastrointestinal tract, and kidneys. The clinical manifestations include a rash, which initially is urticarial and then frequently evolves into a maculopapular eruption; after this eruption, petechiae and then purpuric plaques distributed predominantly on the buttocks and over the lower extremities develop (Fig. 40.20). These plaques usually are raised from the skin surface, which gives the rash its characteristic feature of "palpable purpura." Associated findings that are variably present include arthralgias and arthritis; edema of the feet, hands, face, scrotum, and scalp; melena, which may accompany intussusception; and an abnormal urinalysis that demonstrates hematuria and proteinuria. Fever, if present, is low grade and not a dominant feature of HSP. Laboratory testing is not necessary but can be of use to the clinician in excluding the infectious or hematologic causes of purpura if the patient does not present with classic features. Specifically, the results of both the platelet count and the coagulation profile are normal, and blood cultures are sterile. A Gram stain of the lesion is not usually needed, but the results are negative. Skin biopsy demonstrates the characteristic leukocytoclastic vasculitis involving the vessels in the dermis with IgA deposition. This finding is not specific for HSP, nor is it required for clinical confirmation.

Other Disorders

The diagnosis of other disorders manifesting with fever and rash is also based on formal syndromic criteria. SJIA (see Chapter 33), acute rheumatic fever (see Chapter 8), hemophagocytic lymphohistiocytosis (see Chapter 41), and SLE are examples. Representative diagnoses usually necessitating tissue confirmation are sarcoidosis and other vasculitides, such as polyarteritis nodosa or Wegener granulomatosis.

◆ Management

Treatment of patients with fever and rash includes both anticipatory guidance and specific interventions. Anticipatory guidance alone

FIGURE 40.17 Stevens–Johnson syndrome. Mucous membrane involvement with severe swelling and hemorrhagic crusting of the lips. (From Paller AS, Mancini AJ. *Hurwitz Clinical Pediatric Dermatology.* 5th ed. Philadelphia: Elsevier; 2016.)

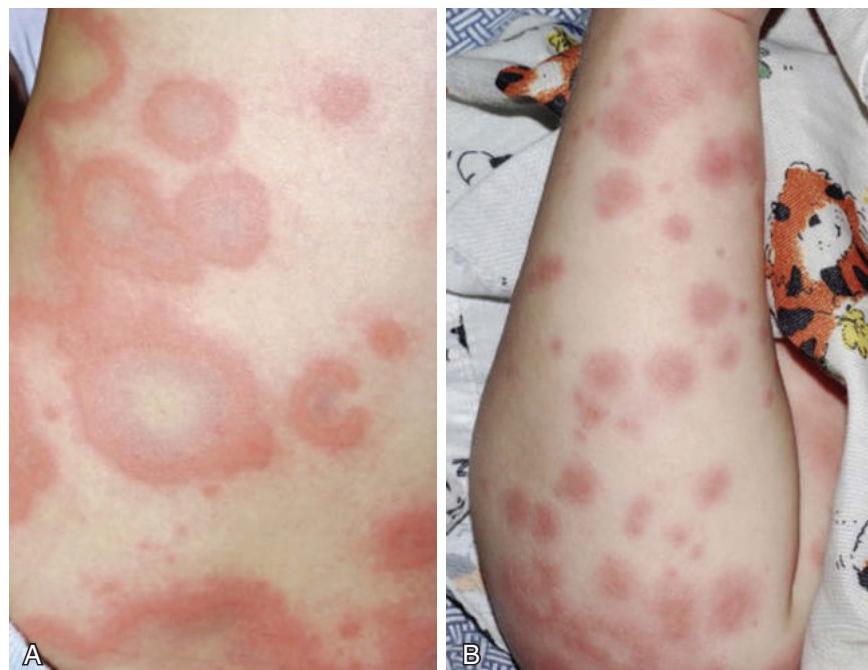
FIGURE 40.18 Stevens–Johnson syndrome. Confluent erythema, blisters, and exfoliation of the epidermis are present. (From Hurwitz S. *Clinical Pediatric Dermatology: A Textbook of Skin Disorders of Childhood and Adolescence.* 2nd ed. Philadelphia: WB Saunders; 1993:528.)


FIGURE 40.19 Urticaria and serum sickness-like reaction. *A,* Giant annular urticaria (urticaria "multiforme") in a young child with a recent viral upper respiratory tract infection. Individual lesions last <24 hours, but they often resolve with a dusky purplish hue that can lead to misdiagnosis as erythema multiforme. *B,* Serum sickness-like reaction due to amoxicillin. Some of the urticarial papules and annular plaques have a purpuric component, and the eruption was accompanied by high fevers, lymphadenopathy, arthralgias, and acral edema. (From Schaffer JV. Fever and rash. In: Bolognia JL, ed. *Dermatology Essentials.* Philadelphia: Elsevier; 2014;3:28-38.)

FIGURE 40.20 Henoch–Schönlein purpura (anaphylactoid purpura). Hemorrhagic macules, papules, and urticarial lesions appear in a symmetric distribution over the buttock. (From Kliegman RM, Stanton BF, St Geme JW III, et al, eds. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016:Fig. 167-2.)

usually suffices for patients who have a clearly identifiable, acute, self-limited, and noninvasive infectious or hypersensitivity disorder. Parents should be informed of the probable duration of illness, the expected evolution of clinical manifestations, potential complications and how to recognize them, and when to recontact the physician (see Tables 40.4 and 40.5).

The use of antipyretics as supportive therapy for patients with fever remains controversial. Arguments in favor of such therapy include decreasing symptomatic discomfort associated with the febrile state and reducing the undesirable metabolic and cardiopulmonary effects. Inadvertent overdose or unwanted side effects of over-the-counter antipyretics argue against their routine use.

Empirical therapy with antibiotics is an appropriate strategy for patients with focal cutaneous infection, such as cellulitis and erythema migrans, for patients with petechial or purpuric rash who are thought to have invasive infectious disorders, or for patients who appear toxic or manifest signs of cardiovascular instability. If epidemiologic evidence or clinical features are suggestive of rickettsial infection, the antimicrobial regimen should include doxycycline, even for children younger than 8 years. Suspected neonatal HSV infection should be treated with parenteral acyclovir.

Patients for whom a diagnosis is established by pattern recognition, case finding, syndromic aggregation, biopsy, or exclusion of other disorders may receive definitive interventions, as available, if the treatment benefits outweigh the risks. SSSS should be treated with an intravenous antistaphylococcal antibiotic. Staphylococcal TSS should be treated by removing vaginal foreign material if present, and administering intravenous vancomycin; toxin and cytokine production should be curtailed with a bacterial protein synthesis inhibitor such as clindamycin. If methicillin-sensitive *S. aureus* is confirmed by vaginal culture, an antistaphylococcal penicillin plus clindamycin is appropriate. Streptococcal TSS should be treated with surgical debridement if indicated, and parenteral penicillin and clindamycin. Intravenous immune globulin (IVIG) may be used as adjunctive therapy for streptococcal TSS to neutralize bacterial exotoxins. Treatment of acute rheumatic fever is directed at group A streptococcus with treatment-dose penicillin followed by prophylactic doses of penicillin to decrease the risk of recurrent rheumatic fever. Diseases caused by drug toxicity are treated by discontinuing the offending medication. SJS and TEN are treated with supportive care, often in a burn center, meticulous skin care, and IVIG.

Infections with HSV or varicella-zoster virus may be treated with oral or intravenous acyclovir. Intravenous therapy is particularly appropriate for immunocompromised patients. The benefits of acyclovir therapy for HSV or varicella-zoster virus in immunocompetent hosts are less clear.

Pharmacologic interventions in the systemic inflammatory disorders include antiinflammatory agents, such as the nonsteroidal agents, and corticosteroids and immunosuppressant or modulating agents. Administration of IVIG is a definitive intervention in all patients with KD to reduce coronary aneurysm formation. The most effective treatment regimen for patients with KD of less than 10 days' duration is 1 dose of IVIG (2 g/kg) given over 12 hours with adjunctive aspirin therapy for at least 6-8 weeks to prevent thrombotic complications. Because 10% of patients may have persistent fever (>48 hours) or recrudescence of fever after the 1-dose IVIG regimen, repeated treatment with IVIG is often necessary. Treatment of IVIG nonresponders is more controversial and may consist of corticosteroids, infliximab, or other immunosuppressant agents.

SUMMARY AND RED FLAGS

Most childhood episodes of fever and rash represent benign, self-limited viral illnesses with little or no sequelae. Diseases with potentially significant sequelae, such as meningococcemia, Rocky Mountain spotted fever, acute rheumatic fever, KD, SJS, DRESS, TSS, and SSSS require efficient evaluation and timely treatment. Red flags include toxic appearance, unstable vital signs, meningismus, or fever with petechiae or purpura.

Recurrent Fever, Infections, Immune Disorders, and Autoinflammatory Diseases

James W. Verbsky and John R. Routes

The immune system functions to prevent and retard the local establishment or systemic dissemination of bacteria, viruses, fungi, and protozoa. Furthermore, it must accomplish this task without excessive inflammation or the development of autoimmunity. The immune system has four primary components:

1. **Antibody-mediated immunity (humoral or B cell immunity)** is mediated by bone marrow-derived B lymphocytes and plasma cells (differentiated antibody-producing cells), which release antibodies (immunoglobulins) into secretions, plasma, and interstitial spaces. Antibodies work to opsonize and promote phagocytosis of organisms, neutralize toxins, and lyse pathogens (with the aid of complements).
2. **Cell-mediated immunity (T cell immunity)** is mediated by thymus-derived T lymphocytes (i.e., CD4 and CD8 T cells) that are activated by antigen-presenting cells (e.g., dendritic cells, macrophages) and antigens. Although T cells do not produce immunoglobulin, CD4 T cells are necessary for optimal B cell function. CD4 T cells also express cytokines that activate phagocytes to efficiently clear intracellular pathogens. CD8 T cells lyse virally infected cells.
3. The **phagocytic system** consists of tissue macrophages and dendritic cells, as well as blood-borne monocytes and neutrophils. In response to specific signals, phagocytes ingest and kill invading microorganisms. Dendritic cells also serve as antigen-presenting cells for T cells.
4. The **complement system** acts synergistically with antibodies and the remainder of the immune system to help clear microbial infections both directly (complement-mediated cytolysis) and indirectly (recruitment of phagocytic cells, opsonization of microbes).

The differential diagnosis for patients with recurrent infections is formidable in view of the complexity of the immune system. The different arms of the immune system are interconnected, thus similar infections may occur as a manifestation of phagocyte, humoral, cell-mediated, or complement disorders that can be inherited or acquired (Table 41.1). Alternatively, highly characteristic infections can point to a defect in a particular arm of the immune system (Table 41.2). Most patients with recurrent infections do not have an underlying identifiable primary immunodeficiency, but they frequently have allergic rhinitis, asthma, or other risks for recurrent infections (Table 41.3). Because of the low probability of identifying a discrete immune defect, the primary physician faces the difficult decision about the extent of the evaluation and which patients merit a complete evaluation. In addition, other genetic defects in the immune system result in recurrent episodes of spontaneous inflammation (i.e., **autoinflammatory disorders**), or immune dysregulation and **autoimmunity**, and these can often be mistaken as recurrent infections.

Although there are no established rules regarding immunologic work-up of a patient with infections, an evaluation should be considered for at least 1 of the following: (1) more than 2 systemic bacterial infections (sepsis, meningitis, osteomyelitis); (2) 2 or more serious respiratory infections (pneumonia, sinusitis) or bacterial infections (cellulitis, draining otitis media, lymphadenitis) per year; (3) the presence of an infection at an unusual site (hepatic or brain abscess); (4) infections with unusual pathogens (*Aspergillus* pneumonia, disseminated candidiasis, or infection with *Serratia marcescens*, *Nocardia* species, or *Burkholderia cepacia*); (5) infections of unusual severity; and (6) recurrent mycobacterial infections or invasive infections with atypical mycobacteria.

HISTORY AND PHYSICAL EXAMINATION

◆ History

The clinician must determine (1) the frequency, location, severity, and complications of the infections; (2) the accuracy of how infections were documented; (3) the presence or absence of a symptom-free interval; (4) the microbiologic features of any isolate; and (5) the response to antibiotic therapy. A single chronic infection may wax and wane with intermittent, inadequate treatment and may manifest as a series of infections. Furthermore, a detailed history can elucidate other risk factors for recurrent infections. Many nonimmune disorders are characterized by an increased susceptibility to infection that must also be considered (see Table 43.3). A detailed history can provide clues as to the likelihood and nature of a primary immune deficiency (Table 41.4).

Perinatal History

The clinician should determine if there was exposure to maternal viral infection during gestation (human immunodeficiency virus [HIV], cytomegalovirus (CMV), herpes simplex virus, rubella), or a history of prematurity, blood transfusions, respiratory distress syndrome (with bronchopulmonary dysplasia), or other pertinent neonatal illnesses. Infants previously placed on ventilators may develop chronic obstructive lung disease (bronchopulmonary dysplasia), predisposing them to recurrent pulmonary infections. Most perinatal HIV infections are seen in children whose mother or mother's partner has engaged in high-risk behavior (i.e., multiple sex partners or use of cocaine or intravenous drugs). Attention should be paid to the time of umbilical cord separation since infants with a history of delayed umbilical cord separation and recurrent episodes of sepsis or pneumonia should be evaluated for **leukocyte adhesion deficiency**.

Medical History

A variety of nonimmune medical issues can result in recurrent infections (see Table 41.3). Approximately 30% of children with recurrent sinopulmonary symptoms can be categorized as **atopic** (allergic on a hereditary basis). These subjects have normal growth and development, and episodes of recurrent illness may be afebrile,

TABLE 41.1	**Cause and Mechanism of Recurrent Infection in Immunodeficiency States**	
Disorder	**Pathogen**	**Deficiency**
Primary Immunodeficiencies		
Humoral immunodeficiency syndromes (predominantly B cell defects)	Bacterial pathogens, enteroviruses	Reduced phagocytic efficiency, failure of lysis and agglutination of bacteria, inadequate neutralization of virus and bacterial toxins
Cellular immunodeficiency syndromes (predominantly T cell defects)	CMV, VZV, *Strongyloides stercoralis; Mycobacterium, Listeria, Nocardia; Cryptococcus, Candida* species; *Pneumocystis carinii*	Absence of or impaired delayed hypersensitivity response; absence of T cell cooperation for B cell synthesis of antibodies to T cell–specific antigens; absence of T cell cytokines that activate mononuclear phagocytes, failure of T cell clearance of viruses
Complement Deficiencies		
C1, C2, C3, C4, and factor B	*Streptococcus pyogenes, Streptococcus pneumoniae, Staphylococcus aureus, Haemophilus influenzae, Klebsiella* species	Defective chemotaxis and opsonization of microbes
C5-C8 and properdin deficiencies	*Neisseria meningitidis, Neisseria gonorrhoeae*	Defective membrane attack mechanism
Phagocyte Defects		
Neutropenia (ANC < 500/mm^3)	Pyogenic bacteria or fungi, *Pseudomonas* species, *Staphylococcus aureus*	Decreased neutrophil numbers
Chronic granulomatous disease	Catalase-positive organisms, e.g., *S. aureus, Serratia* species, *Burkholderia cepacia, Nocardia* species, *Candida* species, *Aspergillus* species	Impaired neutrophil bactericidal activity secondary to impaired production of hydrogen peroxide
Secondary Immunodeficiencies		
AIDS	CMV, VZV, adenovirus, HBV, *Giardia lamblia, Entamoeba histolytica, Mycobacterium avium–intracellulare, Toxoplasma gondii, Mycobacterium tuberculosis, Cryptococcus neoformans, Pneumocystis jirovecii; Campylobacter, Candida, Isospora, Aspergillus, Nocardia, Strongyloides,* and *Cryptosporidium* species	Retrovirus infections transmitted by bodily fluid impair T cell response, reduced T helper cell numbers
Cancer	VZV, HSV, *Escherichia coli; Pseudomonas, Klebsiella, Listeria, Cryptococcus, Pneumocystis,* and *Mycobacterium* species	Neutropenia, lymphopenia, impaired cellular immunity
Immunosuppression	HSV, VZV, CMV, EBV, hepatitis virus, *Pseudomonas* species, *E. coli; Klebsiella, Acinetobacter, Serratia, Candida, Aspergillus, Mucor,* and *Cryptococcus* species	Dependent on agent used, leads often to impaired cellular immunity and neutropenia, lymphopenia
Transplantation	CMV, HSV, VZV, hepatitis virus, *S. aureus; Pseudomonas, Klebsiella, Candida, Aspergillus, Nocardia,* and *Pneumocystis* species; EBV	Related to use of immunosuppressive agents
Malnutrition	Measles, HSV, VZV, *Mycobacterium* species	Impaired T cell function, reduction in complement activity

AIDS, acquired immunodeficiency syndrome; ANC, absolute neutrophil count; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HSV, herpes simplex virus; VZV, varicella-zoster virus.

respond poorly to antibiotics, and be accompanied by upper respiratory symptoms such as coughing, sneezing, or wheezing. There may be a family history of atopic disease, and the patient's past medical history may include episodic wheezing, protracted cough after upper respiratory tract infection (URI) hay fever, allergies to foods, or eczema. The physical examination of allergic school-aged children may reveal typical characteristics including the following: dark circles under the eyes; open mouth with dry lips; coated tongue; evidence of nasal obstruction; transverse nasal crease; boggy, pale nasal mucosa; mucus in the pharynx; posterior pharyngeal "cobble-stoning"; and postnasal drip.

Malnutrition and specific vitamin deficiencies may alter immune cell function. Protein-losing states due to gastrointestinal (e.g.,

inflammatory bowel disease, protein-losing enteropathy) or renal disease (e.g., nephrotic syndrome) may lead to hypocomplementemia, hypogammaglobulinemia, and recurrent infections. Chronic treatment with corticosteroids and other immunosuppressants can result in acquired immunodeficiency and recurrent infections.

Anatomic Abnormalities

Recurrent infections in primary immune deficiencies typically affect different anatomic locations. Structural or anatomic defects often result in recurrent infections that are generally localized to the affected organ system. Approximately 10% of children with recurrent infections have an underlying chronic disease or a structural defect that predisposes them to recurrent infections (see Table 41.3).

TABLE 41.2 Characteristic Pathogens Affecting Immunocompromised Patients

I. Humoral Defects
A. Antibody Deficiency (B Cell Defects)
1. Bacteria
Staphylococcus aureus (sepsis, sinopulmonary infection)
Haemophilus influenzae (sepsis, meningitis, arthritis, sinopulmonary infection)
Streptococcus pneumoniae (sepsis, meningitis, arthritis)
Pseudomonas aeruginosa (sepsis, pneumonia)
Mycoplasma species (arthritis, pneumonia)
Salmonella species (enteritis)
Campylobacter species (enteritis)
2. Viruses
Enterovirus, including polio vaccine (encephalitis, paralysis, myositis, arthritis)
Rotavirus (enteritis)
3. Protozoa
Giardia lamblia (enteritis)
B. Complement Deficiencies
1. C1, C2, C3, C4, factor B
S. pyogenes
S. pneumoniae, S. aureus, H. influenzae, Neisseria meningitidis, Klebsiella species (sepsis, meningitis, arthritis)
2. C5-8, properdin deficiency
N. meningitidis, N. gonorrhoeae (meningitis, sepsis, arthritis)

II. Combined B and T Cell Defects (Congenital, Acquired Immunodeficiency Syndrome, Immunosuppression Malignancies)
A. Bacteria
Listeria monocytogenes (sepsis, meningitis)
Salmonella (sepsis)
Mycobacterium tuberculosis (pneumonia, disseminated disease)
Atypical mycobacteria (*Mycobacterium avium, Mycobacterium intracellulare*) (sepsis, pneumonia, disseminated disease)
Nocardia species (pneumonia, CNS infection)
Legionella species (pneumonia)
B. Fungi
Cryptococcus neoformans (sepsis, meningitis)
Histoplasma capsulatum (pneumonia, disseminated disease)
Coccidioides immitis (pneumonia, meningitis)
C. Viruses
Varicella-zoster (cutaneous and CNS infection, pneumonia, hepatitis)
Cytomegalovirus (bone marrow infection, pneumonia, retinitis, esophagitis, colitis, CNS infection)
Herpes simplex (CNS infection, pneumonia, esophagitis, hepatitis, disseminated disease)
Epstein-Barr virus (lymphoma)
Measles (pneumonia, encephalitis)
Polyomavirus BK (hemorrhagic cystitis, ureteric stenosis, renal insufficiency)
Polyomavirus JC (progressive multifocal leukoencephalopathy)
D. Protozoa
Pneumocystis carinii (pneumonia, rare extrapulmonary spread)
Toxoplasma gondii (CNS infection, myocarditis)
Cryptosporidium species (enteritis)
E. Helminths
Strongyloides stercoralis (enteritis, pneumonia, sepsis, meningitis)

III. Neutropenia (Severe Chronic Neutropenia, Aplastic Anemia, Myelosuppression, Myelophthisis Myelosuppressive Agents, Bone Marrow Transplantation)
A. Bacteria
Escherichia coli (sepsis, pneumonia, pyelonephritis)
Klebsiella pneumoniae (sepsis, pneumonia)
P. aeruginosa (sepsis, pneumonia, cutaneous lesions)
Mixed anaerobic and aerobic enteric bacteria (typhlitis, perianal abscess)
S. aureus (sepsis, cellulitis, soft tissue infection)
Staphylococcus epidermidis (line infection)
Corynebacterium JK strain (sepsis)
α-Hemolytic streptococci (sepsis)
B. Fungi
Candida species (sepsis, pneumonia, ophthalmitis, liver and spleen abscesses)
Aspergillus species (sepsis, pneumonia, sinusitis, CNS infection, cutaneous lesions)
Mucor (pneumonia, sinusitis, CNS infection)
Fusarium species (sepsis, cutaneous lesions, pneumonia)
Alternaria species (sepsis, cutaneous lesions)

IV. Phagocytic Dysfunction
A. Chronic Granulomatous Disease
Bacteria (soft tissue, lymphadenitis, pneumonia, osteomyelitis)
Catalase-positive organisms, e.g., *S. aureus, Serratia marcescens, Burkholderia cepacia, Nocardia* species
Fungi (pneumonia, liver infection, soft tissue), *Candida* species, *Aspergillus* species
B. Other Phagocyte Defects (Leukocyte Adhesion Deficiency Hyperimmunoglobulin E, Chédiak-Higashi syndrome, specific granule deficiency, Rac-2 deficiency)
Bacteria (soft tissue, pneumonia, lymphadenitis)
Pseudomonas species, *S. aureus, E. coli, Klebsiella, Enterobacter* species
Fungus (pneumonia)
Candida infection if diabetic

V. Splenic Dysfunction (e.g., Asplenia, Sickle Cell Anemia)
A. Bacteria
S. pneumoniae (sepsis, meningitis)
H. influenzae type b (sepsis, meningitis)
N. meningitidis (sepsis, meningitis)
Capnocytophaga canimorsus
B. Protozoa
Babesiosis
Malaria

CNS, central nervous system.

TABLE 41.3	**Infections in Patients without Primary Immunodeficiency Syndromes**
Predisposing Causes	**Organism and Type of Infection**
Alteration of Mucocutaneous Barriers	
Indwelling Catheter	
Central venous catheter (Broviac, Hickman)	*Staphylococcus aureus; S. epidermidis;* and *Bacteroides, Candida, Pseudomonas* species: bacteremia, fungemia
Urinary catheter	*Escherichia coli, Enterococcus* species, *Staphylococcus saprophyticus*: pyelonephritis
Tenckhoff catheter (continuous ambulatory peritoneal dialysis)	*Staphylococcus epidermidis, S. aureus, E. coli, Pseudomonas aeruginosa, Candida* species: peritonitis
Cerebrospinal fluid shunts	*S. epidermidis, S. aureus*, diphtheroid, *Bacillus* species: meningitis
Aspirated pulmonary foreign body	*S. aureus*, anaerobes: pneumonia, pulmonary abscess, empyema
Burns	*P. aeruginosa, S. epidermidis, Candida* species: cutaneous lesions, sepsis
Inhalation Therapy: Contaminated Solutions	*P. aeruginosa, Serratia marcescens, Legionella* species: pneumonia
Surgical Wounds	
Abdominal	Gram-negative bacteria, *S. aureus, S. epidermidis, Candida* species: peritonitis
Nongastrointestinal	*S. aureus, S. epidermidis,* streptococci, gram-negative bacteria: wound abscess, sepsis
Fistula-Sinus Communications	
Neurocutaneous fistula	*S. aureus, S. epidermidis, E. coli*: meningitis
Neuroenteric fistula	Gram-negative bacteria: meningitis
Otic, facial sinus-meningeal sinus tract	Pneumococcus: meningitis
Facial sinus fracture (CSF rhinorrhea)	Pneumococcus: meningitis
Intravenous Drug Abuse	*S. aureus, P. aeruginosa,* streptococci: endocarditis, osteomyelitis Hepatitis B, C, D viruses: AIDS
Prosthetic Devices	
Cardiac valves	*S. epidermidis,* streptococci, *S. aureus*, diphtheroid, *Candida* species: endocarditis
Pacemaker	*S. epidermidis, S. aureus, Candida* species: subcutaneous pocket or endocardial infection
Chronic Disease	
Malnutrition	Measles; tuberculosis; herpes simplex virus; bacterial, parasitic, and viral diarrhea, gram-negative bacteria: sepsis, pneumonia
Cystic fibrosis	*S. aureus, Haemophilus influenzae,* mucoid *P. aeruginosa, Burkholderia cepacia;* pneumonia
Diabetes mellitus	Urinary tract infections, *Mucor,* and other fungi: sinus-orbital infection
Nephrotic syndrome	Pnemococcus, *E. coli*: peritonitis
Uremia	*S. aureus,* gram-negative bacteria, fungi: sepsis, soft tissue infection
Cirrhosis, ascites	Pnemococcus, *E. coli*: peritonitis
Prolonged broad-spectrum antibiotic therapy	*Candida* species, *Enterococcus* species, multidrug-resistant gram-negative or gram-positive bacteria: sepsis
Spinal cord injury	Gram-negative or gram-positive bacteria: pneumonia, pyelonephritis, pressure sores, abscesses, osteomyelitis
Sickle cell anemia	Pnemococcus: sepsis, meningitis, osteoarticular infection *Salmonella* species, *S. aureus*: osteomyelitis
Congenital heart disease	*S. aureus, Streptococcus viridans* group: endocarditis
Urinary tract anomaly	*E. coli, S. saprophyticus, Enterococcus* species: pyelonephritis
Kartagener syndrome (dysmotile cilia)	*H. influenzae, Moraxella catarrhalis,* pnemococcus: pneumonia, sinusitis
Eczema/atopic disease	*S. aureus, Streptococcus* species, varicella, herpes simplex, molluscum: cutaneous infection, cellulitis
Protein-losing enteropathy (lymphangiectasia)	Pneumococcus: sepsis, peritonitis *Giardia* species: diarrhea
Periodontitis	*Fusobacterium* species: cellulitis, facial space infection

AIDS, acquired immunodeficiency syndrome; CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; HHV-6, human herpesvirus 6.

TABLE 41.4 **Clinical Aids to the Diagnosis of Immunodeficiency**
Suggestive of B Cell Defect (Humoral Immunodeficiency)
Recurrent bacterial infections of the upper and lower respiratory tracts
Recurrent skin infections, meningitis, osteomyelitis secondary to encapsulated bacteria *(Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus, Neisseria meningitidis)*
Paralysis after vaccination with live attenuated poliovirus
Reduced levels of immunoglobulins
Suggestive of T Cell Defect (Combined Immunodeficiency)
Systemic illness after vaccination with any live virus or bacille Calmette-Guérin (BCG)
Unusual life-threatening complication after infection with benign viruses (giant cell pneumonia with measles; varicella pneumonia)
Chronic oral candidiasis after 6 months of age
Chronic mucocutaneous candidiasis
Graft-versus-host disease after blood transfusion
Reduced lymphocyte counts for age
Low level of immunoglobulins
Absence of lymph nodes and tonsils
Small thymus
Chronic diarrhea
Failure to thrive
Recurrent infections with opportunistic organisms
Suggestive of Macrophage Dysfunction
Disseminated atypical mycobacterial infection, recurrent *Salmonella* infection
Fatal infection after BCG vaccination
Congenital Syndromes with Immunodeficiency
Ataxia-telangiectasia: ataxia, telangiectasia
Autoimmune polyglandular syndrome: hypofunction of 1 or more endocrine organs, chronic mucocutaneous candidiasis
Cartilage-hair hypoplasia: short-limbed dwarfism, sparse hair, neutropenia
Wiskott–Aldrich syndrome: thrombocytopenia, male gender, eczema
Chédiak–Higashi syndrome: oculocutaneous albinism, nystagmus, recurrent bacterial infections, peripheral neuropathies
DiGeorge syndrome (22q deletion syndrome): unusual facies, heart defect, hypocalcemia
Suggestive of Asplenia
Heterotaxia, complex congenital heart disease, Howell–Jolly bodies on blood smear, sickle cell anemia

Eustachian tube abnormalities or cleft palate result in recurrent or chronic otitis media; congenital heart disease results in an increased risk of endocarditis; and posterior urethral valves, vesicoureteral reflux, or ureteral pelvic junction obstruction results in recurrent urinary tract infections. Recurrent pneumonia may result from congenital malformations (trachea-esophageal fistulas, cystic adenomatoid malformation, or sequestration), from aspiration of a foreign body (peanut, small toys) or chronic aspiration (gastroesophageal reflux or swallowing disorders), and from bronchopulmonary dysplasia. Repeated pneumonias in dependent lobes warrant evaluation for recurrent aspiration. Chronic illnesses that result in recurrent pulmonary infections include cystic fibrosis, primary ciliary dyskinesia, or α_1-antitrypsin deficiency. Recurrent sinus infections can occur due to anatomic defects of the sinuses (polyps, stenotic os). Endotracheal intubation predisposes the patient to recurrent pulmonary infections

with nosocomial organisms. Right middle lobe syndrome and sequestered lung can appear as recurrent pneumonia in the same anatomic location.

Any direct communication to the cerebrospinal fluid that bypasses the blood–brain barrier predisposes patients to a central nervous system infection. Basilar skull fractures and dermal sinus tracts or fistulas may communicate with the subarachnoid space or neural tissue. Other conditions predisposing patients to opportunistic infections of the central nervous system include penetrating foreign body, cerebrospinal fluid shunts, myelomeningocele, and encephalocele. Local infections of the sinuses or of the middle ear may spread to contiguous structures to form cerebral abscesses or subdural-epidural empyema. Intravenous drug abuse, bacterial endocarditis, and heart disease with right-to-left shunt are associated with an increased risk of central nervous system infections.

Family History

Specific patterns of inheritance have been determined for a variety of immunologic defects. Genetic defects of immunity can be inherited as X-linked, autosomal recessive, or autosomal dominant disorders. Monogenic primary immunodeficiencies may exhibit reduced penetrance (some people with the genetic abnormality do not exhibit a clinical phenotype) and variable expressivity (different signs and symptoms with same genetic defect). A family history of unexplained infant deaths or serious infection should be sought, particularly in male infants since a number of important immune deficiencies are X-linked. Evidence of consanguinity should be sought as many serious primary immune deficiencies are autosomal recessive. Since allergic diseases can appear as recurrent infections, a family history of atopy is important. A child who has 1 allergic parent or 2 allergic parents is predisposed to allergic reactions by 25% and 50%, respectively.

Environmental History

The incidence of respiratory disease is increased in children exposed to cigarette or marijuana smoke or other noxious fumes (wood-burning stove) in the home. Respiratory and dermatologic findings are seen as a result of exposure to environmental allergens and toxins. Specific bacteriologic and parasitic exposures are associated with certain pets (i.e., *Salmonella* organisms and iguanas or turtles; psittacosis and birds; *Bartonella* organisms in kittens). A travel history may suggest exposure to unusual organisms that are regionally endemic, such as certain parasites and specific insect or animal bites, or to contaminated water. A move to a new house or to a new nursery school or exposure to a new babysitter, pet, or housekeeper may suggest possible allergic and infectious risks.

◆ Physical Examination

The physical examination may provide important clues to the diagnosis of a primary immune deficiency (see Table 41.4). Longitudinal evaluation of height and weight are crucial in identifying infants with failure to thrive or acute weight loss. Chronic upper respiratory infections are suggested by scarred tympanic membranes, postnasal drip, and cervical adenopathy. Transverse nasal creases, circles under the eyes, and posterior pharyngeal "cobblestoning" suggest respiratory allergy. Recurrent cough, wheezing, digital clubbing, and chest deformity are suggestive of pulmonary disease. Mouth ulceration or stomatitis can be a sign of immune deficiency or autoinflammatory disorder. Auscultation of the apex of the heart in the right side of the thorax (dextrocardia) may be accompanied by ciliary motility abnormalities or asplenia. Lymphadenopathy, hepatosplenomegaly, pallor, wasting, and recent weight loss are suggestive of systemic disease. Absence of lymph tissue (tonsils and lymph nodes) is suggestive of a B cell

deficiency, while absence of thymic tissue on chest radiograph in an infant is suggestive of T cell deficiency. Parotid enlargement with lymphadenopathy and hepatosplenomegaly is suggestive of HIV infection. Skin abnormalities including alopecia, eczema, pyoderma, and telangiectasia can be important clues. Evidence of hematologic disease, such as pallor, petechiae, and jaundice can be associated with immunodeficiencies. Generalized lymphadenopathy and splenomegaly may be suggestive of HIV disease, a phagocyte disorder with recurrent infections, or a lymphoproliferative disorder.

◆ Diagnostic Categories

The information obtained from the history and physical examination is usually sufficient to make a tentative classification:
1. The patient who is probably healthy.
2. The atopic or allergic patient.
3. The patient with a nonimmunologic defect in host defense (see Table 41.3).
4. The patient with hereditary inflammatory disorders (Table 41.5).
5. The immunodeficient patient.

Patient Who Is Probably Healthy

Many healthy children have repeated minor infections, or have a relatively brief history of repeated infections, or a single prolonged illness from which recovery has been delayed. Most upper respiratory tract infections last less than 7 days, and duration of longer than 14 days is unusual. Most children younger than 1 year who have a large family or who attend daycare develop respiratory or gastrointestinal infections about 6 times during the 1st year of life. The onset of the recurrent infection may coincide with entry into day care, preschool, or kindergarten. The healthy child has normal growth and development before the illness and usually a normal physical examination finding. When a discrepancy exists between the severity of an illness as reported by the parent and the child's physical appearance, it is often prudent to delay a detailed evaluation until more objective findings are documented by repeat examinations during acute episodes. Laboratory testing might include a complete blood cell count, inflammatory markers (i.e., erythrocyte sedimentation rate [ESR], C-reactive protein [CRP]) to exclude rheumatic disorders or occult infections, and measurement of immunoglobulin levels and vaccine specific titers as a screen. Cultures and imaging of the affected area may provide additional data. With reassurance of the parents, these children recover spontaneously. Simple measures, rather than a complex set of laboratory studies, are often the only treatment required.

Patient with Hereditary Inflammatory Disorders

Autoinflammatory syndromes, formerly known as **periodic fever syndromes**, are a heterogeneous and ever increasing group of rare inflammatory disorders that manifest with recurrent fevers and/or inflammatory episodes (see Table 41.5). Recurrent fevers or inflammation can often be mistaken for recurrent infections. Patients exhibit characteristic physical findings during these episodes, such as fever, various rashes, lymphadenopathy, aphthous stomatitis, arthritis, and serositis with abdominal, chest, or testicular pain. These episodes can be periodic or sporadic, but the characteristic features occur with each episode. Laboratory evaluation may show elevated white blood cell (WBC) counts and elevated inflammatory markers during the episode that typically resolve between episodes. Importantly, infectious work-ups are often repeatedly negative, and the patient is typically well between febrile episodes.

There are also an increasing number of disorders of **immune dysregulation** that have been described (Table 41.6). Unlike autoinflammatory disorders, these disorders result in a failure to control T and B

cell responses, resulting in **autoimmunity**. These disorders are not typically episodic, and once autoimmunity develops it continues until treated. Many of these disorders are *also* associated with immune deficiency and recurrent infection, thus patients experience recurrent infections simultaneously with autoimmune manifestations.

Immunodeficient Patient

Approximately 5-10% of children with recurrent infections have an underlying immunodeficiency. Frequently, the onset of infections occurs between the ages of 6 and 12 months, but delays in diagnosis are not uncommon. In addition, certain immune deficiencies such as common variable immunodeficiency disease (CVID) can present in adolescence or young adulthood; thus it is critical to consider immune defects in children of any age. Infections in patients with primary immune deficiencies often vary in type, location, and severity, although sinopulmonary infections are common. Failure to thrive may occur and can be a sign of a serious immune defect. Patients with primary immune defects often require repeated courses of antibiotics or intravenous antibiotics, or may have infections with unusual organisms or exhibit unexpected complications. Such children may respond to antibiotics but become ill when the medications are discontinued.

◆ Diagnostic Approach to the Patient with Recurrent Infections

Patients with recurrent, severe, or unusual infections involving multiple sites or organ systems should be investigated for an immunodeficiency (Fig. 41.1). Initial tests are recommended for patients suspected of a primary immune deficiency, although a variety of immune defects can occur despite normal screening tests. *Thus it is recommended that advanced testing be performed in consultation with a clinical immunologist.*

A complete blood count with *manual* differential should always be obtained in the evaluation of any child suspected of immunodeficiency. A neutrophil count below 500/mm^3 might indicate severe congenital neutropenia, cyclic neutropenia, idiopathic neutropenia, marrow failure, or replacement of marrow by leukemia or a tumor if other hematopoietic cell lines are affected. Analysis of the peripheral blood smear is important as this can detect neutrophil abnormalities (e.g., abnormal granules in Chédiak-Higashi) or evidence of asplenia (i.e., Howell-Jolly bodies).

Serum immunoglobulin levels (IgG, IgA, IgM, IgE) are essential to the work-up of suspected primary immunodeficiency. Antibody levels vary with age, with normal adult values of IgG at birth from transplacental transfer of maternal IgG, a physiologic nadir occurring between 3 and 6 months of age, and a gradual increase to adult values over several years. IgA and IgM are low at birth and levels increase gradually over several years, with IgA taking the longest to reach normal adult values. When IgG levels are low, albumin levels should be measured because increased loss of proteins, as in protein-losing enteropathy or nephrotic syndrome, can result in hypogammaglobulinemia. High immunoglobulin levels suggest intact B cell immunity and can be found in diseases with recurrent infections, such as chronic granulomatous disease (CGD), immotile cilia syndrome, cystic fibrosis, HIV infection, autoimmune diseases (lupus), and other disorders leading to chronic inflammation. Elevated IgE levels can be found in a number of immune deficiencies such as hyper-IgE syndrome, but more likely represent atopic diseases (atopic dermatitis).

Specific antibody titers after childhood vaccination (tetanus, diphtheria, *Haemophilus influenzae* type b, or *Streptococcus pneumoniae*) reflect the capacity of the immune system to synthesize specific antibodies and to develop memory B cells. If titers are low, immunization

TABLE 41.5　Autoinflammatory Disorders

Disease	Genetic Defect/ Presumed Pathogenesis	Inheritance	Affected Cells	Functional Defects	Associated Features
Familial Mediterranean fever	Mutations of *MEFV* (lead to gain of pyrin function, resulting in inappropriate IL-1β release)	AR	Mature granulocytes, cytokine-activated monocytes	Decreased production of pyrin permits ASC-induced IL-1 processing and inflammation following subclinical serosal injury; macrophage apoptosis decreased	Recurrent fever, serositis, and inflammation responsive to colchicine. Predisposes to vasculitis and inflammatory bowel disease
Mevalonate kinase deficiency (hyper 0 IgD syndrome)	Mutations of *MVK* (lead to a block in the mevalonate pathway). Interleukin-1β mediates the inflammatory phenotype	AR		Affecting cholesterol synthesis; pathogenesis of disease is unclear	Periodic fever and leukocytosis with high IgD levels
Muckle–Wells syndrome	Mutations of *NLRP3* (also called PYPAF1 or NALP3) lead to constitutive activation of the NLRP3 inflammasome	AD	PMNs, monocytes	Defect in cryopyrin, involved in leukocyte apoptosis and NF-κB signaling and IL-1 processing	Urticaria, SNHL, amyloidosis
Familial cold autoinflammatory syndrome	Mutations of *NLRP3* (see above) Mutations of NLRP12	AD	PMNs, monocytes	Same as above	Nonpruritic urticaria, arthritis, chills, fever, and leukocytosis after cold exposure
Neonatal-onset multisystem inflammatory disease (NOMID) or chronic infantile neurologic cutaneous and articular syndrome (CINCA)	Mutations of *NLRP3* (see above)		PMNs, chondrocytes	Same as above	Neonatal-onset rash, chronic meningitis, and arthropathy with fever and inflammation
TNF receptor–associated periodic syndrome (TRAPS)	Mutations of *TNFRSF1A* (resulting in increased TNF inflammatory signaling)	AD	PMNs, monocytes	Mutations of 55-kDa TNF receptor leading to intracellular receptor retention or diminished soluble cytokine receptor available to bind TNF	Recurrent fever, serositis, rash, and ocular or joint inflammation
Pyogenic sterile arthritis, pyoderma gangrenosum, acne (PAPA) syndrome	Mutations of *PSTPIP1* (also called C2BP1) (affects both pyrin and protein tyrosine phosphatase to regulate innate and adaptive immune responses)	AD	Hematopoietic tissues, upregulated in activated T cells	Disordered actin reorganization leading to compromised physiologic signaling during inflammatory response	Destructive arthritis, inflammatory skin rash, myositis
Blau syndrome	Mutations of *NOD2* (also called CARD15) (involved in various inflammatory processes)	AD	Monocytes	Mutations in nucleotide binding site of CARD15, possibly disrupting interactions with lipopolysaccharides and NF-κB signaling	Uveitis, granulomatous synovitis, camptodactyly, rash, and cranial neuropathies, 30% develop Crohn disease
Chronic recurrent multifocal osteomyelitis and congenital dyserythropoietic anemia (Majeed syndrome)	Mutations of *LPIN2* (increased expression of the proinflammatory genes)	AR	Neutrophils, bone marrow cells	Undefined	Chronic recurrent multifocal osteomyelitis, transfusion-dependent anemia, cutaneous inflammatory disorders

TABLE 41.5	**Autoinflammatory Disorders—cont'd**				
Disease	**Genetic Defect/ Presumed Pathogenesis**	**Inheritance**	**Affected Cells**	**Functional Defects**	**Associated Features**
Early-onset inflammatory bowel disease	Mutations in *IL-10* (results in increase of many proinflammatory cytokines)	AR	Monocyte/ macrophage, activated T cells	IL-10 deficiency leads to increase of TNFγ and other proinflammatory cytokines	Enterocolitis, enteric fistulas, perianal abscesses, chronic folliculitis
Early-onset inflammatory bowel disease	Mutations in *IL-10RA* (see above)	AR	Monocyte/ macrophage, activated T cells	Mutation in IL-10 receptor alpha leads to increase of TNFγ and other proinflammatory cytokines	Enterocolitis, enteric fistulas, perianal abscesses, chronic folliculitis
Early-onset inflammatory bowel disease	Mutations in *IL-10RB* (see above)	AR	Monocyte/ macrophage, activated T cells	Mutation in IL-10 receptor beta leads to increase of TNFγ and other proinflammatory cytokines	Enterocolitis, enteric fistulas, perianal abscesses, chronic folliculitis

with a specific vaccine and obtaining titers 4-6 weeks later should be performed to confirm a response to the immunization. Poor response to bacterial polysaccharide antigens is often found before 24 months of age; even in older individuals the antibody response to polysaccharide vaccines is typically less robust and less long-lived than protein antigens. The development of protein-conjugate polysaccharide vaccines to *Streptococcus pneumoniae* and *Haemophilus influenzae* has

dramatically reduced invasive infections with these organisms in early childhood by improving the response to vaccination. Antibody responses to the *S. pneumoniae* serotypes found in the 23-valent polysaccharide vaccine, but not in the conjugate vaccine, can be used to test antibody responses to polysaccharide antigens.

Complement assays include the CH50 test, which measures the presence of proteins in the classical pathway of complement (C1, C2,

TABLE 41.6   Disorders of Immune Regulation

Disease	Inheritance	Genetic Defect/Presumed Pathogenesis	Circulating T Cells	Circulating B Cells	Functional Defect	Associated Features
Perforin deficiency (FHL2)	AR	Mutations in *PRF1*; perforin is a major cytolytic protein	Increased activated T cells	Normal	Decreased to absent NK and CTL activities (cytotoxicity)	Fever, hepatosplenomegaly (HSMG), hemophagocytic lymphohistiocytosis (HLH), cytopenias
UNC13D/Munc13-4 deficiency (FHL3)	AR	Mutations in *UNC13D*, required to prime vesicles for fusion	Increased activated T cells	Normal	Decreased to absent NK and CTL activities (cytotoxicity and/or degranulation)	Fever, HSMG, HLH, cytopenias
Syntaxin 11 deficiency (FHL4)	AR	Mutations in *STX11*, required for secretory vesicle fusion with the cell membrane	Increased activated T cells	Normal	Decreased NK activity (cytotoxicity and/or degranulation)	Fever, HSMG, HLH, cytopenias
STXBP2/Munc18-2 deficiency (FHL5)	AR	Mutations in *STXBP2*, required for secretory vesicle fusion with the cell membrane	Increased activated T cells	Normal	Decreased NK and CTL activities (cytotoxicity and/or degranulation)	Fever, HSMG, HLH, cytopenias
Chediak–Higashi syndrome	AR	Mutations in *LYST*, Impaired lysosomal trafficking	Increased activated T cells	Normal	Decreased NK and CTL activities (cytotoxicity and/or degranulation)	Partial albinism, recurrent infections, fever, HSMG, HLH, giant lysosomes, neutropenia, cytopenias, bleeding tendency, progressive neurologic dysfunction
Griscelli syndrome, type 2	AR	Mutations in *RAB27A* encoding a GTPase that promotes docking of secretory vesicles to the cell membrane	Normal	Normal	Decreased NK and CTL activities (cytotoxicity and/or degranulation)	Partial albinism, fever, HSMG, HLH, cytopenias
SH2D1A deficiency (XLP1)	XL	Mutations in *SH2D1A* encoding an adaptor protein regulating intracellular signaling	Normal or increased activated T cells	Reduced memory B cells	Partially defective NK cell and CTL cytotoxic activity	Clinical and immunologic features triggered by EBV infection: HLH, lymphoproliferation, aplastic anemia, lymphoma, hypogammaglobulinemia, absent iNK T cells
XIAP deficiency (XLP2)	XL	Mutations in *XIAP* encoding an inhibitor of apoptosis	Normal or increased activated T cells; low/normal iNK T cells	Normal or reduced memory B cells	Increased T cells susceptibility to apoptosis to CD95 and enhanced activation-induced cell death (AICD)	EBV infection, splenomegaly, lymphoproliferation, HLH, colitis, IBD, hepatitis, low iNK T cells
IPEX, immune dysregulation, polyendocrinopathy, enteropathy X-linked	XL	Mutations in *FOXP3*, encoding a T cell transcription factor	Normal	Normal	Lack of (and/or impaired function of) CD4+ CD25+ FOXP3+ regulatory T cells (Tregs)	Autoimmune enteropathy, early-onset diabetes, thyroiditis, hemolytic anemia, thrombocytopenia, eczema, elevated IgE, IgA
CD25 deficiency	AR	Mutations in *IL2RA*, encoding IL-2Rα chain	Normal to decreased	Normal	No CD4+ C25+ cells with impaired function of Tregs	Lymphoproliferation, autoimmunity. Impaired T cell proliferation

Disease	Genetic defect	Inheritance	T cells	B cells / Ig	Mechanism	Clinical features
STAT5b deficiency	Mutations in *STAT5B*, signal transducer, and transcription factor, essential for normal signaling from IL-2 and IL-15, key growth factors for T and NK cells	AR	Modestly decreased	Normal	Impaired development and function of γδ T cells, Tregs, and NK cells, low T cell proliferation	Growth hormone–insensitive dwarfism, dysmorphic features, eczema, lymphocytic interstitial pneumonitis, autoimmunity
LRBA deficiency	Mutations in *LRBA* (lipopolysaccharide responsive beige like anchor protein)	AR		Reduced I IgG and IgA in most	Defect CTLA4 expression on surface	Recurrent infections, inflammatory bowel disease, autoimmunity; EBV infections
CTLA4	Mutations or deletions in *CLTA4*	AD	Variable	IgG reduced	Hypogammaglobulinemia	Recurrent infections, autoimmune cytopenia, brain inflammation
APECED (APS-1), autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy	Mutations in *AIRE*, encoding a transcription regulator needed to establish thymic self-tolerance	AR	Normal	Normal	AIRE/1 serves as checkpoint in the thymus for negative selection of autoreactive T cells and for generation of Tregs	Autoimmunity: hypoparathyroidism hypothyroidism, adrenal insufficiency, diabetes, gonadal dysfunction, and other endocrine abnormalities, chronic mucocutaneous candidiasis, dental enamel hypoplasia, alopecia areata, enteropathy, pernicious anemia
ALPS–FAS	Germinal mutations in *TNFRSF6*, encoding CD95/Fas cell surface apoptosis receptor	AR	Increased CD4$^-$ CD8$^-$ TCRα/β double negative (DN) T cells	Normal, low memory B cells	Apoptosis defect FAS mediated	Splenomegaly, adenopathies, autoimmune cytopenias, increased lymphoma risk, IgG and IgA normal or increased, elevated FasL and IL-10, vitamin B$_{12}$
ALPS–FASLG	Mutations in *TNFSF6*, Fas ligand for CD95 apoptosis	AR	Increased DN T cells	Normal	Apoptosis defect FAS mediated	Splenomegaly, adenopathies, autoimmune cytopenias, SLE, soluble FasL is not elevated
ALPS–caspase 10	Mutations in *CASP10*, intracellular apoptosis pathway	AD	Increased DN T cells	Normal	Defective lymphocyte apoptosis	Adenopathies, splenomegaly, autoimmunity
ALPS–caspase 8	Mutations in *CASP8*, intracellular apoptosis, and activation pathways	AR	Slightly increased DN T cells	Normal	Defective lymphocyte apoptosis and activation	Adenopathies, splenomegaly, bacterial and viral infections, hypogammaglobulinemia
FADD deficiency	Mutations in *FADD* encoding an adaptor molecule interacting with FAS, and promoting apoptosis	AR	Increased DN T cells	Normal	Defective lymphocyte apoptosis	Functional hyposplenism, bacterial and viral infections, recurrent episodes of encephalopathy and liver dysfunction

AD, autosomal dominant; AR, autosomal recessive; CTL, cytotoxic T lymphocyte; IBD, inflammatory bowel disease; NK, natural killer cell; XL, X-linked.

C3, C4), and the AH50 test, which tests the proteins of the alternative pathway of complement (C3, factor B, properdin). In patients with deficiencies in complement protein, the CH50 levels or AH50 levels are generally zero, whereas they are low but not absent in disorders leading to complement consumption (e.g., systemic lupus erythematosus). If both the CH50 and AH50 levels are abnormal, a defect in the common pathway is likely (C5-C9). Specialized laboratories can measure the presence or function of specific complement proteins.

If the above studies are normal but a primary immune deficiency is still suspected, advanced studies can be performed. One such advanced study is **flow cytometry** to enumerate the percentage and absolute numbers of T cells, B cells and markers of B cell maturation, and NK cell subsets. Flow cytometry can also test for the presence of surface proteins that are necessary for normal immunity, such as major histocompatibility complex molecules or adhesion molecules. Functional T cell tests include T cell proliferation assays in response to mitogens (phytohemagglutinin or concanavalin A) or antigens (tetanus toxoid or *Candida*). These in vitro assays assess the capacity of T cells to proliferate in response to a nonspecific stimulus (mitogens) or antigen-specific memory T cells (antigens). T cell proliferation in response to specific antigens requires a prior exposure to that unique antigen. Delayed-type hypersensitivity skin tests to protein antigens such as tetanus, diphtheria, *Candida,* or mumps demonstrate the presence and function of both antigen-specific T cells and antigen-presenting cells. If delayed-type hypersensitivity skin test results are negative, one may consider a booster vaccination and retesting 4 weeks later.

Tests for **neutrophil function** include the nitroblue tetrazolium (NBT) or dihydrorhodamine 123 (DHR) test for CGD. In the NBT test, oxygen radicals generated by activated neutrophils oxidize NBT to an insoluble dark blue dye that can be detected in neutrophils by microscopic examination. In the DHR test, oxygen radicals generated by activated neutrophils oxidize DHR, which results in the emission of light that is detected by flow cytometry. Neutrophils that are activated in patients with CGD cannot generate oxygen radicals and therefore have an abnormal NBT test (no blue neutrophils) or DHR test (no increase in light emitted from activated neutrophils).

Genetic testing to confirm the diagnosis of a primary immunodeficiency disease can be performed in specialized laboratories and may be helpful for deciding on a course of treatment, determining the natural history and prognosis of the disease, and to allow for genetic counseling. Chromosomal deletion/duplication microarrays are increasingly used to diagnose specific syndromic disorders that may have immunodeficiency due to genomic copy number variants (CNV) such as DiGeorge Syndrome. Specific gene or multiple gene sequencing is available commercially. With the advent of next generation sequencing techniques, it is now possible to sequence nearly all the genes in a subject. Because there are hundreds of genes known to cause primary immune deficiencies, this technology is being used in the diagnosis of primary immune deficiencies.

HUMORAL IMMUNE DISORDERS

Immune disorders that result in impaired immunoglobulin production can result in recurrent infections, typically of the sinopulmonary tract (pneumonia, sinusitis, otitis media), although more disseminated infections can occur (meningitis, sepsis, cellulitis) (Table 41.7). These individuals do not typically have infections with opportunistic pathogens such as *Cryptosporidium, Pneumocystis,* or fungi that are characteristic of combined immune deficiencies (T cell or cell-mediated defects).

X-Linked Agammaglobulinemia (XLA)

X-linked agammaglobulinemia (Bruton agammaglobulinemia) is caused by mutations in the gene that encodes Bruton tyrosine kinase (BTK) and accounts for approximately 85% of all inherited forms of agammaglobulinemias (see Table 41.7). BTK is a cytoplasmic tyrosine kinase that is essential for pre-B cell differentiation into mature B cells. Affected children exhibit severe reductions in serum immunoglobulins and a serious risk for recurrent and sometimes life-threatening infections. Expression of the BTK gene also occurs in myeloid cells, which may account for the **neutropenia** associated with this condition, which typically occurs at the time of their initial presentation.

Although some affected children are asymptomatic until the age of 2 years, most show symptoms between 6 and 9 months of age when maternal transplacental acquired antibodies disappear. Affected individuals develop recurrent infections (recurrent otitis media, sinusitis, pneumonia, meningitis) with pyogenic bacteria, such as pneumococci, staphylococci, streptococci, and *Haemophilus* species. They also have an unusual susceptibility to infection by enteroviruses, which can lead to chronic diarrhea, hepatitis, pneumonitis, and persistent meningoencephalitis. Most live attenuated viral or bacterial vaccines are contraindicated in patients with XLA. The live attenuated polio vaccine is particularly problematic and has caused paralysis in some XLA patients. XLA patients have marked hypoplasia of lymphoid tissue (adenoids, tonsils, lymph nodes) with absence of germinal centers and rare plasma cells. The diagnosis should be considered if the serum IgG, IgM, and IgA levels are less than 5% of age-adjusted control values in a patient with normal T cell function. In the majority of patients, the number of B cells in the peripheral blood is severely reduced or absent. Treatment includes aggressive antibiotic management of infections and replacement immunoglobulin therapy, although chronic pulmonary and gastrointestinal diseases may still occur.

A variety of genetic defects involved in B cell development also lead to agammaglobulinemia, including μ heavy chain, λ5, Igα, Igβ, *PI3KR1*, and *BLNK* (see Table 41.7). These are inherited in an autosomal recessive manner and exhibit similar hypogammaglobulinemia, lack of B cells, and infectious complications.

Common Variable Immunodeficiency

CVID is a heterogeneous immunodeficiency characterized by hypogammaglobulinemia developing after an initial period of normal immune function, most commonly in the 2nd and 3rd decades of life (see Table 41.7). The etiology of CVID in the majority of cases is unknown, although a minority of patients has mutations in the genes encoding for ICOS ("inducible costimulator" on activated T cells), TACI (transmembrane activator and calcium-modulating cyclophilin ligand interactor), CD19, CD21, CD81, or BAFF-R (see Table 41.7).

Patients with CVID are susceptible to frequent respiratory tract infections due to *Streptococcus pneumoniae, Haemophilus influenzae* type b, and *Mycoplasma*. Bronchiectasis due to recurrent pyogenic lung infections is a frequent complication. Gastrointestinal infections with *Giardia*, *Campylobacter*, *Salmonella*, *Helicobacter,* and enteroviruses are common. Bacterial overgrowth in the gut may lead to diarrhea, steatorrhea, malabsorption, and protein-losing enteropathy. Patients exhibit normal-sized or enlarged tonsils and lymph nodes, and frequently have splenomegaly.

In addition to the infectious complications of CVID, **autoimmune complications** are common and an increasing cause of morbidity and mortality. Autoimmune hemolytic anemia and autoimmune thrombocytopenia occur frequently. Multisystemic granulomatous disease occurs in approximately 20-30% of patients, with noncaseating granulomas occurring most frequently in the liver, spleen, lungs, and skin.

TABLE 41.7 Humoral Immune Deficiencies

Severe Reduction in All Serum Immunoglobulin Isotypes with Profoundly Decreased or Absent B Cells

Disease	Genetic Defect/Presumed Pathogenesis	Inheritance	Serum IgG	Associated Features
BTK deficiency	Mutations in *BTK*, a cytoplasmic tyrosine kinase activated by cross-linking of the BCR	XL	All isotypes decreased in majority of patients; some patients have detectable immunoglobulins	Severe bacterial infections; normal numbers of pro-B cells
μ Heavy chain deficiency	Mutations in *IGHM*; essential component of the pre-BCR	AR	All isotypes decreased	Severe bacterial infections; normal numbers of pro-B cells
λ5 Deficiency	Mutations in *IGLL1*; part of the surrogate light chain in the pre-BCR	AR	All isotypes decreased	Severe bacterial infections; normal numbers of pro-B cells
Igα deficiency	Mutations in *CD79A*; part of the pre-BCR and BCR	AR	All isotypes decreased	Severe bacterial infections; normal numbers of pro-B cells
Igβ deficiency	Mutations in *CD79B*; part of the pre-BCR and BCR	AR	All isotypes decreased	Severe bacterial infections; normal numbers of pro-B cells
BLNK deficiency	Mutations in *BLNK*; a scaffold protein that binds to BTK	AR	All isotypes decreased	Severe bacterial infections; normal numbers of pro-B cells
PI3 kinase deficiency	Mutations in *PIK3R1*; a kinase involved in signal transduction in multiple cell types	AR	All isotypes low	Severe bacterial infections; normal numbers of pro-B cells

Severe Reduction in at Least Two Serum Immunoglobulin Isotypes with Normal or Low Number of B Cells

Disease	Genetic Defect/Presumed Pathogenesis	Inheritance	Serum IgG	Associated Features
Common variable immunodeficiency disorders	Unknown	Variable	Low IgG and IgA and/or IgM	Clinical phenotypes vary: most have recurrent infections, some have polyclonal lymphoproliferation, autoimmune cytopenias, and/or granulomatous disease
ICOS deficiency	Mutations in *ICOS*; a co-stimulatory molecule expressed on T cells	AR	Low IgG and IgA and/or IgM	Recurrent infections; autoimmunity, gastroenteritis, granuloma in some
CD19 deficiency	Mutations in *CD19*; transmembrane protein that amplifies signal through BCR	AR	Low IgG and IgA and/or IgM	Recurrent infections; may have glomerulonephritis
CD81 deficiency	Mutations in *CD81*; transmembrane protein that amplifies signal through BCR	AR	Low IgG, low or normal IgA and IgM	Recurrent infections; may have glomerulonephritis
CD20 deficiency	Mutations in *CD20*; a B cell surface receptor involved in B cell development and plasma cell differentiation	AR	Low IgG, normal or elevated IgM and IgA	Recurrent infections
CD21 deficiency	Mutations in *CD21*; also known as complement receptor 2 and forms part of the CD19 complex	AR	Low IgG; impaired antipneumococcal response	Recurrent infections
TACI deficiency	Mutations in *TNFRSF13B* (TACI); a TNF receptor family member found on B cells and is a receptor for BAFF and APRIL	AD or AR or complex	Low IgG and IgA and/or IgM	Variable clinical expression
BAFF receptor deficiency	Mutations in *TNFRSF13C* (BAFF-R); a TNF receptor family member found on B cells and is a receptor for BAFF	AR	Low IgG and IgM	Variable clinical expression
AID deficiency	Mutations in *AICDA* gene	AR	IgG and IgA decreased; IgM increased	Bacterial infections, enlarged lymph nodes, and germinal centers

	Genetic Defect/Presumed			
Disease	**Pathogenesis**	**Inheritance**	**Serum IgG**	**Associated Features**
UNG deficiency	Mutations in *UNG*	AR	IgG and IgA decreased; IgM increased	Bacterial infections, enlarged lymph nodes, and germinal centers
Selective IgA deficiency	Unknown	Variable	IgA decreased/absent	Usually asymptomatic; may have recurrent infections with poor antibody responses to carbohydrate antigens; may have allergies or autoimmune disease. A very few cases progress to CVID, others coexist with CVID in the family

TABLE 41.7 Humoral Immune Deficiencies—cont'd

AD, autosomal dominant; AR, autosomal recessive; BCR, B cell receptor; CVID, common variable immunodeficiency disease; Ig, immunoglobulin; TNF, tumor necrosis factor; XL, X-linked.

When the disease affects the lungs it causes an interstitial lung disease known as granulomatous and lymphocytic interstitial lung disease (GLILD). GLILD is frequently misdiagnosed as sarcoidosis and may lead to significant pulmonary fibrosis. The enteropathy that occurs in CVID can be confused with celiac disease and can lead to chronic diarrhea, protein loss, and poor nutrition. Patients with CVID are also at increased risk for inflammatory bowel disease. Liver disease, in particular nodular regenerative hyperplasia, is an important cause of morbidity and mortality in patients with CVID. There is also a markedly increased susceptibility to B cell lymphomas in patients with CVID. GLILD, enteropathy, lymphoma, and liver disease are independent risk factors for early mortality in CVID.

The diagnosis of CVID requires that age-adjusted serum IgG levels be less than 2 standard deviations (SD) below normal values together with low serum IgA levels (mg/dL) and/or low serum IgM levels. Specific antibody production following immunization with polysaccharide antigens (e.g., unconjugated pneumococcal vaccine) is low or absent, and responses to protein antigens (e.g., tetanus and diphtheria) may be impaired. T cell numbers and function are highly variable, and B cell numbers are usually normal but may be low. It is important to exclude X-linked agammaglobulinemia, X-linked lymphoproliferative disease, or hyper-IgM syndrome as well as other causes of hypogammaglobulinemia, such as hypogammaglobulinemia associated with thymoma, hypogammaglobulinemia secondary to protein-losing enteropathy or other protein-losing states, or hypogammaglobulinemia secondary to medications before making the diagnosis of CVID.

Transient Hypogammaglobulinemia of Infancy

The fetus is capable of producing IgM or IgG by the 20th week of gestation when adequately stimulated (intrauterine infection), but under normal conditions neonatal levels of IgG are a reflection of prior maternal immunity via transplacental passage of maternal IgG. Significant antibody production does not normally begin until the 2nd or 3rd month of life; elevated IgA and IgM in a newborn can be a sign of an intrauterine or perinatal infection. Because maternal antibodies have a half-life of approximately 30 days, the term infant may develop a variable *physiologic* hypogammaglobulinemia between the ages of 4 and 9 months. In *transient* hypogammaglobulinemia of infancy, the immunoglobulin nadir at 6 months of age is accentuated, with immunoglobulin levels less than 200 mg/dL. Immunoglobulin levels remain diminished throughout the 1st year of life and usually increase to normal, age-appropriate levels, generally by 2-4 years of age. If the hypogammaglobulinemia is profound in extent or duration, recurrent viral and pyogenic infections can occur. The diagnosis is supported by normal levels of both B and T cells, and normal antibody responses to protein antigens such as diphtheria and tetanus toxoids. The transient nature of this disorder cannot be confirmed, however, until immunoglobulin levels return to normal ranges. Most patients do not require immune globulin replacement therapy.

Immunoglobulin A Deficiency

Selective IgA deficiency is defined as serum IgA levels less than 10 mg/dL with normal levels of other immunoglobulins. The diagnosis cannot be confirmed until the patient is at least 4 years of age when IgA levels should reach adult levels. Selective IgA deficiency is the most common immune disorder, occurring in approximately 1 in 500 individuals. Most patients with selective IgA deficiency are asymptomatic. In others, it is associated with recurrent sinopulmonary infections, food allergy, autoimmune disease, or celiac disease. IgA deficiency rarely occurs in families, and can exhibit either autosomal recessive or autosomal dominant inheritance with variable penetrance. Antibody replacement therapy is not indicated for IgA deficiency. In patients with IgA deficiency and increased infections, other reasons for recurrent infection should be sought (atopic disease). Blood products often contain IgA and IgA-deficient patients may develop antibodies against IgA. Therefore, IgA-deficient patients may be prone to anaphylactic reactions upon administration of blood products containing IgA; this is a relatively rare complication of IgA deficiency.

Specific Antibody Deficiency

Specific antibody deficiency syndrome is characterized by recurrent sinopulmonary infections with normal immunoglobulin levels and normal lymphocyte numbers and subsets, but a decreased ability to make specific antibodies in response to polysaccharide vaccines, such as to the 23-valent pneumococcal vaccine. Children less than 2 years of age may not respond well to polysaccharide vaccines, so interpreting these results must include consideration of the age of the child. The pathogenesis of this disorder is unknown. Lack of specific antibody titers to polysaccharide vaccines and recurrent sinopulmonary infections with encapsulated bacteria may necessitate the use of prophylactic antibiotics or uncommonly replacement antibody therapy. Specific antibody deficiency many times resolves as the child becomes older.

Hyperimmunoglobulin M Syndrome

Hyper-IgM syndrome results from a failure of B cells to undergo class switching from IgM to IgA, IgG, or IgE. The failure to efficiently class switch can result in recurrent infections. Hyper-IgM syndrome was first described as a result of defects in CD40 ligand or CD40, although these disorders are actually combined immunodeficiency disorders and are discussed later. Deficiencies in AID and UNG, 2 enzymes involved in class switch recombination, can result in hyper-IgM syndrome without cell-mediated defects (see Table 41.7).

COMBINED IMMUNODEFICIENCY DISORDERS

Disorders of T lymphocytes result in defects in both cell-mediated and humoral immunity since T cells are required to activate macrophages and to optimally activate B lymphocytes, and thus these disorders are often referred to as combined immune deficiencies. Patients with combined defects in T and B cell function have infections with the usual community acquired pathogens as well as opportunistic or unusual pathogens, and infections may be more severe or in unusual anatomic sites compared to normal individuals (see Table 41.2). In many cases they may have other associated problems such as autoimmune problems, malignancies, or failure to thrive.

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) is a primary immunodeficiency caused by mutations in 1 of several genes whose function is essential for the normal development of T cells (Table 41.8). In all forms of SCID there are profound abnormalities in T cells and subsequently B cell function is abnormal. Clinical manifestations of SCID generally begin within the first 4 months of life with the waning of maternal antibody and include failure to thrive, severe bacterial, viral, or fungal infections, and intractable diarrhea. Infections with opportunistic pathogens such as *Pneumocystis jiroveci (carinii)* and *Cryptosporidium* are common. Infections with *Candida* frequently involve the mucous membranes (mouth, esophagus, vagina), face, and diaper area, which are difficult to treat. Chronic viral infections including pneumonitis caused by adenovirus or CMV, disseminated varicella and measles infections occur. Chronic infection following immunization with live viral vaccines (measles, mumps, rubella, varicella, rotavirus) are frequent. Fatal, disseminated mycobacterial infection following bacille Calmette-Guérin (BCG) vaccination is frequently seen in parts of the world that use the BCG vaccine.

Patients with SCID may have skin disease similar to eczema due to graft-versus-host disease (GVHD) from engraftment of maternal lymphocytes or Omenn syndrome. **Omenn syndrome**, a variant form of SCID, is characterized by erythroderma and desquamation, lymphadenopathy, hepatosplenomegaly, marked eosinophilia, elevated serum IgE, and impaired T cell function and is caused by hypomorphic mutations that preserve limited function in SCID-causing genes, usually *RAG1, RAG2,* or Artemis *(DCLRE1C)*. Patients with Omenn syndrome have T cells in the periphery, but these T cells are typically expanded oligoclonal T cells. Omenn syndrome is fatal unless corrected by bone marrow transplantation. Patients with SCID are extremely susceptible to fatal GVHD from lymphocytes in blood transfusions, and these patients should always receive irradiated blood products.

Patients with SCID exhibit severe deficits in immunoglobulin synthesis and the responses to specific antigens are impaired. B cells may be absent or increased, but a profound decrease in naive T cells is always present. The number of T cells in the peripheral blood is generally fewer than 10% of normal (<200 cells/mm^3), and T cells show decreased proliferative responses to mitogens, decreased cytotoxicity, and decreased immunoregulatory activity. SCID is uniformly fatal without definitive treatment, which is hematopoietic stem cell transplantation (HSCT) or in some cases gene therapy. **Newborn screening for SCID** using the T cell receptor excision circle (TREC) assay has been implemented in several states in the United States and in an increasing number of countries on a pilot basis. TRECs are formed during DNA recombination of the T cell receptor, are biomarkers of naive T cells, and can be enumerated on the dried blood spots obtained for routine newborn screening tests. The TREC assay is highly sensitive at detecting SCID in newborns before life-threatening infectious complications occur. Early detection and treatment of newborns with SCID improves long-term survival to greater than 90%.

X-linked recessive SCID, which is caused by mutations in the common gamma chain of the IL-2 receptor gene *(IL2RG)*, is the most common form of SCID (see Table 41.8). The IL2RG protein is shared by several interleukin receptors (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21). The lack of T and NK cells is due to defective signaling through the IL-7 and IL-15 receptors, respectively. IL-21 is required for efficient B cell function. Female carriers can be identified because lymphocytes and natural killer cells exhibit nonrandom inactivation of the X chromosome.

Autosomal recessive SCID is less common than X-linked SCID, and is caused by many different genetic defects that can be broken down based on the cell types that are lacking. A lack of T cells but not B cells is seen in genetic defects in T cell signaling proteins including *JAK3, IL7R,* and CD3 subunits (see Table 41.8). A lack of T and B cells is seen in defects in genes that affect DNA recombination, which is required to generate T and B cell receptors, including *RAG1, RAG2,* and *DCLRE1C* (artemis) (see Table 41.8). **Adenosine deaminase (ADA) deficiency**, an autosomal recessive trait, results in an inability to catalyze the conversion of adenosine and deoxyadenosine to inosine and deoxyinosine, respectively. Deficiency of ADA results in the accumulation of deoxyadenosine and deoxy-ATP which is toxic to lymphocytes, resulting in loss of T, B, and NK cells. Regardless of the genetic cause of SCID, all patients have extremely low numbers of naive T cells and all exhibit the typical clinical features in terms of susceptibility to infection, failure to thrive, and 100% mortality without definitive treatment.

COMBINED IMMUNE DEFICIENCIES

Combined immunodeficiencies are genetic defects that result in defective T cell function with or without intrinsic B cell abnormalities (Table 41.9). Because T cell function is abnormal, B cell function is also compromised leading to a combined immunodeficiency, albeit less severe than SCID.

Hyperimmunoglobulin M (hyper-IgM) syndrome is characterized by normal or increased concentrations of IgM and IgD but decreased levels or absence of IgG, IgA, and IgE (see Table 41.9). The most common form of these disorders is X-linked hyper-IgM syndrome, which is due to a mutation in the gene encoding the T cell surface protein CD40 ligand *(CD40L)*. A rarer, autosomal recessive form of this disorder is caused by mutations in the *CD40* gene, which is expressed on the surface of B cells and antigen-presenting cells (see Table 41.9). The CD40/CD40L pathway is essential for B cell isotype switching, which allows a B cell to maintain antigen specificity while altering immunoglobulin function. This switching is directed by cytokines and interaction between CD40 ligand on CD4 T cells and CD40 on B cells. All patients with hyper-IgM syndrome due to genetic defects in CD40L or CD40 have increased susceptibility to sinopulmonary infections with pyogenic bacteria. These individuals are also susceptible to opportunistic infections including *P. jiroveci (carinii)* and *Cryptosporidium parvum*. Signaling via CD40 on B cells accounts for the defects in antibody production and class switching, while defective CD40 signaling in phagocytes and antigen-presenting cells accounts for the susceptibility to opportunistic pathogens. In addition, as many as 50% of patients with CD40L deficiency will exhibit neutropenia.

Signal transduction via CD40 activates several signaling molecules and transcription factors, including nuclear factor-κB (NF-κB), and 2 enzymes, activation-induced cytidine deaminase (AID) and uracil DNA-glycosylase (UNG), which are also required for class switching. Damaging mutations in AID or UNG cause a failure of

TABLE 41.8 Severe Combined Immunodeficiency (SCID)

Disease	Genetic Defect/Pathogenesis	Inheritance	Circulating T Cells	Circulating B Cells	Serum Ig	Associated Features
γc Deficiency	Mutation of *IL-2RG:* defect in γ chain of receptors for IL-2, -4, -7, -9, -15, -21	XL	Markedly decreased	Normal or increased	Decreased	Markedly decreased NK cells
JAK3 deficiency	Mutation of *JAK3:* defect in Janus-activating kinase 3	AR	Markedly decreased	Normal or increased	Decreased	Markedly decreased NK cells
IL7Rα deficiency	Mutation of *IL7RA:* defect in IL-7 receptor α chain	AR	Markedly decreased	Normal or increased	Decreased	Normal NK cells
CD45 deficiency	Mutation of *PTPRC:* defect in CD45	AR	Markedly decreased	Normal	Decreased	Normal γ/δ T cells
CD3δ deficiency	Mutation of *CD3D;* defect in CD3δ chain of T cell antigen receptor complex	AR	Markedly decreased	Normal	Decreased	Normal NK cells, no γ/δ T cells
CD3ε deficiency	Mutation of *CD3E:* defect in CD3ε chain of T cell antigen receptor complex	AR	Markedly decreased	Normal	Decreased	Normal NK cells, no γ/δ T cells
CD3ζ deficiency	Mutation of *CD3Z:* defect in CD3ζ chain of T cell antigen receptor complex	AR	Markedly decreased	Normal	Decreased	Normal NK cells, no γ/δ T cells

SCID Characterized by Lack of T and B Cells (DNA Recombination Defects)

Disease	Genetic Defect/Pathogenesis	Inheritance	Circulating T Cells	Circulating B Cells	Serum Ig	Associated Features
RAG 1 deficiency	Mutation of *RAG1:* defective VDJ recombination; defect of recombinase activating gene (RAG) 1	AR	Markedly decreased	Markedly decreased	Decreased	
RAG 2 deficiency	Mutation of *RAG2:* defective VDJ recombination; defect of recombinase activating gene (RAG) 2	AR	Markedly decreased	Markedly decreased	Decreased	
DCLRE1C (artemis) deficiency	Mutation of *ARTEMIS:* defective VDJ recombination; defect in artemis DNA recombinase repair protein	AR	Markedly decreased	Markedly decreased	Decreased	Radiation sensitivity
DNA PKcs deficiency	Mutation of *PKRDC:* defective VDJ recombination; defect in DNA PKcs recombinase repair protein	AR	Markedly decreased	Markedly decreased	Decreased	Radiation sensitivity, microcephaly, and developmental defects
Reticular dysgenesis, AK2 deficiency	Mutation of *AK2:* defective maturation of lymphoid and myeloid cells (stem cell defect)	AR	Markedly decreased	Decreased or normal	Decreased	Granulocytopenia and deafness
Adenosine deaminase (ADA) deficiency	Mutations in *ADA:* defective ADA activity	AR	Absent from birth or progressive	Decreased or normal	Decreased	Decreased NK cells, often with costochondral junction defects, neurologic features, partial ADA activity may result in delayed or milder presentation

AR, autosomal recessive; Ig, immunoglobulin; NK, natural killer cell; XL, X-linked.

TABLE 41.9 Combined Immune Deficiencies

Disease	Genetic Defect/ Presumed Pathogenesis	Inheritance	Circulating T Cells	Circulating B Cells	Serum Ig	Associated Features
CD40L deficiency	Mutations in *CD40LG* (also called TNFSF5 or CD154)	XL	Normal	B cell numbers may be normal or increased	IgG and IgA decreased; IgM may be normal or increased	Bacterial and opportunistic infections, neutropenia, autoimmune disease
CD40 deficiency	Mutations in *CD40* (also called TNFRSF5)	AR	Normal	B cell numbers may be normal or increased	IgG and IgA decreased; IgM may be normal or increased	Bacterial and opportunistic infections, neutropenia, autoimmune disease
Purine nucleoside phosphorylase (PNP) deficiency	Mutation of *PNP*, absent PNP, and T cell and neurologic defects from elevated toxic metabolites, especially dGTP	AR	Progressive decrease	Normal	Normal or decreased	Autoimmune hemolytic anemia, neurologic impairment
ZAP70 deficiency	Mutation in *ZAP70* intracellular signaling kinase, acts downstream of TCR	AR	Decreased CD8, normal CD4 cells	Normal	Normal	Autoimmunity in some cases
MHC class I deficiency	Mutations in *TAP1, TAP2,* or *TAPBP* (tapasin) genes giving MHC class I deficiency	AR	Decreased CD8, normal CD4	Normal	Normal	Vasculitis; pyoderma gangrenosum
MHC class II deficiency	Mutation in transcription factors for MHC class II proteins (*CIITA, RFX5, RFXAP, RFXANK* genes)	AR	Normal number, decreased CD4 cells	Normal	Normal or decreased	Failure to thrive, diarrhea, respiratory tract infections, liver/biliary tract disease
AD hyperimmunoglobulin E syndrome (HIES) (Job syndrome)	Dominant negative heterozygous mutations in STAT3	AD; often de novo defect	Normal Th-17 and T follicular helper cells decreased	Normal; switched and nonswitched memory B cells are reduced; BAFF level increased	Elevated IgE; specific antibody production decreased	Distinctive facial features (broad nasal bridge), eczema, osteoporosis, and fractures, scoliosis, delay of shedding primary teeth, hyperextensible joints, bacterial infections (skin and pulmonary abscesses, pneumatoceles) due to *Staphylococcus aureus*, candidiasis, aneurysm formation
DOCK8 deficiency	Mutations in *DOCK8* – regulator of intracellular actin reorganization	AR	Decreased impaired T lymphocyte proliferation	Decreased, low CD27+ memory B cells	Low IgM, increased IgE	Low NK cells with impaired function, hypereosinophilia, recurrent infections; severe atopy, extensive cutaneous viral and bacterial (staph.) infections, susceptibility to cancer
Omenn syndrome	Hypomorphic mutations in *RAG1, RAG2, artemis, IL7RA, RMRP, ADA, LIG4, IL2RG, AK2,* or associated with DiGeorge syndrome; some cases have no defined gene mutation	Variable	Present; restricted T cell repertoire, and impaired function	Normal or decreased	Decreased, except increased IgE	Erythroderma, eosinophilia, adenopathies, hepatosplenomegaly
ITK deficiency	Mutations in ITK encoding IL-2-inducible T cell kinase required for TCR-mediated activation	AR	Progressive decrease	Normal	Normal or decreased	EBV-associated B cell lymphoproliferation, lymphoma, normal or decreased IgG
Activated PI3K-δ	Mutation in *PIK3CD*, PI3K-δ	AD; gain of function			High IgM, low IgA or IgG. Reduced IgG2 and impaired antibody to pneumococci and *Haemophilus*	Respiratory infections, bronchiectasis; autoimmunity, chronic EBV, CMV infection; lymphoma

AD, autosomal dominant; AR, autosomal recessive; Ig, immunoglobulin; IL, interleukin; MHC, major histocompatibility complex; TCR, T cell receptor; XL, X-linked.

immunoglobulin isotype switching without opportunistic infections since these proteins function only in isotype class switching and not cell-mediated immunity.

The hyper-IgM phenotype is seen in a number of primary immune deficiencies including an X-linked immunodeficiency associated with ectodermal dysplasia resulting from defects in the gene encoding the **NF-κB essential modulator (NEMO)**. NF-κB signaling is important for function of both innate and adaptive immune systems. Therefore, patients with defects in NEMO have a combined immunodeficiency and are susceptible to a wide spectrum of viruses and bacteria, in particular pyogenic bacteria (e.g., *S. pneumoniae, H. Influenzae)* and atypical mycobacteria. Gain-of-function mutations in the catalytic domain of PI3 kinase *(PIK3CD)* can also lead to a hyper-IgM pheno-type. PIK3CD is expressed in B cells and T cells, and therefore gain-of-function mutations in PIK3CD lead to the constitutive activation of PI3 kinase resulting in impaired T cell and B cell function. These patients present with recurrent sinopulmonary infections and have an increased susceptibility to infection with herpes viruses. Autoimmunity, lymphoproliferation (including an increased incidence of B cell lymphomas), and structural lung diseases commonly occur.

Purine Nucleoside Phosphorylase Deficiency

Purine nucleoside phosphorylase (PNP) is an enzyme that follows adenosine deaminase in the purine salvage pathway and catalyzes the conversion of inosine and guanosine to hypoxanthine and guanine, respectively (see Table 41.9). PNP deficiency, which is inherited as an autosomal recessive disorder, leads to the intracellular buildup of deoxy-guanosine triphosphate (deoxy-GTP), which is toxic to rapidly dividing cells. Although PNP is ubiquitously expressed, PNP deficiency affects T cells and not B cells and leads to T cell lymphopenia with preserved numbers of B cells. Although serum immunoglobulins are usually normal, specific antibody production is impaired. A low serum uric acid level is suggestive of PNP deficiency. Patients with PNP deficiency are predisposed to infection with common and opportunistic pathogens. Autoimmunity and neurologic manifestations are also common. The only curative treatment for PNP deficiency is HSCT.

Hyperimmunoglobulin E Syndrome

Classic hyperimmunoglobulin E syndrome (HIES), also known as **Job syndrome** is an autosomal dominant disorder caused by mutations in STAT3, an important signaling molecule required for the signaling of several cytokines such as IL-6 and IL-10 (see Table 41.9). Classic HIES is characterized by markedly elevated levels of serum IgE, early onset, severe eczematous dermatitis, recurrent bacterial infections (skin, respiratory tract, bone), and chronic candidiasis (thrush, onychomycosis). Other associated features include coarse facial features, manifested by a broad nasal bridge, prominent nose, dental abnormalities, and irregular proportional cheeks and jaw. The eczematous rash is typically papular and pruritic, involving the face and extensor surfaces of arms and legs and may start at birth or soon thereafter. The skin abscesses typically due to *S. aureus* are remarkable for their absence of surrounding erythema or warmth, leading to term of "cold abscesses." By 5 years of age, all patients have had a history of recurrent skin abscesses and recurrent pneumonias with pneumatoceles, along with chronic otitis media and sinusitis. Patients may also develop septic arthritis, cellulitis, or osteomyelitis. Fungal infections with *Candida albicans* and *Aspergillus* species occur. Serum IgE levels typically exceed 2500 IU/mL. Usually, patients with HIES have normal concentrations of IgG, IgA, and IgM, and frequently have eosinophilia. The clinical manifestations of **DOCK8 deficiency** display considerable overlap with classic HIES, with high IgE levels, eczema, and recurrent infections (see Table 41.9). However, patients with DOCK8 deficiency typically lack pneumatoceles, and bone and tooth abnormalities. The optimal treatment of classic HIES is largely supportive and includes antimicrobial therapy and, in selected patients, replacement antibody. In contrast, HSCT is curative for DOCK8 deficiency.

IMMUNODEFICIENCIES WITH SYNDROMIC FEATURES

Several genetic defects that affect the immune system also affect other organ systems and thus represent a clinical syndrome (Table 41.10). A careful history and exam can lead a clinician to the diagnosis. Most of these conditions present with combined T and B cell defects.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disorder caused by mutation in the gene that encodes the protein Wiskott-Aldrich syndrome protein or WASP. WASP controls the assembly of actin filaments and intracellular vesicle transport in lymphocytes and megakaryocytes. WAS is characterized by abnormalities in lymphocyte, platelet, and phagocyte function (see Table 41.10). Classic WAS is characterized by the triad of recurrent infections involving encapsulated bacteria and opportunistic pathogens, hemorrhage secondary to thrombocytopenia and platelet dysfunction, and atopic dermatitis. Mutations in the WAS gene can also cause X-linked neutropenia and X-linked thrombocytopenia. The clinical manifestations of WAS begin in early infancy with pneumonia, otitis media, meningitis, and bleeding. Patients are susceptible to recurrent and severe infections with encapsulated bacteria and viruses (herpes simplex virus, varicella, EBV, CMV). Fungal and pneumocystis infections may occur as well. Autoimmunity is common and includes cytopenias, vasculitis, arthritis, and inflammatory bowel disease. Patients are also susceptible to malignancy, in particular lymphoreticular malignancies. In classic WAS there is thrombocytopenia with abnormally small platelets. Deficiency of this protein results in elevated levels of IgE and IgA, decreased IgG and/or IgM, poor responses to polysaccharide antigens, and waning T cell function. One-third of patients with Wiskott-Aldrich syndrome die as a result of hemorrhage, and two-thirds die as a result of recurrent infection caused by bacteria, cytomegalovirus, *P. jiroveci (carinii),* or herpes simplex virus. In classic WAS the only curative therapy is hematopoietic stem cell transplantation.

Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is an autosomal recessive disorder characterized by neurologic dysfunction, endocrine abnormalities, oculocutaneous telangiectasia, immunodeficiency, and radiation sensitivity with a high rate of malignancy (see Table 41.10). The defective gene is the ataxia-telangiectasia mutated gene *(ATM)* that encodes for a phosphatidylinositol 3-kinase involved in sensing DNA damage and DNA repair. Cerebellar ataxia is usually the 1st clinical manifestation, occurring when the child begins to walk. The patient's neurologic status often worsens, and choreoathetosis and oculomotor abnormalities develop. Telangiectasias first appear in the bulbar conjunctivae between 2 and 5 years of age and later spread to areas of trauma. Endocrine abnormalities, such as insulin-resistant diabetes mellitus and hypogonadism are common. There is a 15% risk of malignancy with non-Hodgkin lymphoma being the most common. Patients with ataxia-telangiectasia are extremely sensitive to ionizing radiation, and radiographic studies should be avoided if possible. Radiation sensitivity accounts for the high incidence of chromosomal translocations involving chromosomes 7 and 14 at the site of T cell receptor genes and immunoglobulin heavy-chain genes.

TABLE 41.10   Combined Immune Deficiencies with Syndromic Features

Disease	Genetic Defect/ Presumed Pathogenesis	Inheritance	Circulating T Cells	Circulating B Cells	Serum Ig	Associated Features
Wiskott–Aldrich Syndrome (WAS)	Mutations in *WAS*; cytoskeletal, and immunologic synapse defect affecting hematopoietic stem cell derivatives	XL	Progressive decrease, abnormal lymphocyte responses to anti-CD3	Normal	Decreased IgM: antibody to polysaccharides particularly decreased; often increased IgA and IgE	Thrombocytopenia with small platelets; eczema; lymphoma; autoimmune disease; IgA nephropathy; bacterial and viral infections. XL thrombocytopenia is a mild form of WAS, and XL neutropenia is caused by missense mutations in the GTPase binding domain of WASP
Ataxia–telangiectasia	Mutations in *ATM*; disorder of cell cycle checkpoint; and DNA double-stranded break repair	AR	Progressive decrease	Normal	Often decreased IgA, IgE, and IgG subclasses; increased IgM monomers; antibodies variably decreased	Ataxia; telangiectasia; pulmonary infections; lymphoreticular and other malignancies; increased α-fetoprotein and increased radiosensitivity
Cartilage-hair hypoplasia	Mutations in *RMRP* (RNase MRP RNA) involved in processing of mitochondrial RNA and cell cycle control	AR	Varies from severely decreased (SCID) to normal; impaired lymphocyte proliferation	Normal	Normal or reduced; antibodies variably decreased	Short-limbed dwarfism with metaphyseal dysostosis, sparse hair, bone marrow failure, autoimmunity, susceptibility to lymphoma and other cancers, impaired spermatogenesis, neuronal dysplasia of the intestine
CHARGE syndrome	Variable defects of the thymus and associated T cell abnormalities often due to deletions or mutations in *CHD7, SEMA3E*, or as yet unknown genes	De novo defect (majority) or AD	Decreased or normal; some have <1500 CD3 T cells/μL	Normal	Normal or decreased	Coloboma, heart anomaly, choanal atresia, retardation, genital and ear anomalies
DiGeorge anomaly	Contiguous gene defect in 90% affecting thymic development; may also be due to heterozygous mutation in *TBX1* (chromosome 22q11.2 deletion or TBX1 haploinsufficient syndrome)	AD; often de novo	Decreased or normal; 5% have <1500 CD3 T cells/μL	Normal	Normal or decreased	Hypoparathyroidism, conotruncal malformation; abnormal facies; large deletion (3 Mb) in 22q11.2 (or rarely a deletion in 10p)

AD, autosomal dominant; AR, autosomal recessive; Ig, immunoglobulin; XL, X-linked.

The degree of immunodeficiency in AT is quite variable and may include abnormalities in T cells and B cells. Respiratory tract disease is an important cause of morbidity and mortality and includes sino-pulmonary infection with encapsulated organisms, interstitial lung disease, and lung disease associated with neuromuscular deficits including recurrent aspiration. Opportunistic respiratory tract infections are uncommon. There is no curative therapy for AT, although antimicrobial prophylaxis and intravenous immunoglobulin (IVIG) replacement is used to prevent infections.

DiGeorge Syndrome (22q Deletion Syndrome) and Other Thymic Defects

DiGeorge syndrome is a disorder caused in the majority of cases by microdeletion at chromosome 22q11.2, although a deletion at a 2nd loci at chromosome 10p13 results in a similar clinical picture. DiGeorge syndrome, also known as velocardiofacial syndrome or CATCH 22 syndrome (cardiac anomalies, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcemia), is characterized by a constellation of clinical features that include dysmorphic facies, hypoparathyroidism, congenital heart defects, and T cell lymphopenia (see Table 41.10). The clinical anomalies are caused by maldevelopment of structures derived from the 1st through the 6th branchial pouches during embryogenesis, resulting in variable hypoplasia of the thymus, parathyroid glands, face, ears, aortic arch, and heart. Congenital heart defects include truncus arteriosus, ventricular septal defect, interrupted aortic arch, and tetralogy of Fallot. Hypocalcemia with tetany is often the initial problem in the 1st and 2nd months after birth. Facial abnormalities include microstomia, hypertelorism, and low-set ears.

The degree of immunodeficiency is highly variable and related to the extent of residual thymic function. In complete DiGeorge syndrome, which occurs in less than 1% of patients, severe T cell deficiency leads to a disorder resembling SCID with failure to thrive, and recurrent infections with opportunistic organisms (*P. jiroveci*, viruses, and fungi). In contrast, many other patients with DiGeorge exhibit relatively normal immune function or relatively minor immunodeficiency (incomplete DiGeorge syndrome). Autoimmunity, including autoimmune cytopenias, is common. The total T cell count may vary from severely depressed to normal. No correlation has been shown between severity of congenital defects and the severity of immunodeficiency, and immune function often improves with age.

The diagnosis is established by chromosomal microarray or fluorescent in situ hybridization to detect the usual deleted region in chromosome 22q11.2. Approximately 10% of patients have hypogammaglobulinemia with a minority requiring antibody replacement therapy. Importantly, due to intrinsic defects in the thymus, patients with DiGeorge syndrome cannot be treated with hematopoietic stem cell transplantation, although transfer of mature T cells during transplant may confer some immune function.

CHARGE syndrome (coloboma, heart anomaly, choanal atresia, retardation, genital and ear anomalies) is related to DiGeorge syndrome since both involve thymic aplasia. Mutations in *CHD7* are the most common known cause of CHARGE syndrome, although mutations in *SEMA3E* are found in a minority of patients (see Table 41.10). The degree of immunodeficiency is related to the extent of thymic hypoplasia and T cell numbers, and can be highly variable. Similar to DiGeorge syndrome, some mutations of CHD7 are a cause of SCID with a profound T cell lymphopenia.

Cartilage-Hair Hypoplasia

Cartilage-hair hypoplasia (CHH) is an autosomal recessive disease caused by mutations in the ribonuclease mitochondrial RNA-processing (RMRP) gene. CHH is characterized by metaphyseal dysostosis, sparse and thin hair, and variable immunodeficiency (see Table 41.10). Lymphocyte counts over time become low in all patients due to low numbers of T cells. Proliferative responses to mitogens are generally depressed, and immune function may deteriorate with time. The immunodeficiency can range from mild to severe, but in many affected patients it is relatively mild. Patients benefit most from replacement immunoglobulin. Patients may have moderate to severe neutropenia, making them susceptible to both viral and bacterial infections.

COMPLEMENT SYSTEM DEFICIENCIES

The complement system consists of plasma and membrane proteins that function in the innate immune response as well as facilitating adaptive immunity. Complement proteins can kill pathogens with or without antibodies, opsonize pathogens to facilitate their uptake by phagocytes, or mediate inflammation. The complement system can be activated through 3 pathways—the classical, alternative, or lectin pathways—that involve the sequential activation of complement factors resulting in an amplified response. Disorders of the complement system predispose to recurrent infection, autoimmunity, and angioedema (Table 41.11).

The 3 pathways for complement activation are initiated by different mechanisms. The classical pathway is activated by antigen-antibody complexes. The alternative pathway may be activated by C3b generated through the classical pathway or by spontaneous hydrolysis of C3 on microbial surfaces. The lectin pathway is initiated by the interaction of mannose-binding lectin with microbial carbohydrate. Activation of the classical pathway by an antigen-antibody complex is initiated by the binding of C1q to the Fc portion of an antibody molecule in the immune complex. C1r autoactivates and cleaves C1s, which cleaves C4 and then C2, forming the C3 convertase, C4b2b. C4b2b is activated by the lectin pathway when mannose-binding protein binds to sugar residues on the surface of pathogens, and mannose-binding protein–associated proteases (MASP) cleave C4 and C2. The alternative pathway is always active at a low level and is amplified when active C3 binds to a surface that lacks regulatory proteins. C3b generated from C3 binds to factor B, which is cleaved by factor D to form the alternative pathway C3 convertase, C3bBb. Properdin binds to and stabilizes the C3 convertase. The C3 convertase can cleave C3 resulting in further C3b deposition and activation of the alternative pathway, which acts as an amplification loop by generating more C3b, or it can form the C5 convertase, which initiates the formation of a membrane attack complex (MAC). The MAC is a complex of C5b, C6, C7, C8, and several C9 molecules that is common to all 3 pathways. The MAC generates pores in the cell membrane, leading to lysis of the cells.

C3a and C5a produced by cleavage of C3 and C5 respectively, release histamine from mast cells and basophils, leading to increased vascular permeability and smooth muscle contraction. In addition, C5a has chemotactic activity, attracting phagocytes to the site of complement activation, and it can cause degranulation of phagocytic cells. C3b acts as an opsonin when attached to the surface of a pathogen by binding to phagocytes.

The complement system is under tight regulation because it has potent inflammatory activity and the potential to cause significant damage to host cells, and therefore there are a number of complement regulatory proteins. C1 inhibitor regulates the cascade by blocking active sites on C1r, C1s, and the MASP. Factor I destabilizes C3 convertase complexes and degrades the active fragments. Other inhibitors include membrane proteins, such as decay accelerating factor (DAF), CR1, membrane cofactor protein (MCP), and plasma proteins such as C4 binding protein. Formation of the MAC can be blocked by cell surface CD59. Deficiency of any of these regulatory proteins can result

TABLE 41.11 Complement Defects

Disease	Genetic Defect/Presumed Pathogenesis	Inheritance	Functional Defect	Associated Features
C1q deficiency	Mutation in *C1QA, C1QB, C1QC*: classical complement pathway components	AR	Absent CH50 hemolytic activity; defective activation of the classical pathway, diminished clearance of apoptotic cells	SLE, infections with encapsulated organisms
C1r deficiency	Mutation in *C1R*: classical complement pathway component	AR	Absent CH50 hemolytic activity; defective activation of the classical pathway	SLE, infections with encapsulated organisms
C1s deficiency	Mutation in *C1S*: classical complement pathway component	AR	Absent CH50 hemolytic activity; defective activation of the classical pathway	SLE, infections with encapsulated organisms
C4 deficiency	Mutation in *C4A, C4B*: classical complement pathway components	AR	Absent CH50 hemolytic activity; defective activation of the classical pathway, defective humoral immune response to carbohydrate antigens in some patients	SLE, infections with encapsulated organisms
C2 deficiency	Mutation in *C2*: classical complement pathway component	AR	Absent CH50 hemolytic activity; defective activation of the classical pathway	SLE, infections with encapsulated organisms, atherosclerosis
C3 deficiency	Mutation in *C3*: central complement component	AR, gain-of-function AD	Absent CH50 and AH50 hemolytic activity; defective opsonization, defective humoral immune response	Infections; glomerulonephritis, aHUS with gain-of-function mutations
C5 deficiency	Mutation in *C5*: terminal complement component	AR	Absent CH50 and AH50 hemolytic activity; defective bactericidal activity	Neisserial infections
C6 deficiency	Mutation in *C6*: terminal complement component	AR	Absent CH50 and AH50 hemolytic activity; defective bactericidal activity	Neisserial infections
C7 deficiency	Mutation in *C7*: terminal complement component	AR	Absent CH50 and AH50 hemolytic activity; defective bactericidal activity	Neisserial infections
C8 α–γ deficiency	Mutation in *C8A, C8G*: terminal complement components	AR	Absent CH50 and AH50 hemolytic activity; defective bactericidal activity	Neisserial infections
C8b deficiency	Mutation in *C8B*: terminal complement component	AR	Absent CH50 and AH50 hemolytic activity; defective bactericidal activity	Neisserial infections
C9 deficiency	Mutation in *C9*: terminal complement component	AR	Reduced CH50 and AH50 hemolytic activity; deficient bactericidal activity	Mild susceptibility to neisserial infections
C1 inhibitor deficiency	Mutation in *C1NH*: regulation of kinins and complement activation	AD	Spontaneous activation of the complement pathway with consumption of C4/C2; spontaneous activation of the contact system with generation of bradykinin from high molecular weight kininogen	Hereditary angioedema
Factor B	Mutation in *CFB*: activation of the alternative pathway	AD	Gain-of-function mutation with increased spontaneous AH50	aHUS
Factor D deficiency	Mutation in *CFD*: regulation of the alternative complement pathway	AR	Absent AH50 hemolytic activity	Neisserial infections
Properdin deficiency	Mutation in *CFP*: regulation of the alternative complement pathway	XL	Absent AH50 hemolytic activity	Neisserial infections
Factor I deficiency	Mutation in *CFI*: regulation of the alternative complement pathway	AR	Spontaneous activation of the alternative complement pathway with consumption of C3	Infections, neisserial infections, aHUS, preeclampsia, membranoproliferative glomerulonephritis
Factor H deficiency	Mutation in *CFH*: regulation of the alternative complement pathway	AR	Spontaneous activation of the alternative complement pathway with consumption of C3	Infections, neisserial infections, aHUS, preeclampsia, membranoproliferative glomerulonephritis
MASP1 deficiency	Mutation in *MASP1*: cleaves C2 and activates MASP2	AR	Deficient activation of the lectin activation pathway, cell migration	Infections, 3MC syndrome

AD, autosomal dominant; aHUS, atypical hemolytic uremic syndrome; AR, autosomal recessive; SLE, systemic lupus erythematosus; XL, X-linked.

in an inflammatory response, tissue damage, or excessive complement consumption. Deficiency in the expression of CD59 results in paroxysmal hemoglobinuria. Deficiencies in the complement regulatory proteins (factor H, factor I, and MCP) result in atypical hemolytic uremic syndrome, membranoproliferative glomerulonephritis type II, and have been linked to age-related macular degeneration (see Table 41.11).

Although protein deficiencies or abnormalities have been identified for components in the classical complement pathway, the severity and the type of infection vary because of the considerable overlap between the 2 pathways (see Table 41.11). Disorders of complement proteins can result from inherited deficiency or can be secondary to increased consumption. Deficiencies of early components of the classical pathway (C1, C2, or C4) are not usually associated with severe infections, although patients with C2 deficiency may present with recurrent respiratory tract infections with encapsulated bacteria. Patients with C1, C2, or C4 deficiency are susceptible to autoimmune diseases, especially systemic lupus erythematosus. The exact mechanism of this susceptibility is not known but is thought to arise from the role of these early components in clearing immune complexes. Deficiency of C3, the major opsonin, due to a genetic defect or secondary to excessive consumption or protein loss (e.g., nephrotic syndrome, systemic lupus erythematosus) predisposes patients to infections, especially with encapsulated organisms. Deficiency of 1 of the terminal components that compose the MAC or properdin predisposes patients to invasive infections (e.g., meningitis, septicemia) with *Neisseria meningitidis* and *Neisseria gonorrhoeae.* Complement deficiency may be found in 40% of patients presenting with recurrent neisserial infections, particularly with meningococcal disease caused by uncommon serogroups (see Table 41.11).

C1 inhibitor deficiency causes **hereditary angioedema**, an autosomal dominant disorder that results in dysregulation of the classical complement pathway. After minor trauma, affected patients develop local angioedema without urticaria, pain, or erythema. The angioedema may be severe and untreated leads to significant morbidity and mortality. Angioedema involving the larynx or upper airways can be life-threatening, and involvement of the bowel leads to abdominal pain, vomiting, and diarrhea. Lack of inhibition of plasma kallikrein by C1 inhibitor and dysregulated production of bradykinin is the cause of the angioedema. Treatment of hereditary angioedema includes administration of C1 inhibitor, administration of a pharmacologic inhibitor of plasma kallikrein (ecallantide), or administration of a bradykinin β_2-antagonist (icatibant).

Diagnosis of Complement Deficiencies

The CH50 test is a widely available test of classical complement pathway function based on an antibody-dependent hemolytic assay. The CH50 test depends on the function of all 9 complement proteins, C1 through C9. The AH50 test, which activates the alternative pathway, depends on the alternative pathway components and C5-C9. An abnormal CH50 but not AH50 are consistent with defects in C1, C2, or C4. Alternatively, an abnormal AH50 but normal CH50 indicates a defect in properdin or factor B. Abnormal results of both tests indicate a deficiency in a terminal component common to both pathways (C3, C5-C9). If the CH50 or AH50 levels are abnormal, individual components can be analyzed in specialized laboratories. In hereditary angioedema, C4 levels are generally low, but C3 levels are normal. Determination of C1 inhibitor levels and/or function is needed to definitively diagnose hereditary angioedema. Low C3 and C4 levels are seen when the classical pathway is activated (e.g., systemic lupus erythematosus), whereas activation of the alternative pathway characteristically results in low C3 levels and normal C4 levels.

Specific treatment of complement deficiencies with component replacement is not available. Frequent courses of antibiotics or prophylactic antibiotics have been utilized. Immunization of patients and close contacts with pneumococcal and meningococcal vaccines may be useful, but infections may still occur in immunized complement-deficient patients. Replacement of complement proteins by plasma transfusion has been used in some patients with C2 deficiency, factor H deficiency, or factor I deficiency. MCP deficiency presenting with atypical hemolytic uremic syndrome is treated with renal transplantation since it is a membrane protein.

PHAGOCYTE DISORDERS

Neutrophils are important in protecting the skin, mucous membrane, and the lining of the respiratory and gastrointestinal tracts. They form the 1st line of defense against microbial invasion. During the critical 1st 2-4 hours after tissue invasion by pathogenic organisms, the arrival of phagocytic cells at the site of infection is crucial for the containment of the infection, limiting the size of the local lesion, and preventing dissemination. Monocytes/macrophages are also important in cell-mediated immunity, and in response to T cell cytokines (IFN-γ), these cells become effective killers of intracellular pathogens.

Neutrophils develop in the bone marrow from hematopoietic stem cells, and upon leaving the bone marrow mature neutrophils are found in the circulation or roll along the endothelium (known as the marginating pool). Adhesion molecules are necessary for neutrophils to roll and adhere to vascular endothelium and extravasate from the blood into sites of infection, where they phagocytose and kill pathogens, especially those coated by complement or antibodies. Chemotactic factors, including the complement fragment C5a, IL-8, leukotriene B_4, and bacterial formylated peptides (fMLP) mobilize neutrophils to enter tissues and sites of infections. Once in tissues these cells ingest the offending organisms (phagocytosis), and activate biochemical pathways important in intracellular microbial killing (degranulation and oxidative metabolism). The respiratory burst consists of the de novo synthesis of highly toxic and often unstable derivatives of molecular oxygen. Degranulation is the process by which lysosomal granules, containing preformed polypeptide antibiotics and proteases, fuse with the phagocytic vacuoles containing the ingested microbes.

Patients with neutrophil disorders are susceptible to a variety of bacterial infections and certain fungi. Infections associated with neutrophil disorders include infections of mucosal surfaces (e.g., respiratory tract infections, rectal and vaginal infections, gingivostomatitis), abscesses in the skin and viscera, lymphadenitis, poor wound healing, delayed umbilical cord separation, or absence of pus.

Disorders of Neutrophil Numbers

Neutropenia is defined as an absolute neutrophil count (ANC) less than 1500/mm³ for children 1 year of age or older, although African-American children can have lower neutrophil numbers. The susceptibility to infection is minimally increased until the ANC is less than 1000/mm³. Most patients do well with an ANC greater than 500/mm³. At these levels, localized infections are more common than generalized bacteremia. Serious bacterial infections are more common with an ANC less than 200/mm³. Neutropenia may be congenital and caused by mutations in several genes (Table 41.12) or acquired (e.g., autoimmune neutropenia, drug reactions, marrow replacement with cancer cells).

Inherited Forms of Neutropenia

Severe congenital neutropenia (Kostmann syndrome) is an autosomal recessive disorder caused by mutations in the HCLS-associated protein

X-1 *(HAX1)* gene and is characterized by severe persistent neutropenia (absolute neutrophil count <500 cells/mm^3) and recurrent bacterial infections (Table 41.12). Affected patients often have increased plasma concentrations of granulocyte colony-stimulating factor (G-CSF) as well as circulating eosinophils and monocytes. In severe congenital neutropenia, the neutrophil counts increase in response to exogenous G-CSF despite the elevated level of G-CSF at baseline.

Autosomal dominant inherited mutations in the elastase 2 gene *(ELA2)* are the most common cause of **cyclic neutropenia** although the disorder may present as persistent neutropenia as well. In the cyclic form of neutropenia, there are periodic episodes of profound neutropenia (absolute neutrophil counts <200 cells/mm^3), generally lasting 3-6 days and occurring in 21-day cycles (see Table 41.12). During the episodes of neutropenia, individuals develop aphthous ulcers, gingivitis, stomatitis, and cellulitis. Death from overwhelming infection with *Clostridium perfringens* occurs in about 10% of patients.

Severe congenital neutropenia, which may be either persistent or cyclic, is also seen in **Shwachman-Diamond syndrome**, an autosomal recessive syndrome of pancreatic insufficiency accompanying bone marrow dysfunction. Metaphyseal dysostosis and dwarfism may occur. A gain-of-function mutation in the Wiskott-Aldrich syndrome protein has also been associated with an X-linked form of severe congenital neutropenia. Severe congenital neutropenia may be associated with SCID in reticular dysgenesis, a disorder of hematopoietic stem cells affecting all bone marrow lineages due to mutations in the *AK2* gene.

The mainstay of treatment of all congenital neutropenias is recombinant human granulocyte colony-stimulating factor (rhG-CSF). Approximately 10% of patients with the diagnosis of severe congenital neutropenia and Shwachman-Diamond syndrome develop myelodysplasia/acute myelogenous leukemia. No cases of malignant transformations have been observed in patients with either cyclic or idiopathic neutropenia.

Acquired Neutropenia

Isoimmune neutropenia occurs in neonates as the result of transplacental transfer of maternal antibodies to fetal neutrophil antigens. The mother produces antibodies to specific neutrophil antigens on the surface of fetal leukocytes that are inherited from the father and are not present on maternal cells. Isoimmune neonatal neutropenia, similar to isoimmune anemia and thrombocytopenia, is a transient process that resolves as maternal antibodies wane. Cutaneous infections are common, and sepsis is rare. Early treatment of infection while the infant is neutropenic is the major goal of therapy. Intravenous immune globulin may decrease the duration of neutropenia. *Autoimmune neutropenia* usually develops in children 5-24 months of age. Neutrophil autoantibodies may be IgG, IgM, IgA, or a combination of these. Usually, the condition spontaneously resolves in 6 months to 4 years. Although intravenous immune globulin and corticosteroids have been used, most patients respond to G-CSF.

Disorders of Neutrophil Adhesion and Chemotaxis

Leukocyte adhesion deficiency type 1 (LAD-1) is an autosomal recessive inherited disorder resulting from mutations in the gene encoding the β_2 integrin CD18. CD18 is the common β-subunit of lymphocyte function-associated antigen-1 (LFA-1) (CD11a/CD18), Mac-1 (CD11b/CD18), and P150,95 (CD11c/CD18), proteins that are expressed on lymphocytes, monocytes/macrophages, and neutrophils, respectively. Diminished or absent surface expression of these proteins accounts for a profound impairment of neutrophil and monocyte cell migration and phagocytosis. The severity of the immunodeficiency is dependent on the level of expression of CD18. Infants affected with this disorder may present in early infancy with failure of separation of the umbilical cord (often 2 months after birth) with attendant omphalitis and sepsis (see Table 41.12). Cutaneous, respiratory, gingival, and mucosal infections are common, and sepsis may lead to death in early childhood. Due to a failure of neutrophils to adhere normally to vascular endothelium (marginate), absolute neutrophil counts are usually greater than 20,000/mm^3 even when patients are not infected. The diagnosis of LAD-1 can be made measuring the amount of LFA-1 on the surface of lymphocytes by flow cytometry. Hematopoietic stem cell transplantation is curative.

Leukocyte adhesion deficiency type 2 (LAD-2) is an autosomal recessive congenital disorder of glycosylation (type iic) caused by mutations in the *SLC35C1* gene. The *SLC35C1* gene encodes a GDP-fucose transporter, and mutation in this gene results in the absence of sialylated Lewis X blood group on the surface of neutrophils and other leukocytes, resulting in failure to roll and subsequently adhere to vascular endothelium. Patients with LAD-2 manifest with growth retardation, dysmorphic features, and neurologic deficits in addition to the increased susceptibility to infection. LAD-3 is a rare disorder caused by defects in the KINDLIN-3 protein resulting in defective neutrophil adhesion as well as platelet defects. Patients with LAD-3 present similar to LAD-1 with recurrent severe infections as well as a bleeding disorder.

Depressed neutrophil chemotaxis has been observed in a wide variety of clinical conditions (see Table 41.12). In addition to LAD-1 and LAD-2, defective migration of neutrophils has been described in hyper-IgE syndrome due to STAT3 mutations and with mutations in the *RAC2* gene (see Table 41.12). RAC2 is the predominant GTPase in human neutrophils, and it is integral to the function of the actin cytoskeleton. Deficiency in RAC2 is associated with decreased neutrophil chemotaxis, superoxide generation, and decreased degranulation in response to formylated peptides.

Disorders of Neutrophil Function

Chronic granulomatous disease (CGD) is a disorder of phagocytes due to mutations in any 1 of the subunits of the enzyme nicotinamide adenine dinucleotide phosphate (NADPH) oxidase (see Table 41.12). NADPH oxidase consists of 4 subunits (gp91^{phox}, p22^{phox}, p47^{phox}, and p67^{phox}) and is responsible for the generation of the respiratory burst, which involves the catalytic conversion of molecular oxygen to superoxide (O_2^-) that is essential for the killing of a variety of bacterial and fungal pathogens by neutrophils and macrophages. Mutations in the gene encoding the gp91^{phox} protein are inherited in an X-linked manner and account for approximately 65% of CGD. All other forms of CGD are inherited in in an autosomal recessive manner.

Although the clinical manifestations are variable, several clinical features suggest the diagnosis of CGD. The onset of clinical signs and symptoms may occur from early infancy to young adulthood, and the attack rate and severity of infections are dependent on the amount of residual oxidase activity generated by NADPH oxidase in affected individuals. Affected patients may have recurrent lymphadenitis, bacterial hepatic abscesses, or osteomyelitis. Infections also occur in the lungs, the middle ear, gastrointestinal tract, skin, and urinary tract. Patients characteristically exhibit lymphadenopathy, hypergammaglobulinemia, hepatosplenomegaly, dermatitis, failure to thrive, anemia, chronic diarrhea, and abscesses. Granulomas are prominent and may obstruct the pylorus or ureters or lead to inflammatory bowel disease. The most common pathogen is *S. aureus*, and infection with *S. marcescens, B. cepacia, Aspergillus* sp., *C. albicans,* or *Salmonella* sp. can occur. The diagnosis of CGD is made by either the DHR test or the NBT dye test.

The treatment of CGD is rapidly evolving. CGD is traditionally treated with prophylactic trimethoprim-sulfamethoxazole, itraconazole, long-term continuous interferon-γ therapy, and bactericidal

TABLE 41.12	**Phagocyte Disorders**				
Disease	**Genetic Defect/ Presumed Pathogenesis**	**Inheritance**	**Affected Cells**	**Affected Function**	**Associated Features**
Severe congenital neutropenia 1 (ELANE deficiency)	Mutation in *ELANE:* misfolded protein response, increased apoptosis	AD	N	Myeloid differentiation	Susceptibility to MDS/ leukemia
SCN2a (GFI1 deficiency)	Mutation in *GFI1:* loss of repression of ELANE	AD	N	Myeloid differentiation	B/T lymphopenia
SCN3 (Kostmann disease)	Mutation in *HAX1:* control of apoptosis	AR	N	Myeloid differentiation	Cognitive and neurologic defects in patients with defects in both HAX1 isoforms, susceptibility to MDS/leukemia
SCN4 (G6PC3 deficiency)	Mutation in *G6PC3:* abolished enzymatic activity of glucose-6-phosphatase, aberrant glycosylation, and enhanced apoptosis of N and F	AR	N + F	Myeloid differentiation, chemotaxis, O⁻ production	Structural heart defects, urogenital abnormalities, inner ear deafness, and venous angiectasias of trunks and limbs
SCN5	Mutation in *VPS45:* controls vesicular trafficking	AR	N + F	Myeloid differentiation, migration	Extramedullary hematopoiesis, bone marrow fibrosis, nephromegaly
Cyclic neutropenia	Mutation in *ELANE:* misfolded protein response	AD	N	Differentiation	Oscillations of other leukocytes and platelets
X-linked neutropenia/ myelodysplasia	Mutation in *WAS:* regulator of actin cytoskeleton (loss of autoinhibition)	XL, gain-of- function	N + M	Mitosis	Monocytopenia
Leukocyte adhesion deficiency type 1 (LAD1)	Mutation in *ITGB2:* adhesion protein (CD18)	AR	N + M + L + NK	Adherence, chemotaxis, endocytosis, T/NK cytotoxicity	Delayed cord separation, skin ulcers, periodontitis, leukocytosis
Leukocyte adhesion deficiency type 2 (LAD2)	Mutation in *SLC35C1* GDP-fucose transporter	AR	N + M	Rolling, chemotaxis	Mild LAD type 1 features plus hh-blood group plus mental and growth retardation
Leukocyte adhesion deficiency type 3 (LAD3)	Mutation in *KINDLIN3:* Rap1-activation of β1–3 integrins	AR	N + M + L + NK	Adherence, chemotaxis	LAD type 1 plus bleeding tendency
Rac 2 deficiency	Mutation in *RAC2:* regulation of actin cytoskeleton	AD	N	Adherence, chemotaxis, O⁻ production	Poor wound healing, leukocytosis
X-linked chronic granulomatous disease (CGD)	Mutation in *CYBB:* electron transport protein (gp91phox)	XL	N + M	Killing (faulty O⁻ production)	Recurrent bacterial infection, susceptibility to fungal infection, inflammatory gut manifestations; McLeod phenotype in patients with deletions extending into the contiguous Kell locus
Autosomal recessive CGD – p22 phox deficiency	Mutation in *CYBA:* electron transport protein (p22phox)	AR	N + M	Killing (faulty O⁻ production)	Recurrent bacterial infection, susceptibility to fungal infection, and inflammatory gut manifestations
Autosomal recessive CGD – p47 phox deficiency	Mutation in *NCF1:* adapter protein (p47phox)	AR	N + M	Killing (faulty O⁻ production)	Recurrent bacterial infection, susceptibility to fungal infection, and inflammatory gut manifestations

TABLE 41.12	Phagocyte Disorders—cont'd				
Disease	**Genetic Defect/ Presumed Pathogenesis**	**Inheritance**	**Affected Cells**	**Affected Function**	**Associated Features**
Autosomal recessive CGD – p67 phox deficiency	Mutation in *NCF2:* activating protein (p67phox)	AR	N + M	Killing (faulty O^- production)	Recurrent bacterial infection, susceptibility to fungal infection, and inflammatory gut manifestations
Autosomal recessive CGD – p40 phox deficiency	Mutation in *NCF4:* activating protein (p40phox)	AR	N + M	Killing (faulty O^- production)	Inflammatory gut manifestations only
IL-12 and IL-23 receptor β1 chain deficiency	Mutation in *IL-12RB1:* IL-12 and IL-23 receptor β1 chain	AR	L + NK	IFN-γ secretion	Susceptibility to *Mycobacteria* and *Salmonella*
IL-12p40 deficiency	Mutation in *IL-12B:* subunit p40 of IL-12/IL-23	AR	M	IFN-γ secretion	Susceptibility to *Mycobacteria* and *Salmonella*
IFN-γ receptor 1 deficiency	Mutation in *IFNGR1:* IFN-γR ligand binding chain	AR, AD	M + L	IFN-γ binding and signaling	Susceptibility to *Mycobacteria* and *Salmonella*
IFN-γ receptor 2 deficiency	Mutation in *IFNGR2:* IFN-γR accessory chain	AR	M + L	IFN-γ signaling	Susceptibility to *Mycobacteria* and *Salmonella*
STAT1 deficiency (AD form)	Mutation in *STAT1* (loss of function)	AD	M + L	IFN-γ signaling	Susceptibility to *Mycobacteria*

AD, autosomal dominant; AR, autosomal recessive; B/T, B and T cells; IFN, interferon; IL, interleukin; L, lymphocyte; M, monocyte/macrophage; MDS, myelodysplasia syndrome; N, neutrophil; NK, natural killer cell; XL, X-linked.

antibiotics. Steroids and antibiotics are used to treat granulomatous complications of the gastrointestinal, urinary, and respiratory tracts. Definitive treatment of CGD by HSCT in properly HLA-matched patients has achieved excellent outcomes (>90% survival) even for patients at high risk for transplant-associated morbidity and mortality.

Chédiak-Higashi syndrome (CHS), an abnormality of secondary granules, is an autosomal recessive disorder caused by a mutation in the *LYST* gene, which encodes a cytoplasmic protein thought to be involved in organellar protein trafficking resulting in fusion of the primary and secondary granules in neutrophils. Despite normal ingestion of particles and normal production of superoxide, neutrophils and macrophages in patients with CHS have delayed killing of microorganisms. Large azurophilic lysosomal granules are present in all granule-bearing cells including neutrophils and melanocytes. A smear of peripheral blood can demonstrate these giant granules in neutrophils and are virtually pathognomonic of CHS when other features are present.

Recurrent infections affect the skin, respiratory tract, and mucous membranes and are caused by both gram-positive and gram-negative bacteria as well as by fungi. *S. aureus* is the most common organism. Despite normal platelet counts, patients with Chédiak-Higashi syndrome have prolonged bleeding times due to a platelet storage pool abnormality. Patients usually have partial oculocutaneous albinism. Most patients progress to an accelerated phase associated with Epstein-Barr virus infection and characterized by a lymphoproliferative syndrome with generalized lymphohistiocytic infiltrates, fever, jaundice, hepatomegaly, lymphadenopathy, and pancytopenia (see Table 41.6). Neuropathy, which can be sensory or motor, and ataxia may be present.

DISORDERS OF MACROPHAGE FUNCTION

The interferon-γ (IFNγ)/interleukin-12 (IL-12) axis is crucial to host defense against intracellular pathogens, including mycobacteria, *Listeria*, and *Salmonella* species. Dendritic cells and macrophages produce interleukin-12 in response to bacterial pathogens that in turn stimulate the secretion of IFNγ by T cells and natural killer cells. IFNγ binds to receptors on macrophages, stimulating the production of tumor necrosis factor-α and inducible nitric oxide synthetase, promoting antigen presentation, and augmenting the respiratory burst and bactericidal activities of macrophages.

The classic members of this group of disorders involve mutations in the IFNγ receptor, the IL-12 receptor, or IL-12. The IFNγ receptor contains 2 chains: IFNγ receptor 1 (IFNγ-R1), which binds ligand, and IFNγ receptor 2 (IFNγ-R2), which is necessary for ligand-induced signaling. Complete absence of IFNγ-R1 or IFNγ-R2 is inherited in an autosomal recessive manner and causes the most severe disease, manifesting early in infancy often with disseminated atypical mycobacterial infection, recurrent *Salmonella* infection, or fatal infection after bacille Calmette-Guérin vaccination. Partial IFNγ-R1 or IFNγ-R2 defects typically have milder disease, present often in early childhood, but nonetheless with increased susceptibility to nontuberculous mycobacterial disease. Patients with partial IFNγ-R1 deficiency are especially prone to osteomyelitis due to atypical mycobacteria. Mutations leading to a deficiency in the production of the p40 subunit of IL-12 or in the expression of the IL-12Rβ1 receptor are inherited in an autosomal recessive manner. These patients have an increased susceptibility to serious infection with environmental mycobacteria, BCG, and *Salmonella* sp. Unexpectedly, these patients are also susceptible to skin and, rarely, invasive infections with *Candida albicans.* Mutations in STAT1, which mediates the signal transduction following the binding of IFNγ with the IFNγ receptor, also causes susceptibility to mycobacterial infections and is inherited in an autosomal recessive pattern. In addition, these patients are susceptible to a variety of viral pathogens since STAT1 is required for signal transduction of IFN-α/β in addition to IFN-γ.

ASPLENIA

The spleen plays a particularly important role in preventing invasive infections, especially during the 1st year of life before specific immunity to certain bacteria has developed. The spleen is able to bind and phagocytose unopsonized encapsulated bacteria, and produces natural antibodies against polysaccharides, demonstrating the critical role of the spleen in preventing sepsis in immunologically immature subjects

from encapsulated bacteria. The spleen is also an important location for the phagocytosis of complement and antibody opsonized bacteria, and a key location for the production of antibodies.

Functional asplenia occurs in children with sickle cell disease, initially as a result of vascular occlusion by the sickle cells in the splenic circulation. Congenital absence of the spleen may occur alone or as part of an asplenia syndrome with congenital heart disease. Mutations in NKX2 and ribosomal protein SA have been found in a small number of patients with congenital asplenia. Trauma and surgical splenectomy are also important causes of asplenia.

Individuals without spleens (anatomic or functional) are subject to a severe form of sepsis that is rapid in onset and can lead to sudden death if it is not recognized and treated promptly. Pneumococci are responsible for more than 50% of such infections; infections with *H. influenzae*, *S. aureus*, group A streptococci, gram-negative enteric bacilli, and meningococci also occur (see Table 41.1).

The diagnosis of anatomic or functional asplenia is suggested by the presence of red blood cell inclusions, particularly Howell-Jolly bodies on peripheral blood smear. Failure of uptake of technetium 99–sulfur colloid, which is normally taken up by the entire reticuloendothelial system or the lack of erythrocyte pitting are also noted in asplenic patients. Lack of a spleen by ultrasonography of the abdomen is suggestive of asplenia, but accessory splenic tissue may still be present. Functional tests of splenic tissue are a better indicator of asplenia.

The risk of fulminant infection in patients who have undergone splenectomy (from surgery or trauma), or in those with functional asplenia or congenital asplenia is highest in the 1st few years. The risk is lower in older children and in adults, probably because they have developed opsonizing antibodies through previous exposure. The management of functional or anatomic asplenia lies mainly in prevention. When splenectomy becomes necessary, partial protection against life-threatening infections can be obtained by immunizing patients with conjugated and polyvalent pneumococcal, *H. influenzae* type b, and meningococcal vaccines. Booster immunization may be needed because of waning immunity with time. Prophylactic antibiotics may be given continuously in a single daily dose for 1-3 years or up to the age of 16 years (some authorities suggest longer periods or even for life) after splenectomy. Parents of older asplenic children are advised to have their children seen by a physician or to administer the antibiotics at the 1st sign of a febrile illness.

AUTOINFLAMMATORY DISORDERS

Autoinflammatory disorders are genetic defects in the immune system with predominant inflammatory complications in the absence of significant infectious complications. Autoinflammatory disorders present with spontaneous, episodic, or persistent inflammation, but without the development of autoantibodies or autoreactive lymphocytes. Autoinflammatory disorders were formerly known as periodic fever syndromes, but this term has fallen out of favor since fever is a frequent but not universal finding.

Familial Mediterranean Fever

Familial Mediterranean fever (FMF) is caused by mutations in the *MEFV* gene that encodes the protein pyrin and was the 1st autoinflammatory disorder in which a genetic defect was elucidated. Although FMF is considered a recessive disorder, a substantial percentage of patients with clinical FMF have only 1 demonstrable mutation in *MEFV*. FMF is characterized by short episodes of fever (i.e., 1-3 days), serositis/peritonitis, prominent arthritis, and erythematous rash. Early in life fever may be the only symptom. However, more classic features

typically appear within 3 years. The arthritis is typically monoarticular, and aspirates of affected joints are sterile with a predominance of neutrophils. In some cases, splenomegaly and even systemic vasculitis can ensue. The most serious long-term comorbidity with FMF is amyloidosis, which occurs frequently in patients who are not compliant with colchicine prophylaxis. Pyrin interacts with the inflammasome, a macromolecular complex involved in the processing of IL-1β, and mutations that result in FMF result in greater IL-1 production. Daily colchicine prophylaxis prevents many of the long-term complications of this disorder.

Pyogenic Arthritis, Pyoderma Gangrenosum, and Acne Syndrome

Pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA) is an autosomal dominant inherited syndrome caused by mutations in *PSTPIP1* (see Table 41.5), which leads to hyperphosphorylation of PSTPIP1, increased interaction with pyrin, leading to increased IL-1β production. PAPA begins in childhood with episodes of sterile mono-articular arthritis, and later in life pyoderma gangrenosum-like ulcerative skin lesions and cystic acne. The episodes of arthritis are the most common presentation, start in early childhood, and typically affect 1-3 joints at a time. The joint effusions are typically neutrophil-rich and sterile. Treatment of the arthritis with surgical drainage, or treatment with intraarticular or systemic steroids has shown benefit in resolving arthritis. Several reports demonstrated successful treatment with an IL-1 receptor antagonist (anakinra) or tumor necrosis factor (TNF)-α inhibitors (etanercept and infliximab).

Cryopyrin-Associated Periodic Syndromes

Cryopyrin-associated periodic syndromes (CAPS) are a spectrum of autoinflammatory disorders that are inherited in an autosomal dominant manner due to mutations in the *NLRP3* gene (see Table 41.5). *NLRP3* encodes cryopyrin, a protein that is part of the inflammasome. Mutations that cause CAPS prevent autoinhibition of the cryopyrin protein, resulting in spontaneous activation of the inflammasome and excessive production of IL-1β.

CAPS consists of 3 diseases: familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disorder (NOMID), which represent a spectrum of disorders that present with recurrent or continual systemic inflammation, rash, fevers, arthritis, neurologic deficits, and amyloidosis. FCAS is the mildest form of this disorder that presents with fevers, an evanescent rash, headache, conjunctivitis, and joint pain after generalized cold exposure. Although the rash can have some visual features of urticaria, it lacks angioedema or signs of mast cell degranulation, and is histologically characterized by a neutrophilic infiltrate. MWS presents similar to FCAS but cold exposure is not necessary for symptoms to occur. Unlike FCAS, chronic meningitis occurs with papilledema and sensorineural hearing loss, joint pain and swelling is more severe, and untreated, amyloidosis develops over time. NOMID is the most severe variant of CAPS. Like MWS, all patients with NOMID exhibit a rash at or shortly after birth. Neurologic symptoms, such as aseptic meningitis, headache, cerebral atrophy, uveitis, hearing loss, and intellectual disability, are common and severe. In NOMID and MWS, chronic inflammation of the joints leads to a chronic arthropathy with epiphyseal and patellar overgrowth. FCAS, MWS, and NOMID exhibit laboratory evidence of acute-phase response with leukocytosis, neutrophilia, anemia, thrombocytosis, and elevated erythrocyte sedimentation rate and CRP levels.

Historically, a variety of immunosuppressive treatments, including corticosteroids and colchicine, have been used to treat CAPS. IL-1 inhibitors (anakinra, rilonacept, canakinumab) are now the treatment

of choice for these disorders based on their ability to induce rapid and sustained clinical response. Laboratory abnormalities typically normalize in days, and the rash responds rapidly. Importantly, IL-1 blockade improves long-term morbidity such as hearing loss, joint deformity, and amyloidosis.

Hyperimmunoglobulin D Syndrome

Hyperimmunoglobulin D syndrome (HIDS) is an autoinflammatory disorder caused by mutations in the mevalonate kinase *(MVK)* gene (see Table 41.5). MVK is an enzyme involved in the biosynthesis of cholesterol and isoprenoids. Patients with HIDS have low but detectable MVK enzyme activity resulting in elevated levels of mevalonic acid in the urine during attacks. Complete absence of MVK results in mevalonic aciduria, an inborn error of metabolism, which is also associated with fevers. It is unclear how mutations in MVK lead to an autoinflammatory disease.

The clinical manifestations of HIDS occur at an early age with recurrent fevers with lymphadenopathy, abdominal pain, arthralgia and arthritis, and painful migratory erythematous macules. These episodes may last 4-7 days and are often triggered by stress, trauma, or vaccination. Serum IgD and IgA levels are usually elevated but may be normal. Acute-phase reactants are elevated during attacks. Although high-dose corticosteroids and TNF-α antagonists have been used with variable success, IL-1β inhibitors appear more effective at preventing the inflammatory episodes. Amyloidosis may occur but is relatively rare.

Deficiency of the Interleukin-1 Receptor Antagonist

Deficiency of the IL-1 receptor antagonist (DIRA) is an autosomal recessive disorder due to mutations in the IL-1 receptor antagonist gene *(IL-1RN)* (see Table 41.5). IL-1 receptor antagonist (IL-1RA) is a decoy protein that binds to the IL-1 receptor but does not result in signaling, and the absence of IL-1RA in patients with DIRA leads to cellular hyperresponsiveness to IL-1β.

The clinical manifestations of DIRA occur within the 1st 2 weeks of life and include pustular rash, osteopenia, lytic bone lesions, and prominent systemic inflammation. All patients develop cutaneous pustulosis, and biopsies of the skin lesions revealed a neutrophilic predominance. Respiratory distress, aphthous ulcers, hepatomegaly, and failure to thrive occurred, with approximately one-third of infants expiring prior to effective treatment. Bone is prominently involved, with osteopenia, multiple osteolytic lesions, and rib widening. Laboratory abnormalities reflect an acute-phase response with elevated ESR and CRP, leukocytosis, anemia, and thrombocytosis.

Anakinra, a recombinant IL-1RA, is highly effective in the treatment of DIRA. Anakinra essentially replaces the IL-1RA that patients with DIRA cannot synthesize. Longer-acting anti-IL1 agents, canakinumab and rilonacept, also work with the advantage of less frequent dosing compared to anakinra but are considerably more expensive.

TNF Receptor–Associated Periodic Syndrome (TRAPS)

TNF receptor–associated periodic syndrome (TRAPS) is an autosomal dominant disease associated with missense mutations in the extracellular domain of the TNF receptor 1 gene *(TNFRSF1A)* (see Table 41.5). The clinical manifestations of TRAPS patients include recurrent and often prolonged fevers, abdominal pain, and arthralgias. A migratory rash with underlying fascial inflammation and myalgia can be seen, as well as conjunctivitis and periorbital edema. Increased serum levels of CRP, ESR, leukocytosis, and thrombocytosis are evident during and in between attacks. Initial insights into the pathophysiology of this disorder came when patients with TRAPS exhibited low serum levels of soluble TNFR1, suggesting that shedding of TNF receptors acts as a natural antagonist to TNF-α. In support of this, the TNF-α antagonist etanercept has been shown to reduce the severity of symptoms in some cases of TRAPS. However, not all patients with TRAPS have low serum TNFR1 levels, and TNF-α inhibition is not completely effective. Reports have also shown the beneficial effects of IL-1 inhibition and the anti–IL-6 receptor antibody tocilizumab.

Deficiency of Adenosine Deaminase 2

Deficiency of adenosine deaminase 2 (DADA2) is an autosomal recessive disorder due to null mutations in *CECR1*, which encodes adenosine deaminase 2 (ADA2) (see Table 41.5). The clinical manifestations of DADA2 begin in childhood with intermittent fevers, recurrent lacunar strokes, organomegaly, hypogammaglobulinemia, and systemic vasculitides. The lacunar strokes begin before the age of 5 years and typically occur during inflammatory episodes. A livedo-like rash is a prominent feature with biopsies showing a predominance of neutrophils and macrophages as well as vasculitis in medium-sized vessels. Some of these patients are diagnosed with early-onset polyarteritis nodosa. Treatment with glucocorticoids, TNF-α inhibitors, and IL-1 blockers has been utilized with some benefit.

Blau Syndrome

Blau syndrome is an autosomal dominant disease caused by mutation in *NOD2* (see table 41.5) that result in spontaneous activation of the NOD2 protein, activation of NF-κB, and production of proinflammatory cytokines. Blau syndrome was originally described as a granulomatous disease affecting the skin, joints, and uveal tract, and should be considered in any individual presenting with early-onset sarcoidosis. Blau syndrome presents with a boggy synovitis of large joints, particularly the wrist and ankles, and an erythematous papular rash similar to erythema nodosum. Biopsy of these lesions demonstrates noncaseating granulomas. Unlike sarcoidosis, respiratory involvement and hilar adenopathy are rare, although granulomatous liver disease, cranial neuropathies, and large vessel vasculitis can occur. Laboratory studies in Blau syndrome are typically normal, although elevated ESR and angiotensin-converting enzyme levels can be seen, and hypergammaglobulinemia can occur. Most patients with Blau syndrome have been treated with corticosteroids, although limited reports have shown effectiveness of infliximab, thalidomide, and possibly anakinra.

Majeed Syndrome

Majeed syndrome is an autosomal recessive disorder caused by mutations in the *LPIN2* gene (see Table 41.5). The clinical manifestations of Majeed syndrome begin in childhood with recurrent fevers, sterile osteomyelitis, congenital dyserythropoietic anemia (CDA), neutrophilic dermatosis, failure to thrive, and hepatomegaly. Treatment of Majeed syndrome has included nonsteroidal antiinflammatory drugs, corticosteroids, and IL-1 receptor antagonists. How mutations in the *LPIN2* gene lead to an autoinflammatory disorder is not known.

IMMUNE DYSREGULATION SYNDROMES

Immune dysregulation disorders are genetic defects in the regulation of the adaptive immune system (T and B cells) resulting in early-onset inflammatory bowel disease, eczema, autoimmune cytopenias, and other autoimmune or inflammatory complications. Abnormalities of immune regulation are frequently important components of the clinical manifestations in patients with primary immune deficiencies, which have been described previously in this chapter. Unlike autoinflammatory disorders, these disorders are not episodic and are associated with autoimmune manifestations. Additionally, the clinical phenotype includes varying degrees of susceptibility to infection.

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is caused by mutations in the gene encoding perforin or genes encoding other proteins involved in the cytotoxic function of NK cells and CD8 cells, such as Munc13-4, syntaxin11, and syntaxin11 binding protein (see Table 41.6). HLH is a life-threatening disorder of infants and is characterized by high fever, rash, hyperferritinemia, coagulopathy, and hematologic cytopenias. HLH is typically triggered in response to viral infections, in particular EBV and CMV. The various molecular defects that underlie HLH all result in ineffective clearance of viral infections by NK cells and CD8 T cells, resulting in prolonged antigen exposure and protracted activation of CD8 T cells and NK cells. CD8 T cells and NK cells produce large amounts of IFNγ that activate macrophages, resulting in phagocytosis of bone marrow elements and end-organ damage. This disorder is fatal if not treated aggressively with combined immunosuppressive medications and chemotherapy. HSCT is the only curative treatment.

X-Linked Lymphoproliferative Disease Type 1 and Type 2

X-linked lymphoproliferative disease type 1 (XLP-1) is caused by a mutation in the gene called *SH2D1A*, which encodes for an adapter protein involved in signal transduction of T cells and NK cells. XLP-2 is a similar disorder caused by mutations in *XIAP*. XLP-1 is characterized by fulminant infection with Epstein-Barr virus (EBV) with immunodysregulation and/or lymphoma. Boys with this disease may be relatively normal until infected with EBV, which is acutely fatal in 80% of patients and due to the development of HLH. Boys who survive the initial EBV infection develop hypogammaglobulinemia and are at high risk for developing aplastic anemia and B cell lymphomas. XLP-2 presents similarly with HLH following EBV infection, but can also present with early onset colitis. Definitive therapy of both forms of XLP is HSCT.

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked and Related Disorders

The maintenance of peripheral tolerance is critically dependent on T regulatory cells, CD4-positive T cells that prevent autoimmunity and excessive immune responses. These cells are generated in the thymus to self-antigens, express the transcription factor Foxp3, and constitutively express high levels of the IL-2 receptor (CD25). T regulatory cells express numerous immunosuppressive molecules including CTLA4, which inhibits T cell activation, and IL-10 and TGF-β.

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) is caused by mutations in the *FOXP3* gene, an X-linked transcription factor essential for the production and function of T regulatory cells (see Table 41.6). In males with a null mutation in FOXP3, the clinical manifestations begin at birth or soon thereafter, and consist of inflammatory gastrointestinal tract disease, failure to thrive, autoimmune diabetes mellitus, thyroiditis, Addison disease, severe food allergies, eczema, and autoimmune cytopenias. Hypomorphic mutations in Foxp3 that encode a protein with residual functional activity lead to a later onset and milder clinical phenotoype, but allergic disease and failure to thrive are common. Patients with this disorder are aggressively immunosuppressed to be stabilized, but bone marrow transplantation is the only curative therapy.

CD25 Deficiency

CD25 (α chain of the high-affinity IL-2 receptor) deficiency is an autosomal recessive disorder due to mutations in the *IL2RA* gene (see Table 41.6). T regulatory cells constitutively express CD25 and respond to IL-2 generated by T cells during an immune response for their immunoregulatory functions. CD25 deficiency results in a syndrome similar to IPEX with severe enteropathy, diabetes mellitus, autoimmune hemolytic anemia, eczema, and lymphoproliferation. Importantly, patients with CD25 deficiency exhibit several unique features not seen in IPEX, namely chronic herpetic viral infections and an increased susceptibility to infections.

Signal Transducer and Activator of Transcription Protein 5B Deficiency

Signal transducer and activator of transcription protein 5b (STAT5b) deficiency is an autosomal recessive disorder due to mutations in the STAT5b gene, 1 of 2 STAT5 proteins involved in IL-2 signaling (see Table 41.6). Similar to CD25 deficiency, STAT5b deficiency results in T regulatory cell dysfunction leading to a syndrome of immune deficiency with autoimmunity. These infants also suffer from autoimmune diseases such as autoimmune thrombocytopenia and hemolytic anemia, eczema, and arthritis. Unlike IPEX or CD25 deficiency, growth failure occurs in STAT5b since this signaling protein is required for growth hormone signaling. Additionally, patients with STAT5b deficiency also develop pulmonary disease that pathologically resembles interstitial lymphocytic pneumonia, although whether this represents an autoimmune phenomenon or a response to infectious episodes is unclear.

Cytotoxic T Lymphocyte Antigen 4 Deficiency

Cytotoxic T lymphocyte antigen 4 (CTLA4) deficiency is an autosomal dominant inherited disorder due to mutations of the gene encoding for the CTLA4 protein (see Table 41.6). Null mutations or point mutations that encode a nonfunctional protein can result in haploinsufficiency. Not all patients who have damaging mutations in CTLA4 develop any clinical phenotype (i.e., reduced penetrance) and the onset of the disease and clinical manifestations are variable as well (variable expressivity). The clinical manifestations of CTLA4 deficiency may occur in early childhood or adulthood. The most common clinical manifestations include enteropathy; granulomatous and lymphocytic lung infiltration; lymphocytic infiltration of the bone marrow, brain, kidney, or liver; respiratory tract infections; splenomegaly; lymphadenopathy; and immune cytopenias. Patients frequently have hypogammaglobulinemia, which explains their propensity to infection. Autoimmune thyroiditis and psoriasis also occur. Treatment of CTLA4 deficiency includes the use of replacement immunoglobulin therapy for patients with hypogammaglobulinemia and recombinant CTLA4 for the autoimmune manifestations.

A phenotypically similar disorder is caused by mutations in the LPS-responsive vesicle trafficking, beach and anchor containing *(LRBA)* gene, which regulates the expression of CTLA4 on the surface of T cells. CTLA4 is essential for the function of T regulatory cells, which explains the common autoimmune and autoinflammatory features of both LRBA deficiency and CTLA4 deficiency.

Autoimmune Polyendocrinopathy-Candidiasis–Ectodermal Dystrophy

Autoimmune polyendocrinopathy-candidiasis–ectodermal dystrophy (APECED) is an autosomal recessive disorder caused by mutations in the gene encoding the autoimmune regulator *(AIRE)* gene (see Table 41.6). AIRE is a transcription factor that is essential for expression of peripheral tissue antigens in the thymus, allowing for deletion of self-reactive T cells in the thymus (i.e., negative selection) and for the production of T regulatory cells with the correct antigen specificity. The clinical manifestation of APECED includes chronic or recurrent *Candida* infections of the mucous membranes, skin, and nails;

autoimmune hypoparathyroidism; and Addison disease. Other autoimmune disorders, such as vitiligo, thyroiditis, and pernicious anemia may occur. The insidious and variable onset of the endocrinopathies requires the need for frequent evaluation for autoimmune endocrine disorders. The propensity to develop fungal infections is explained by autoantibodies to certain immune cytokines, such as IL-17, that are critical to the defense of fungal infections.

Autoimmune Lymphoproliferation Syndrome

Autoimmune lymphoproliferation syndrome (ALPS) is a group of disorders most commonly caused by mutations in the *FAS* gene or less commonly the FAS ligand *(FASL)* gene (see Table 41.6). Other genetic causes of ALPS have been described. FAS is a protein that is involved in the normal apoptotic pathway of lymphocytes, and defective apoptosis due to defects in FAS or FASL underlies the autoimmune manifestations of this disorder. The clinical manifestations of ALPS include lymphoproliferation (i.e., splenomegaly and lymphadenopathy) and autoimmune manifestations, particularly autoimmune thrombocytopenia and autoimmune hemolytic anemia, and an increased susceptibility to lymphoma. Autoimmune manifestations are usually responsive to immunosuppressive medication.

■ SUMMARY AND RED FLAGS

Recurrent *benign* infections are common, especially in large families or in day care settings, in which children may manifest 6-10 upper respiratory tract infections or gastroenteritis episodes a year. These infections usually last less than 1 week. The child continues to grow and develop normally, and his or her activities are not restricted. Screening tests to evaluate immune function are typically normal. Red flags to consider disorders of the immune system include absent lymphoid tissue, failure to thrive, digital clubbing, chronic diarrhea, prolonged infections, infections with unusual organisms, repeated serious infections, eczematous dermatitis, a family history of early childhood deaths (presumably from infection), and other diseases associated with increased risks for infection (sickle cell anemia, malignancy, asplenia). In these cases, immunologic workup, genetic testing, and consultation with a clinical immunologist can lead to a diagnosis and definitive treatment.

Disorders of Puberty

Peter M. Wolfgram

Puberty is defined by both biologic and social standards. Puberty is the time when there is an increase in sex steroid production, resulting in physical changes such as breast development in girls and testicular enlargement in boys, as well as maturation of processes required for future fertility. Puberty, also known as adolescence, is the time when children make the transition to adult patterns of behavior, which involve maturity, responsibility, and sexuality.

NORMAL PUBERTAL DEVELOPMENT

Terminology
Various terms are used to discuss puberty (Table 42.1). **Bone age** refers to the degree of epiphyseal calcification, width, and proximity to adjacent metaphyses and is a marker of physical maturity that normally corresponds to chronologic age. **Dental age** generally correlates with bone age. Bone age is usually determined from a radiograph of the left hand and wrist, with comparison to gender-appropriate standards in Greulich and Pyle's bone age atlas. In infants and toddlers, a more accurate assessment of bone age can be determined from a radiograph of the hemiskeleton, with primary attention to epiphyses of the long bones. Delayed or advanced bone age occurs in many conditions; bone age is strongly influenced by sex steroid production. The timing of the onset of puberty is usually more closely linked to the bone age than to the chronologic age when the 2 are significantly discordant. Regardless of chronologic age, linear growth ceases when the bone age reaches 15 years in females and 18 years in males.

Anatomy
Puberty is controlled by the production of gonadotropin-releasing hormone (GnRH) in the anterior hypothalamus. GnRH-containing cell bodies project axons to the median eminence, where they terminate on the hypothalamic portal vessels. This system is referred to as the **GnRH pulse generator**. After GnRH reaches the anterior pituitary gland via the portal vasculature, it stimulates the production of both follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by the gonadotroph cells. In females, both FSH and LH are required for estrogen production by ovarian granulosa cells. The regulated secretion of FSH and LH is also required for follicle growth, ovulation, and maintenance of the corpus luteum. In males, FSH regulates spermatogenesis by Sertoli cells within the seminiferous tubules, and LH activates Leydig cells to produce testosterone. Androgens cause development of male internal and external reproductive organs and secondary

sexual characteristics in both sexes by binding to receptor proteins in the cells of target tissues. Sex steroids also exert a negative feedback effect on the pituitary gland and hypothalamus.

Physiology
Perinatal Period and Infancy
Maternal estrogens stimulate breast development in both male and female fetuses. Maternal estrogens also stimulate uterine developmental and endometrial growth; at birth, withdrawal of the high levels of maternal estrogen and placental progesterone causes the infant endometrium to regress or even slough and manifests as vaginal bleeding.

At birth, levels of LH and FSH in both sexes rise markedly and remain elevated for several months. In the girl, FSH stimulates ovarian granulosa cells to produce 17β-estradiol sufficient to maintain prenatal breast development for up to 8 months of life. Estrogen-induced vaginal cornification is generally evident as abundant vaginal discharge at birth and is maintained as long as estrogens are produced. Ovarian size from birth to 3 months ranges from 0.7-3.6 cm³, decreasing to 2.7 cm³ by 12 months and to 1.7 cm³ by 24 months; this size persists until the onset of puberty. Ultrasound studies of the ovaries in normal infants show many microcysts.

Male breast development regresses rather quickly after birth. Elevated LH levels after birth stimulate Leydig cell production of testosterone for 6-12 months, leading to further genital development. Penis length increases from 3-5 cm in the full-term newborn to 4.5-6 cm by 2-3 years.

Childhood
By 2 years of age, serum gonadotropin levels decrease, and thus serum sex steroid levels also decrease, frequently to levels undetectable by conventional assays.

Beginning approximately at ages 6-7 years in females and 7-8 years in males, adrenal androgen production begins to increase and can be detected by the presence of increasing concentrations of the weak adrenal androgen dehydroepiandrosterone (DHEA) and its sulfated derivative, DHEA sulfate (DHEAS). Despite these serum levels, there is initially no secondary sexual (pubic or axillary) hair development.

Adolescence
Beginning on average at about 10.5 years in females and 11.5 years in males, there is the return of activity of the hypothalamic GnRH pulse

(See *Nelson Textbook of Pediatrics,* p. 2655.)

TABLE 42.1
Puberty Terminology
Gonadarche: maturation of the gonads under the control of the hypothalamus (GnRH) and pituitary gland (FSH and LH)
Thelarche: presence of breast development in girls
Gynecomastia: presence of breast development in boys
Adrenarche or development of androgen-regulated pubarche: secondary sexual characteristics, including pubic hair, axillary hair, apocrine (underarm) odor, and acne, in both sexes
Menarche: time of the first menstrual period
Spermarche: time when a boy is first able to produce sperm

TABLE 42.2	**Estrogen Effects**

generator, leading to increased serum levels of FSH and LH. The trigger mechanism for this resurgence is unknown, but it may be linked to attainment of a critical body mass or fat mass. Leptin, a hormone produced by fat cells, may be the connection between weight (fat mass) and pubertal events. In early puberty, the activity of the hypothalamic GnRH pulse generator is mostly evident overnight (sleep-entrained), with pulses increasing in number and amplitude and eventually occurring every 60-90 minutes. Over time, this process begins to occur during the daytime; there is always greater gonadotropin secretion at night. Because of the longer half-life of sex steroids, serum levels of estradiol and testosterone show little, if any, diurnal variation. Testosterone levels may be slightly higher in the morning with advancing puberty. There is central sensitivity to the negative feedback effects of sex steroids, leading to significant elevations of gonadotropins when sex steroid production is impaired. The function of the hypothalamic GnRH pulse generator can be accelerated in the setting of obesity, and LH and FSH secretion can revert to the prepubertal pattern in the setting of significant weight loss, as occurs in females with anorexia nervosa.

Usually within 6 months of the onset of this heightened GnRH pulse generator activity in females, there is also increasing production of androgens by the adrenal glands, the major source of androgens in females. In males, the testes are the main source of androgens, although male adrenarche also begins about 6 months after gonadarche.

Sex Steroid Effects

In response to FSH, both testes and ovaries enlarge, starting gonadarche. Ovarian granulosa cells produce 17β-estradiol, which causes estrogen effects that generally occur in a fixed order (Table 42.2). Growth increase is one of the early effects of estrogen. Growth is stimulated by estrogen-stimulated increased production of growth hormone and insulin-like growth factor 1. Estrogens along with growth hormone and thyroid hormones increase bone mineralization and growth.

In response to LH, testicular Leydig cells produce testosterone, which is converted to dihydrotestosterone, leading to androgen effects that generally occur in the same order (Table 42.3).

Note that growth is not stimulated early in puberty by rising testosterone; in fact, during the phase when testosterone levels are beginning to rise, growth is usually slowed perceptibly from a prepubertal height velocity of perhaps 5 cm/yr to a velocity as slow as 4 cm/yr for 12-18 months. As levels of testosterone increase closer to 400 ng/dL and testis volume increases to between 10 and 12 cm^3, males make the transition to rapid growth. Rapid growth for males thus occurs for about 2 years in middle puberty, and slower growth continues for 2-3 more years.

Benign adolescent gynecomastia occurs in as many as 40-60% of normal males; enough estrogen relative to the amount of testosterone is produced so that breast development occurs. Gynecomastia usually starts in early to middle puberty (peak age, 13 years), before adult male

concentrations of testosterone are achieved. It typically starts on one side and resolves within 2 years. Gynecomastia is more common in obese males, although true breast tissue in this setting is often difficult to distinguish from fat tissue (lipomastia).

Chronology of Puberty

Females

Females begin puberty at an average age of 10.5 years (range, 8-13 years; mean ± 2.5 standard deviations [SD]). There are data suggesting that female puberty begins at an earlier age and that African-American females begin puberty about 1 year earlier than white females, but this is not universally accepted. In 85% of females, the first clinically detectable sign of puberty is breast development (thelarche), although ovarian enlargement, which is not clinically detectable in a strict sense, occurs first. Breast buds appear as small nodules either directly underneath the nipples or slightly off center, causing the areolae and nipples to be pushed out and sometimes cause minor, transient discomfort as the skin around the nipple is stretched. Breast development may be unilateral and asymmetric in its earliest stages. Pubic hair usually begins to develop within the next 6 months; in approximately 15% of females, pubic hair precedes breast development. Such discordance has no clinical significance. The female adolescent growth spurt commences near the onset of thelarche, generally spanning a 2-year period between the ages of 11 and 13 years. Axillary hair generally begins, on average, between 12 and 13 years. Menarche, a rather late event in female puberty, occurs on average between 12.2 and 12.8 years, typically 2-2.5 years following thelarche. Menarche is often preceded by a whitish, non–foul-smelling vaginal discharge (physiologic leukorrhea) for up to 6 months. At the time of menarche, an adolescent female has reached 96.5% of her adult height potential. However, more linear growth may remain in clinical situations in which menarche occurs at a younger bone age than is typical for the average adolescent female. Menstrual cycles for the 1st 2 years after menarche are often anovulatory and irregular in frequency.

Males

Males begin puberty at an average age of 11.5 years (range, 9-14 years; mean ± 2.5 SD). The 1st clinically detectable sign of puberty is

(See *Nelson Textbook of Pediatrics,* p. 2735.)

testicular enlargement, a fact generally unknown to patients and their parents. From birth to the start of puberty, male testicular volumes range between 1 and 2 mL as determined by the use of an orchidometer (a series of ellipsoid models of varying volumes). Stretched penile length (measured with a rigid tape measure on the dorsum of the penis from the pubic symphysis to the tip of the nonerect penis without considering any foreskin tissue) averages about 3.5 cm (range, 2.8-4.2 cm) at birth and grows by an average of 2.5 cm until the start of puberty. The onset of male puberty is considered to have begun when at least 1 of the 2 testicles reaches 4 mL in volume. It takes approximately 5-6 years for the testicles to reach the average adult volume of 18 mL. Approximately 75-80% of the adult testicle consists of seminiferous tubules; testosterone-producing Leydig cells make up the remainder.

Within 6 months after the start of testicular enlargement, pubic hair can be found; pubic hair precedes testicular enlargement in approximately 15%. The presence of pubic hair is incorrectly considered the 1st evidence of puberty in boys by both patients and parents. Pubic hair is followed by the development of axillary hair at approximately 14 years of age. During this time, penile enlargement also occurs, reaching a mean adult length of 12.4 ± 1.6 cm at 20 years of age. The male adolescent growth spurt typically occurs between the ages of 13 and 15 years, commencing when the testicular volumes reach 12 mL. By age 15 years, a male has attained 98% of his final adult height. The ability of adolescent boys to produce sperm, as evidenced by detection of spermatozoa in urine samples, begins between 13.5 and 15 years.

Clinical Staging of Puberty

Standardized staging of pubertal development in both sexes allows for comparison between children, as well as longitudinal monitoring of individual children.

Breast development in females, genitalia in males, and pubic hair in both sexes are scored according to 5-stage systems originally devised by James M. Tanner and referred to as Tanner stages 1-5. Axillary hair in both sexes is rated by a 3-stage system referred to as stages 1-3. Puberty itself is not staged because different components of puberty may occur at different stages.

Females

For breast development, Tanner stage 1 refers to no breast development; Tanner stage 2, to the presence of just breast buds (1 or 2); Tanner stage 3, to the beginning of formation of the peripheral mound with elevation of the breast; Tanner stage 4, to a further increase in breast size, with the formation of the so-called "double contour," in which the areola and papilla are both raised off the surface of the whole breast; and Tanner stage 5, to adult size, with a return to the single contour in which the surface of the areola is again flush with that of the breast. It may be difficult to differentiate between Tanner stages 3 and 5 because the only difference between these 2 stages is breast size (determined mostly by fat content). Thus, small breasts, especially in an older adolescent female, should not necessarily be construed as Tanner stage 3, especially if she has already menstruated, which typically occurs when the breasts have reached Tanner stage 4 and/or if women in the family typically have small breasts.

Males

For external genitalia, Tanner stage 1 refers to the prepubertal state (testes < 4 mL in volume); Tanner stage 2, to slight enlargement of the testes and scrotum; Tanner stage 3, to lengthening of the penis and further enlargement of the testes and scrotum; Tanner stage 4, to continued penile growth in both length and width with development of the glans; and Tanner stage 5, to adult appearance. An alternative,

simplified, and equally accurate approach involves only sizing of the testicles, whereby 4 mL represents the start of puberty, 12 mL correlates with the start of the growth spurt, and 18 mL is the average adult size. In some cases, the appearance of pubic hair does not occur until the testicular volumes reach 12-15 mL. Testicular volumes may differ at all stages between sides but not usually by more than one size on a standard orchidometer. It is important not to confuse a hydrocele with an enlarged testis.

Females and Males

Tanner staging of pubic hair is similar in both sexes. Tanner stage 1 is defined by having no pubic hair. Tanner stage 2 is characterized by the presence of a few, countable strands of curly, coarse, pigmented hair either in the mons area or perilabially along the midline in females or at the base of the penis and/or on the scrotum in males. Lighter, peach fuzz–like hair (lanugo) in the pubic region is not pubic hair. On occasion, especially in individuals from ethnic populations from Mediterranean countries or Northern India, there may be an extension of coarse body hair (hypertrichosis) to the pubic region that can be difficult to discern from pubic hair. Tanner stage 3 refers to the presence of coarser, darker, and curlier hairs, the number of which is no longer countable, which have spread more laterally. Tanner stage 4 refers to a thick, fully triangular pattern of hair growth, without spread to the thighs. Finally, Tanner stage 5 refers to the adult pattern in which there is spread of hair to the medial thighs. The designation Tanner stage 6 is used to describe hair growing up the linea alba, referring to the so-called male escutcheon.

Axillary hair is the simplest component of puberty to quantify. Stage 1 refers to the absence of any hair. Stage 2 refers to a countable number of curly, coarse, pigmented strands in at least 1 armpit. Stage 3 refers to the adult complement, which is merely more hair than is present in stage 2. For the individual with shaved axillae, it is safe to assume either stage 2 or stage 3 hair is present.

Family Patterns

The timing of puberty is affected by familial patterns; both parents' histories are important in assessing the child with early or late puberty. The following information is useful for establishing the parental effect:
- Age of their mother's menarche
- Age their father began shaving on a daily basis
- Age when their parents stopped growing

PRECOCIOUS PUBERTY

Definition

The onset of puberty, at least in females, may be occurring earlier than in the past; therefore, the definition of precocious puberty has been modified to refer to the appearance of any feature of puberty before 7 years of age in African-American females (and perhaps even before 6 years), before 8 years of age in white females (and perhaps even before 7 years), and before 9 years of age in males (regardless of race). If this conservative definition is applied, it remains important to consider pathologic causes in children who present with signs of puberty in the age range between the new and former definitions. The family pattern must also be considered; an early onset of puberty is frequently familial.

Normal Variants
Idiopathic Isolated Premature Thelarche

This common condition is the development of breast tissue in females before 8 years of age in white children and 7 years of age in African-American children, with no other manifestations of puberty

(See *Nelson Textbook of Pediatrics,* p. 2657.)

(Fig. 42.1). Elevated serum estrogen levels for age have been difficult to demonstrate, although higher levels than in age-matched normal females have been measured by an ultrasensitive estradiol assay. Development of breast tissue commonly begins between 2 and 3 years of age; it may be present from birth. The observed tissue may be asymmetric, unilateral, or bilateral. When asymmetric or unilateral, parents are typically concerned about the possibility of malignancy, an extremely rare occurrence in childhood. The early breast tissue frequently regresses without intervention, but it may persist. If it persists, the degree of development does not usually exceed Tanner stage 3. The bone age, if determined, is not frequently advanced, and there is no associated growth spurt. If these simple clinical criteria are met, no hormonal studies or additional radiologic procedures are necessary.

Physiologic breast enlargement also occurs in neonates from placental transfer of estrogens. Most marked in the 1st weeks of life, it usually regresses by 1-2 months.

Idiopathic Isolated Precocious Adrenarche

This common, normal variant is characterized by the development of pubic hair, axillary hair and odor, and/or a small amount of acne in white females before the age of 8 years, in African-American females before the age of 7 years, and in males before the age of 9 years. It appears to result from early production of adrenal androgens. Precocious adrenarche occurs much more commonly in females than in males and develops most often in obese and/or African-American females and in brain-injured children. There is no associated evidence of virilization (no growth spurt, no significant advancement of bone age, no increase in muscle bulk, no voice deepening, and no temporal hair recession). In females, there is no associated clitoromegaly and no evidence of estrogen-mediated components of puberty; in males, there is no phallic or testicular enlargement. If a child presents at a very young age, it is generally presumed that an organic cause (such as congenital adrenal hyperplasia) will be found. However, in infant males with isolated scrotal hair, typically no cause is found, and the hair subsequently falls out. In most cases of idiopathic precocious

adrenarche (benign premature adrenarche), serum levels of DHEA and/or DHEAS are consistent with the reference range of Tanner staging of the hair growth, and the 8:00 A.M. 17-hydroxyprogesterone level is normal. If these criteria are met, no additional laboratory studies are indicated. This pubertal variant was considered benign and self-limited, but data suggest that at least in females with associated low birth weight, it may suggest an increased risk for **polycystic ovary disease**.

Isosexual Central Precocious Puberty

Central sexual precocity results from activation of the hypothalamic-pituitary-gonadal axis at an earlier-than-normal age (Fig. 42.2). Isosexual development refers to pubertal changes appropriate for the sex of the child, such as breast budding in females and testicular enlargement in males. This is to be distinguished from contrasexual development, in which the pubertal features in females are mediated by male hormones (clitoromegaly) and those in males are mediated by female hormones (breast development).

Causes of isosexual precocious puberty are listed in Tables 42.4 and 42.5. The majority of cases in females, who are at least 10-fold more likely to be affected than males, are idiopathic, whereas only a small percentage of affected males have no definable cause. Ovarian size, as seen on a sonogram, is generally a reflection of ovarian estrogen production. In true central puberty, pituitary gonadotropins cause both ovaries to increase in size.

In true male central puberty, testes enlarge and androgen production increases. The size of testes enlargement sufficient to determine puberty is debatable. In general, prepubertal testes are less than 4 cm³

FIGURE 42.1 Two-year-old twin sisters with idiopathic isolated premature thelarche manifested by isolated breast development to Tanner stage 3.

FIGURE 42.2 A 3-year-old girl *(left)* with isosexual central precocious puberty characterized by both breast and pubic hair development, and tall stature, contrasted to a normal 5-year-old prepubertal girl *(right)*.

TABLE 42.4   Classification of Sexual Precocity

True Precocious Puberty or Complete Isosexual Precocity (GnRH-Dependent Sexual Precocity or Premature Activation of the Hypothalamic GnRH Pulse Generator)
Idiopathic true precocious puberty
CNS tumors
Optic glioma associated with neurofibromatosis type 1
Hypothalamic astrocytoma
Other CNS disorders
Developmental abnormalities including hypothalamic hamartoma of the tuber cinereum
Encephalitis
Static encephalopathy
Brain abscess
Sarcoid or tubercular granuloma
Head trauma
Hydrocephalus
Arachnoid cyst
Myelomeningocele
Vascular lesion
Cranial irradiation
True precocious puberty after late treatment of congenital virilizing adrenal hyperplasia or other previous chronic exposure to sex steroids
True precocious puberty due to gain-of-function mutations:
    in the *KISS1R/GRP54* genes
    in the *KISS1* gene
 	
Incomplete Isosexual Precocity (Hypothalamic GnRH-Independent)
Males
Gonadotropin-secreting tumors
hCG-secreting CNS tumors (e.g., chorioepitheliomas, germinoma, teratoma)
hCG-secreting tumors located outside the CNS (hepatoma, teratoma, choriocarcinoma)
Increased androgen secretion by adrenal gland or testis
Congenital adrenal hyperplasia (CYP21 and CYP11B1 deficiencies)
Virilizing adrenal neoplasm
Leydig cell adenoma
Familial testotoxicosis (sex-limited autosomal dominant pituitary gonadotropin-independent precocious Leydig cell and germ cell maturation)
Cortisol resistance syndrome
	Females
	Ovarian cyst
	Estrogen-secreting ovarian or adrenal neoplasm
	Peutz–Jeghers syndrome
	
	Both Sexes
	McCune–Albright syndrome
	Hypothyroidism
	Iatrogenic or exogenous sexual precocity (including inadvertent exposure to estrogens in food, drugs, or cosmetics)
	
	Variations of Pubertal Development
	Premature thelarche
	Premature isolated menarche
	Premature adrenarche
	Adolescent gynecomastia in boys
	Macroorchidism
	
	Contrasexual Precocity
	Feminization in Males
	Adrenal neoplasm
	Chorioepithelioma
	CYP11B1 deficiency
	Late-onset adrenal hyperplasia
	Testicular neoplasm (Peutz–Jeghers syndrome)
	Increased extraglandular conversion of circulating adrenal androgens to estrogen
	Iatrogenic (exposure to estrogens)
	
	Virilization in Females
	Congenital adrenal hyperplasia
	CYP21 deficiency
	CYP11B1 deficiency
	3β-HSD deficiency
	Virilizing adrenal neoplasm (Cushing syndrome)
	Virilizing ovarian neoplasm (e.g., arrhenoblastoma)
	Iatrogenic (exposure to androgens)
	Cortisol resistance syndrome
	Aromatase deficiency

CNS, central nervous system; CYP11B1, 11-hydroxylase; CYP21, 21-hydroxylase; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; 3β-HSD, 3β-hydroxysteroid dehydrogenase 4,5-isomerase; *KISS1R/GPR54*, kisspeptin/G protein–coupled receptor 54.
Modified from Grumbach MM. True or central precocious puberty. In: Kreiger DT, Bardin CW, eds. *Current Therapy in Endocrinology and Metabolism, 1985-1986.* Toronto, Canada: BC Decker; 1985:4-8.

in volume and 2 cm in length. If on examination both testes are enlarged and androgen signs are present, it is likely puberty is underway and testes-derived testosterone levels are increasing. If basal pituitary gonadotropins are increasing, or if LH levels increase markedly after GnRH stimulation, the diagnosis is central precocious puberty.

Hypothalamic hamartomas, which may be associated with ectopic secretion of GnRH or transforming growth factor-α, are common causes of precocious puberty. Approximately 3% of children with neurofibromatosis type I develop central precocity, usually caused by a hypothalamic optic glioma.

Central precocious puberty in the setting of untreated or undertreated peripheral causes of puberty, such as **virilizing congenital adrenal hyperplasia**, is caused by premature activation of the GnRH pulse generator, presumably as a result of continuous central nervous system exposure to high levels of androgens (or androgens aromatized to estrogens). Precocious puberty with thelarche and menarche in the setting of long-standing severe untreated **primary hypothyroidism** (Van Wyk–Grumbach syndrome) can occur, although the mechanism is not clear. It is clinically distinguished by the usual manifestations of hypothyroidism, including delayed growth and bone age, rather than the advanced bone age present with other causes of precocious puberty.

Incomplete Isosexual Precocity (Precocious Pseudopuberty)

Precocious pseudopuberty refers to gonadal or adrenal sex-steroid secretion *not* resulting from activation of the hypothalamic-pituitary-gonadal axis (pituitary-independent). It is caused by excessive production of or exposure to either androgens or estrogens (see Table 42.4).

TABLE 42.5 Differential Diagnosis of Sexual Precocity

Disorder	Plasma Gonadotropins	LH Response to GnRH	Serum Sex Steroid Concentration	Gonadal Size	Miscellaneous
Gonadotropin Dependent					
True precocious puberty	Prominent LH pulses (premature reactivation of GnRH pulse generator)	Pubertal LH response initially during sleep	Pubertal values of testosterone or estradiol	Normal pubertal testicular enlargement or ovarian and uterine enlargement	MRI of brain to rule out CNS tumor or other abnormality; skeletal survey for McCune–Albright syndrome (by US)
Incomplete Sexual Precocity (Pituitary Gonadotropin Independent)					
Males					
Chorionic gonadotropin-secreting tumor in males	High hCG, low LH	Prepubertal LH response	Pubertal value of testosterone	Slight-to-moderate uniform enlargement of testes	Hepatomegaly suggests hepatoblastoma; CT scan of brain if chorionic gonadotropin-secreting CNS tumor suspected
Leydig cell tumor in males	Suppressed	No LH response	Very high testosterone	Irregular, asymmetric enlargement of testes	
Familial testotoxicosis	Suppressed	No LH response	Pubertal values of testosterone	Testes symmetric and > 2.5 cm but smaller than expected for pubertal development; spermatogenesis occurs	Familial; probably sex-limited, autosomal dominant trait
Virilizing congenital adrenal hyperplasia	Prepubertal	Prepubertal LH response	Elevated 17-OHP in CYP21 deficiency or elevated 11-deoxycortisol in CYP11B1 deficiency	Testes prepubertal	Autosomal recessive; may be congenital or late-onset form, may have salt loss in CYP21 deficiency or hypertension in CYP11B1 deficiency
Virilizing adrenal tumor	Prepubertal	Prepubertal LH response	High DHEAS and androstenedione values	Testes prepubertal	CT, MRI, or US of abdomen
Premature adrenarche	Prepubertal	Prepubertal LH response	Prepubertal testosterone, DHEAS, or urinary 17-ketosteroid values appropriate for pubic hair stage 2	Testes prepubertal	Onset usually after 6 yr of age; more frequent in CNS-injured children
Females					
Granulosa cell tumor (follicular cysts may present similarly)	Suppressed	Prepubertal LH response	Very high estradiol	Ovarian enlargement on physical examination, CT, or US	Tumor often palpable on physical examination
Follicular cyst	Suppressed	Prepubertal LH response	Prepubertal to very high estradiol	Ovarian enlargement on physical examination, CT, or US	Single or recurrent episodes of menses and/or breast development; exclude McCune–Albright syndrome
Feminizing adrenal tumor	Suppressed	Prepubertal LH response	High estradiol and DHEAS values	Ovaries prepubertal	Unilateral adrenal mass
Premature thelarche	Prepubertal	Prepubertal LH, pubertal	Prepubertal or early estradiol response	Ovaries prepubertal	Onset usually before 3 yr of age
Premature adrenarche	Prepubertal	Prepubertal LH response	Prepubertal estradiol; DHEAS or urinary 17-ketosteroid values appropriate for pubic hair stage 2	Ovaries prepubertal	Onset usually after 6 yr of age; more frequent in brain-injured children

TABLE 42.5	**Differential Diagnosis of Sexual Precocity—cont'd**				
Disorder	**Plasma Gonadotropins**	**LH Response to GnRH**	**Serum Sex Steroid Concentration**	**Gonadal Size**	**Miscellaneous**
Late-onset virilizing congenital adrenal hyperplasia	Prepubertal	Prepubertal LH response	Elevated 17-OHP in basal or corticotrophin-stimulated state	Ovaries prepubertal	Autosomal recessive
In Both Sexes McCune–Albright syndrome	Suppressed	Suppressed	Sex steroid pubertal or higher	Ovarian enlargement (visible on US); slight testicular enlargement	Skeletal survey for polyostotic fibrous dysplasia and skin examination for café-au-lait spots
Primary hypothyroidism	LH prepubertal; FSH may be slightly elevated	Prepubertal FSH may be increased	Estradiol may be pubertal	Testicular enlargement; ovaries cystic	TSH and prolactin elevated; T_4 low

CNS, central nervous system; CT, computed tomography; CYP, P450 cytochrome isoenzyme; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; MRI, magnetic resonance imaging; 17-OHP, 17-hydroxyprogesterone; T_4, thyroxine; TSH, thyroid-stimulating hormone; US, ultrasonography.

Androgen Exposure or Overproduction

Anabolic steroids have been taken by males and females to improve muscle development and athletic performance. In males, if anabolic steroids are taken at the age of puberty, secondary sexual development will progress, but the testes will remain small. In females, anabolic steroids can produce clitoral enlargement (particularly in diameter), complexion problems, and hirsutism, as well as emotional lability.

Females. **Ovarian tumors** producing androgens (thecoma) and sometimes also estrogen may be palpable on physical examination and are usually easily seen on a pelvic sonogram. Arrhenoblastoma, a virilizing ovarian tumor, is rare in children. Gonadoblastomas, which are not always virilizing, typically occur in phenotypic females who have a Y chromosome. Granulosa cell tumors usually cause estrogen overproduction but occasionally cause virilization due to excessive androgen production.

Adrenal tumors can be detected with ultrasonography, computed tomography, or MRI. Androgens produced by adrenal tumors are not suppressed by dexamethasone. Excessive adrenal androgens may also be produced as a result of late-onset or nonclassic **congenital adrenal hyperplasia**, but the androgen production can be suppressed by dexamethasone. The enzymatic deficiency in late-onset congenital adrenal hyperplasia is mild, inasmuch as it does not cause ambiguity of genitalia at birth; however, it is associated with an accelerated growth rate and advanced bone age and may be clinically recognized any time after birth.

Males. If both testes are slightly increased in volume and testosterone levels are increased but LH and FSH levels are low, there are 2 possibilities: either the testes are being stimulated by human chorionic gonadotropin (hCG), which acts like LH and does not increase testicular volume, as with FSH, or the testes are functioning autonomously. hCG levels must be determined, and if they are increased, tumors producing hCG must be identified and removed; such tumors may include hepatoma, hepatoblastoma, teratoma, and chorioepithelioma.

If both testes are producing testosterone autonomously without gonadotropin stimulus, the condition of **testotoxicosis** is probable. Children with this autosomal dominant disorder have signs of puberty by 4 years of age (Fig. 42.3). Testosterone production and Leydig cell hyperplasia occur in the setting of prepubertal serum LH levels, because of a gain-of-function mutation in the gene for the LH receptor, resulting in its constitutive activation. Affected males are fertile. Females who carry this mutation do not develop precocious puberty.

If one testis is enlarged, a Leydig cell adenoma in that testicle is probably producing excess testosterone; the tumor must be removed. The high levels of testosterone suppress LH and FSH secretion, so the other testicle remains small. Depending on age, a testicular prosthesis may be inserted to replace the removed testicle.

If androgen signs are developing steadily but neither testis has enlarged, the androgen is presumed to be either from the adrenal glands or from an exogenous source. Inappropriate adrenal production of androgens results from tumors or abnormalities in steroid synthesis enzymatic activity. An adrenal tumor would have affected growth whenever the gland started to function, but not necessarily beginning at birth. A defect in steroid synthesis caused by an enzymatic deficiency (usually 21-hydroxylase) may be congenital, as in congenital adrenal hyperplasia, and the excess androgen production resulting from the enzymatic deficiency would have been produced from the time of birth, leading to increased growth velocity from early life. *Children with congenital adrenal hyperplasia may have severe adrenal crises during an illness or surgery.* A late-onset or nonclassic form of adrenal hyperplasia may also occur. A tumor can be identified by computed tomography, ultrasonography, or MRI and must be removed.

Estrogen Overproduction

The most common cause of premature progressive breast development is simple premature thelarche. In this case, a pelvic ultrasound study may show prepubertal ovaries varying from 1-3 cm³ in volume with many small estrogen-producing follicular cysts. Some cysts may be larger (persistent follicular cysts). Estradiol is produced by the granulosa cells lining the follicles and causes vaginal discharge and breast development. Estradiol may cause uterine development as well but generally does not cause increased growth velocity. LH and FSH levels are low and if estradiol is measured, it might be elevated but minimally so. The follicular cysts regress spontaneously (90% of the time) within a few weeks to months, and the vaginal cornification is lost within 1 week of cyst regression. The breast tissue then softens but can remain for months, and may never completely regress. Typically premature thelarche due to persistent follicular cysts is usually benign and

FIGURE 42.3 A boy with familial testotoxicosis associated with significant penile enlargement, moderate pubic hair growth, and mild-to-moderate testicular enlargement over a 1.75-year period. *Left,* at 2 years of age. *Right,* at 3.75 years of age.

self-limited. However, 10% of the cysts may persist and enlarge, with some follicular cysts becoming large enough to threaten ovarian torsion and to necessitate surgical treatment.

Granulosa cell tumors are usually isolated occurrences but may occur as part of **Peutz–Jeghers syndrome** (oral melanosis and intestinal polyps). Aromatase is the enzyme that is responsible for conversion of androgen to estrogen; aromatase excess is an autosomal dominant disorder that can lead to increased estradiol levels.

McCune–Albright syndrome. This disorder (Fig. 42.4) consists of the clinical triad of polyostotic fibrous dysplasia, hyperpigmented macules (café-au-lait spots) with irregular borders ("coast of Maine"), and multiple autonomous endocrinopathies (most commonly gonadotropin-independent precocious puberty, but also hyperthyroidism, acromegaly, and hypercortisolemia) (Table 42.6). Precocious puberty occurs much more commonly in females than in males. Patients have a mutation in their G_sa gene that occurs early in embryogenesis and results in constitutive activation of adenylyl cyclase only in affected tissues. This activation leads to the autonomous function of involved tissues, resulting, in the case of affected endocrine glands, in unregulated production of hormone. Precocity in females, often heralded by menstrual bleeding, frequently occurs before 2 years of age. The ovaries are enlarged and have many follicular cysts; the patient has elevated levels of estradiol. Later, when the GnRH pulse generator is activated subsequent to unabated sex steroid exposure, the patient may transition from gonadotropin-independent to central precocious puberty.

Vaginal Bleeding

The usual progression of puberty in females dictates that breast and uterine development begin about 2 years before the menses. When the rate of pubertal progression is accelerated, menses may start as early as 1-1.5 years after thelarche; if the rate is slow, menses may start perhaps 3-4 years after thelarche. In any case, vaginal bleeding is always a much later sign than breast development, and whenever vaginal bleeding occurs too early—especially if it ever occurs before breast development starts—it must be investigated thoroughly.

Gynecomastia

Breast tissue frequently develops in males during midpuberty, when the production of estrogen from testosterone in the testes temporarily overbalances the testosterone effects. Only rarely does breast tissue develop in prepubertal males, inasmuch as young males do not respond to transient gonadotropin stimulation with estrogen production. Differential diagnosis includes estrogen-producing tumors (gonadal or adrenal), exogenous estrogen, hCG-producing tumors, aromatase excess, certain types of male pseudohermaphroditism, and Klinefelter syndrome. Certain medications and illicit drugs are associated with gynecomastia. A **prolactinoma** should be considered, especially in the setting of **galactorrhea**.

Evaluation of gynecomastia in prepubertal males may include karyotyping and measurement of gonadotropins, estradiol, testosterone, hCG, and prolactin level. Imaging is dictated by the results.

◆ Diagnostic Approach to Precocious Puberty

In the initial evaluation of the child with precocious puberty, the clinician attempts to determine:
- Whether the process is a normal variant or pathologic
- The rate of progression of the pubertal changes
- Whether the process originates centrally or peripherally

FIGURE 42.4 A 12-year-old girl with McCune–Albright syndrome with a café-au-lait spot with an irregular border ("coast of Maine") on the back *(left)* and representative lesion of fibrous dysplasia involving the left humerus *(right)*.

TABLE 42.6	Clinical Manifestations of McCune–Albright Syndrome in 158 Reported Patients*				
	% OF PATIENTS			**Mean Age at Diagnosis**	
Manifestation	**Total (*n* = 158)**	**Male (*n* = 53)**	**Female (*n* = 105)**	**(yr) and Range**	**Comments**
Fibrous dysplasia	97	51	103	7.7 (0-52)	Polyostotic more common than monostotic
Café-au-lait lesion	85	49	86	7.7 (0-52)	Variable size and number of lesions, irregular border (coast of Maine)
Sexual precocity	52	8	74	4.9 (0.3-9)	Common initial manifestation
Acromegaly/gigantism	27	20	22	14.8 (0.2-42)	17/26 of patients with adenoma on MRI/CT
Hyperprolactinemia	15	9	14	16.0 (0.2-42)	23/42 of acromegalic patients with PRL
Hyperthyroidism	19	7	23	14.4 (0.5-37)	Euthyroid goiter is common
Hypercortisolism	5	4	5	4.4 (0.2-17)	All primary adrenal
Myxomas	5	3	5	34 (17-50)	Extremity myxomas
Osteosarcoma	2	1	2	36 (34-37)	At site of fibrous dysplasia, not related to prior radiation therapy
Rickets/osteomalacia	3	1	3	27.3 (8-52)	Responsive to phosphorus plus calcitriol
Cardiac abnormalities	11	8	9	(0.1-66)	Arrhythmias and CHF reported
Hepatic abnormalities	10	6	10	1.9 (0.3-4)	Neonatal icterus is most common

*Evaluations include clinical and biochemical data; other rarely described manifestations include metabolic acidosis, nephrocalcinosis, developmental delay, thymic and splenic hyperplasia, and colonic polyps.
CHF, congestive heart failure; CT, computed tomography; MRI, magnetic resonance imaging; PRL, prolactin.
Modified from Ringel MD, Schwindinger WF, Levine MA. Clinical implications of genetic defects in G proteins: the molecular basis of McCune-Albright syndrome and Albright hereditary osteodystrophy. *Medicine (Baltimore).* 1996;75:171-184.

Initial evaluation should include:

- Medical history: growth patterns; excessive responses to illness (adrenal crisis); exposure to exogenous sex steroids; history of intracranial insults (hydrocephalus, meningitis, or encephalitis)
- Review of symptoms: growth records, head size since birth, vision problems, headache, age at onset of androgen signs (behavior changes, need for increased hair washing because of oiliness, need for deodorant), age at onset of estrogen signs (vaginal discharge or breast budding), café-au-lait spots ("coast of Maine" in McCune–Albright syndrome or "coast of California" in neurofibromatosis)
- Family history: timing of maternal and paternal growth and pubertal development; siblings and cousins with early development; neurofibromatosis
- Physical examination: vital signs, height, weight, head circumference, tooth age, café-au-lait spots, neurofibromata, pubic and axillary hair, body odor, skin and hair oils, visual fields, optic discs, breast development, vaginal cornification/discharge, penis/clitoris size, scrotal/labial development, testicular volume, pubic hair stages, facial asymmetry or bone abnormalities (fibrous dysplasia of McCune–Albright syndrome), neurologic status, affect or mood, intellectual ability

The 1st test is usually a determination of bone age; if the bone age is not significantly advanced (within 20% of the chronologic age in months) and not associated with an increase in height velocity, the results suggest a normal variant, a slowly progressive process, or a process of relatively short duration. If the bone age is significantly advanced, a workup is mandatory (Table 42.7). Clinical and laboratory findings in sexual precocity are listed in Table 42.5.

For females with breast development, pelvic ultrasonography and determination of central precocity are the initial diagnostic tests. Because of the pulsatile secretion of serum gonadotropins, random measurements of LH and FSH even by ultrasensitive immunochemiluminescent assay (ICMA) are occasionally low and appear prepubertal even in the setting of central activation. If this occurs and there is clinical suspicion nonetheless of maturation of the GnRH pulse generator, a GnRH stimulation test should be performed. With central precocity, as with normal puberty, endogenous GnRH that "primes" the pituitary gonadotrophs is being produced, so that after administration of a single pharmacologic dose of GnRH, there is copious release of LH. If, on the other hand, the precocity has a peripheral basis, the high levels of circulating estradiol, through central negative feedback, prevent the gonadotrophs from releasing LH in response to the exogenous GnRH bolus.

If a female with advanced bone age presents only with contrasexual androgenic effects (specifically, evidence of virilization), measurement of gonadotropins and estradiol is not indicated as an adrenal cause should be considered. Measurement of serum 17-hydroxyprogesterone is the diagnostic test for 21-hydroxylase deficiency, the most common enzyme abnormality associated with nonclassic or late-onset adrenal hyperplasia. On occasion, an adrenocorticotropic hormone (ACTH) stimulation test may need to be performed to determine the specific enzymatic deficiency. Screening for Cushing syndrome with a 24-hour urine collection with measurement of free cortisol (and creatinine to document completeness of the collection) or midnight salivary cortisol may also be indicated if the appropriate "cushingoid" body habitus is present. Generally, linear growth is attenuated with Cushing syndrome, which is in contrast to most other causes of precocious puberty. Given the typical lack of ovarian involvement in the pathology of virilization in girls, magnetic resonance imaging of the head is not usually indicated.

For males, the testicular examination guides the evaluation by suggesting whether there is a testicular or adrenal source of the androgens.

TABLE 42.7   Diagnostic Approach to Precocious Puberty

Girls with Breast Development, with or Without Androgen Effects

Random serum FSH and LH measurement by ICMA; estradiol measurement
GnRH stimulation test (if random FSH and LH levels are uninformative)
Pelvic ultrasonography
Prepubertal ovaries: ultrasonography (or other radiologic imaging) to image adrenal glands and question about exogenous sources
One enlarged ovary: either functioning ovarian cyst or solid granulosa-cell tumor
Bilaterally enlarged ovaries for age: GnRH test to distinguish between central precocity (usual) or McCune–Albright syndrome (rare)
Head MRI with contrast medium (if central precocity is confirmed biochemically and is progressive)

Girls with Contrasexual Androgen Effects (Virilization)

Serum total testosterone (provides an index of the severity of the process)
17-Hydroxyprogesterone (for CAH)
ACTH stimulation test (for CAH) (optional)
Midnight salivary cortisol or 24-hr urine free cortisol and creatinine (for Cushing syndrome)
Abdominal/pelvic MRI (if testing suggests either an adrenal or ovarian tumor)

Boys with Isosexual Precocity

Prepubertal testes: ultrasonography (or other radiologic imaging) of the adrenal glands; question about exogenous sources
One enlarged testis: ultrasonography (or other radiologic imaging) of this testis for an androgen-producing tumor
Bilaterally enlarged testes for age: GnRH test to distinguish between central precocity and other causes (familial testotoxicosis, hCG-producing tumor, CAH with adrenal rests, or hypothyroidism)
If central precocity is confirmed biochemically, head MRI with contrast

Tests to Consider, in Either Sex, Depending on Clinical Presentation

Serum hCG
Prolactin
T_4 and TSH

ACTH, adrenocorticotropic hormone; CAH, congenital adrenal hyperplasia; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; ICMA, immunochemiluminescent assay; LH, luteinizing hormone; MRI, magnetic resonance imaging; T_4, thyroxine; TSH, thyroid-stimulating hormone.

Testotoxicosis and hCG-producing tumors cause some testicular enlargement but less than expected for the degree of virilization.

◆ Treatment of Precocious Puberty
General Issues

Not all cases of precocious puberty necessitate treatment. Cases of idiopathic precocious thelarche and adrenarche should be monitored, because their manifestations are not typically progressive and there is no significant early onset of the other components of puberty or short stature. In addition, not all children with central precocious puberty require treatment, inasmuch as a significant number of cases are either slowly progressive and/or transient. Unless there is rapid progression and/or significant psychosocial difficulties, most children with central precocity should be observed for a 3- to 6-month period before pubertal reversal therapy is initiated. The reasons that favor treatment

include preservation of acceptable final height, prevention of psychologic trauma (menstruation at an early age), reversal of mature physical appearance to decrease the risk of pregnancy in females (because other people assume that affected children are older than they appear), and reduction of aggressiveness and preoccupation with sexuality. Serious psychologic effects of early puberty are not usually encountered. If a decision is made to reverse puberty, the goal of therapy is to inhibit secretion and/or effects of estrogens in females and androgens in males (Table 42.8).

Central Precocious Puberty

The goal of therapy is to inhibit secretion of gonadotropins and reduce production of sex steroids by the administration of GnRH analogs with a prolonged duration of action (Table 42.9). This causes downregulation of pituitary GnRH receptors, preventing the response to endogenous GnRH and thus decreasing LH and FSH secretion. Several doses of GnRH are necessary to produce the antagonistic response because the treatment initially stimulates the axis and only later results in downregulation of pituitary GnRH receptors. Accurate verification of adequate suppression of the axis typically requires repeat GnRH testing, although random LH-ICMA levels may be sufficient.

Therapy is stopped at about 11 years in females and 12 years in males so that puberty can resume. Successful GnRH agonist treatment is associated with a stabilization of androgen effects in males and estrogen effects in females; there is no effect on androgen-mediated events in females as androgens are predominately produced by the adrenal glands. Complete reversal of physical changes to the prepubertal state is unusual. Height velocity and the rate of bone age maturation should slow; on some occasions, height velocity actually becomes subnormal. This is not necessarily problematic as long as bone age maturation slows commensurately. Final height is optimized with earlier initiation of therapy. Once GnRH analog therapy is discontinued, reactivation of the hypothalamic-pituitary-gonadal axis occurs within 12 months. Long-term fertility data in individuals treated with GnRH analogs as children continues to grow, but studies suggest successful childbearing in women and normal testicular function in young adult men following GnRH therapy.

Large tumors in the hypothalamic-pituitary region are surgically removed, and both the tumor or the surgery can precipitate central precocious puberty. However, hypothalamic hamartomas are benign and tend to grow very slowly; therefore, surgery is usually not recommended.

Precocious Pseudopuberty (Incomplete Isosexual Precocity)

Treatment is directed at the underlying cause (Table 42.10). The precocious puberty of McCune–Albright syndrome is treated with inhibitors (testolactone or anastrozole) of aromatase, the enzyme that converts androgen to estrogen. The results of this approach are variable, and sometimes a GnRH agonist must be added if central puberty is also present. Ketoconazole is an effective therapy for familial testotoxicosis (due to a constitutively active LH receptor) because it has the desirable and reversible side effect of interfering with sex steroid synthesis; spironolactone is an androgen receptor blocker.

DELAYED OR ABSENT PUBERTY

Delayed puberty is the failure of development of any pubertal feature by 13 years of age in females or by 14 years of age in males. A lower cutoff may be appropriate in a child with a strong familial pattern of early puberty.

◆ Differential Diagnosis

Delay or absence of puberty is caused by:
- Constitutional delay: a variant of normal
- Hypogonadotropic hypogonadism: low gonadotropin levels as a result of a defect of the hypothalamus and/or pituitary gland (Tables 42.11 and 42.12)
- Hypergonadotropic hypogonadism: high gonadotropin levels as a result of a lack of negative feedback because of a gonadal problem (see Tables 42.11 and 42.12). Girls may have isolated absence of adrenarche with normal breast development (see later discussion).

TABLE 42.8   Objectives for the Management and Treatment of True Precocious Puberty

Detection and treatment of an expanding intracranial lesion

Arrest of premature sexual maturation until the normal age at onset of puberty

Regression of secondary sexual characteristics already present

Attainment of normal mature height; suppression of the rapid rate of skeletal maturation

Prevention of emotional disorders and handicaps and alleviation of parental anxiety; promotion of understanding by counseling, early sex education, and acceleration of social age

Reduction of risk of sexual abuse and early sexual debut

Prevention of pregnancy in girls

Preservation of future fertility

Diminishment of the increased risk of breast cancer associated with early menarche

From Grumbach MM. True or central precocious puberty. In: Krieger DT, Bardin CW, eds. *Current Therapy in Endocrinology and Metabolism, 1985-1986.* Toronto, Canada: BC Decker; 1989:4-8.

TABLE 42.9   GnRH Analogs Used to Treat Precocious Puberty

Leuprolide acetate (Lupron Depot) given as an intramuscular injection every 1-3 mo*

Leuprolide acetate (Lupron) given as a daily subcutaneous injection

Nafarelin acetate (Synarel) given b.i.d. by an intranasal route

*Preferred because of infrequent dosing.

b.i.d., twice a day; GnRH, gonadotropin-releasing hormone.

TABLE 42.10   Treatment of Precocious Pseudopuberty (Incomplete Isosexual Precocity)

Tumors

   Surgical removal

   Chemotherapy and/or radiation as indicated

Illicit or unintentional administration of exogenous estrogens or androgens should be uncovered and eliminated

Familial testotoxicosis: ketoconazole or spironolactone and testolactone

Adrenal hyperplasia: exogenous glucocorticoid

Hypothyroidism: levothyroxine

McCune–Albright syndrome: testolactone or anastrozole

GnRH agonist therapy may need to be added to any of above medical therapies if central puberty becomes superimposed at an early age

GnRH, gonadotropin-releasing hormone.

(See *Nelson Textbook of Pediatrics,* p. 2643.)

TABLE 42.11 Classification of Delayed Puberty and Sexual Infantilism

Idiopathic (Constitutional) Delay in Growth and Puberty (Delayed Activation of Hypothalamic LRF Pulse Generator)

Hypogonadotropic Hypogonadism: Sexual Infantilism Related to Gonadotropin Deficiency

CNS Disorders

Tumors

Craniopharyngiomas

Germinomas

Other germ cell tumors

Hypothalamic and optic gliomas

Astrocytomas

Pituitary tumors (including MEN-1, prolactinoma)

Other Causes

Langerhans histiocytosis

Postinfectious lesions of the CNS

Vascular abnormalities of the CNS

Radiation therapy

Congenital malformations, especially associated with craniofacial anomalies

Head trauma

Lymphocytic hypophysitis

Isolated Gonadotropin Deficiency

Kallmann syndrome

    With hyposmia or anosmia

    Without anosmia

LHRH receptor mutation

Congenital adrenal hypoplasia (*DAX1* mutation)

Isolated LH deficiency

Isolated FSH deficiency

Prohormone convertase 1 deficiency (PCI)

Idiopathic and Genetic Forms of Multiple Pituitary Hormone Deficiencies Including *PROP1* Mutation

Miscellaneous Disorders

Prader–Willi syndrome

Laurence-Moon or Bardet-Biedl syndrome

Functional gonadotropin deficiency

Chronic systemic disease and malnutrition

Sickle cell disease

Cystic fibrosis

Acquired immunodeficiency syndrome (AIDS)

Chronic gastroenteric disease

Chronic renal disease

Malnutrition

Anorexia nervosa

Bulimia

Psychogenic amenorrhea

Impaired puberty and delayed menarche in female athletes and ballet dancers (exercise amenorrhea)

Hypothyroidism

Diabetes mellitus

Cushing disease

Hyperprolactinemia

Marijuana use

Gaucher disease

Hypergonadotropic Hypogonadism

Males

The syndrome of seminiferous tubular dysgenesis and its variants (Klinefelter syndrome)

Other forms of primary testicular failure

Chemotherapy

Radiation therapy

Testicular steroid biosynthetic defects

Sertoli-only syndrome

LH receptor mutation

Anorchia and cryptorchidism

Trauma/surgery

Females

The syndrome of gonadal dysgenesis (Turner syndrome) and its variants

XX and XY gonadal dysgenesis

Familial and sporadic XX gonadal dysgenesis and its variants

Familial and sporadic XY gonadal dysgenesis and its variants

Aromatase deficiency

Other forms of primary ovarian failure

Premature menopause

Radiation therapy

Chemotherapy

Autoimmune oophoritis

Galactosemia

Glycoprotein syndrome type 1

Resistant ovary

FSH receptor mutation

LH/hCG resistance

Polycystic ovarian disease

Trauma/surgery

Noonan or pseudo-Turner syndrome

Ovarian steroid biosynthetic defects

CNS, central nervous system; FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; LH, luteinizing hormone; LHRH, luteinizing hormone-releasing hormone; LRF, luteinizing hormone-releasing factor; MEN, multiple endocrine neoplasia.

Constitutional Delay of Growth and Puberty

This is the most common cause of delayed puberty and is thought to be a normal variant. It is usually diagnosed in males, probably as a result of ascertainment bias of referral patterns. The cause is unknown, but approximately 50% of affected patients have a 1st-degree relative with delayed puberty and/or late growth. This tendency can occur in a child of the same gender as the affected parent or in a child of the opposite gender. An affected child typically presents in early adolescence when peers are beginning to develop and having growth spurts

but the patient is not. The patient's height is usually at or below the 3rd percentile (see Chapter 43). In the classic case, the affected child had a normal length at birth, a slowdown in height velocity between 6 months and 2 years of age that resulted in short stature, and a normal or near-normal height velocity thereafter along the child's current height percentile. The physical examination findings are unremarkable, and, depending on the age, the child may have delayed puberty. The cardinal diagnostic result is a bone age that is moderately delayed in comparison with chronologic age. There may also be a history of delayed dentition. Without intervention, final adult height usually

TABLE 42.12 Molecular Basis for Developmental Disorders Associated with Hypogonadotropic Hypogonadism

Gene	Phenotype	Complex Phenotype
Isolated Hypogonadotropic Hypogonadism		
Kallmann Syndrome or Normosmic IHH (With the Same Mutant Gene)		
KAL1 (Xp22.3)	X-linked Kallmann syndrome	Anosmia/hyposmia, renal agenesis, dyskinesia
FGFR1 (8p11.2)	Autosomal dominant Kallmann syndrome (± recessive)	Anosmia/hyposmia, cleft lip/palate
FGF8 (ligand for FGFR1) (10q25)		
NSMF (9p34.3)	Autosomal dominant/Oligogenetic Kallmann syndrome	
PROK2 (3p21.1)	Autosomal recessive Kallmann syndrome	
PROKR2* (20p12.3)		
CHD7 (8p12.1)	Autosomal dominant (some)	CHARGE syndrome; includes hyposmia
Normosmic Isolated Hypogonadotropic Hypogonadism		
GNRH1 (8p21-11.2)	Autosomal recessive	
GNRHR* (4q13.2-3)	Autosomal recessive (± dominant)	
GPR54* (19p13.3)	Autosomal recessive	
SNRPN Lack of function of paternal 15q11-q13 region or maternal uniparental disomy		Prader–Willi syndrome, obesity
LEP (7q31.3)	Autosomal recessive	Obesity
LEPR (1p31)	Autosomal recessive	Obesity
NR0B1 (X21.3-21.2)	X-linked recessive	Adrenal hypoplasia
TAC3 (12q13-12)	Autosomal recessive	
TACR3 (4q25)	Autosomal recessive	
Multiple Pituitary Hormone Deficiencies		
PROP1 POU1F1	Autosomal recessive GH, PRL, TSH, and LH/FSH (less commonly, later-onset ACTH deficiency)	
HESX1	Autosomal recessive; and heterozygous mutations Multiple pituitary deficiencies including diabetes insipidus, but LH/FSH uncommon	Septo-optic dysplasia
LHX3	Autosomal recessive GH, PRL, TSH, FSH/LH	Rigid cervical spine
PHF6	X-linked; GH, TSH, ACTH, LH/FSH	Börjeson-Forssman-Lehmann: intellectual disability; coarse facies

*A G protein–coupled receptor.
ACTH, corticotrophin; CHD7, chromatin-remodeling factor; DAX1, dosage-sensitive sex reversal-adrenal hyperplasia congenita critical region on the X chromosome, gene 1; FGF, fibroblast growth factor; FSH, follicle-stimulating hormone; GH, growth hormone; GnRH, gonadotropin-releasing hormone; GPR54, kisspeptin G protein–coupled receptor 54; HESX1, homeobox gene expressed in ES cells; IHH, idiopathic hypogonadotropic hypogonadism; LEP, leptin; LH, luteinizing hormone; LHX3, lim homeobox gene 3; NELF, nasal embryonic luteinizing hormone–releasing factor; NR0B1, nuclear receptor family 0, group B, member 1; PHF6, plant homeodomain–like finger gene; PRL, prolactin; PROK2, prokineticin 2; PROP1, prophet of Pit-1; R, receptor; SNRPN, small nuclear ribonucleoprotein polypeptide SmN; TAC3, neurokinin 3; TSH, thyroid-stimulating hormone.

reaches or approximates the target height range. However, children with constitutional delay may have a blunted pubertal growth spurt in relation to their peers, and therefore may not reach their genetic target height range.

Hypogonadotropic Hypogonadism

A variety of central nervous system insults may disrupt production of gonadotropins. The GnRH pulse generator may be disrupted by an interfering substance, such as excess prolactin (with or without hypothyroidism), or by stress, chronic illness, malnutrition, or excessive physical activity. The hypothalamic arcuate nucleus may be damaged by trauma, radiation, infection, infiltration, increased intracranial pressure, or surgery. The most common mass lesions are craniopharyngiomas, gliomas, and cysts. Congenital conditions or malformations may have allowed enough GnRH for infantile development but not enough for pubertal needs.

Kallmann syndrome. This is the combination of an impaired or absent sense of smell and gonadotropin deficiency. Other features include color blindness, atrial septal defects, and renal structural anomalies (unilateral renal agenesis). The X-linked form is caused by a mutation of the *KAL* gene; there are autosomal recessive and autosomal dominant forms.

LH and FSH deficiencies may also be isolated or caused by multiple pituitary hormone deficiencies. The latter condition may be a result of pituitary damage from trauma, radiation, infection, sickle cell disease, compression by infiltrate or tumor, or autoimmune processes. In differentiating primary pituitary deficiency from that secondary to hypothalamic deficiency, the clinician should remember that all pituitary

hormones except prolactin are stimulated by hypothalamic releasing hormones; prolactin is inhibited by hypothalamic prolactin inhibitory factor. Therefore, if all pituitary hormones, including prolactin, are deficient, the problem is in the pituitary gland. If prolactin levels are present or even elevated but the other pituitary hormones are deficient, the problem is above the pituitary gland in the stalk or hypothalamus. In the case of isolated LH and FSH deficiencies, the primary abnormality may lie within the pituitary or hypothalamic neurons producing GnRH; however, increasingly there is evidence of primary abnormalities being further upstream. In particular, defects in molecules required for proper migration of GnRH neurons (including the *KAL* gene) or lack of necessary signaling to GnRH-producing neurons (e.g., defects in kisspeptin or neurokinin B and their receptors) can result in LH and FSH deficiency through inappropriate GnRH secretion.

Hypergonadotropic Hypogonadism: Males

If the testes are small, they may have been damaged by torsion, sickle cell disease, infection, autoimmune disease, chemotherapy, or radiation and may not be able to respond to LH and FSH stimulation. If the bone age is greater than 10 years and the hypothalamus has probably matured, the serum LH and FSH may then be high.

When the testis size is prepubertal and LH is present but testosterone is not increasing, there may be a problem with the LH receptor.

Klinefelter syndrome. This occurs in 1:500 males and is often associated with a 47,XXY karyotype; common features include reduced intelligence, adolescent gynecomastia (often pronounced), and small, firm testes. The testes rarely exceed 5 mL in volume (approximately 25% of the average adult volume). Patients, often tall and thin with an eunuchoid habitus, may have delayed puberty. Virilization may be incomplete, the phallus is often smaller than average, and infertility nears 100%.

Hypergonadotropic Hypogonadism: Females

In this condition, the ovary may be unable to synthesize estrogen (an inherited metabolic defect, possibly associated with excess adrenal mineralocorticoid and hypertension), the ovary may not be formed normally (dysgenesis), or the ovary may have been damaged by any of the factors listed for testicular damage and by galactosemia.

The ovary may be intact but may not be stimulated by gonadotropins. Gonadotropins are present but not effective if there is an FSH receptor problem.

Turner syndrome. The 2 most common features of Turner syndrome are short stature (involving the limbs to a greater degree than the trunk) and ovarian insufficiency (Fig. 42.5). Lymphedema and a webbed neck are diagnostic features present in a neonate. Additional features include a shield chest, increased carrying angle (cubitus valgus), short 4th metacarpal, hypoplastic nails, renal anomalies, and left-sided heart defects (coarctation of the aorta, bicuspid mitral valve, etc.). Approximately 50% of affected girls have no stigmata except short stature and thus are typically identified later. About 20% may have spontaneous puberty with functioning ovaries for at least a short period of time, which is in large part dependent on the child's karyotype, but the infertility rate is greater than 99%.

Females with Delayed or Absent Adrenarche

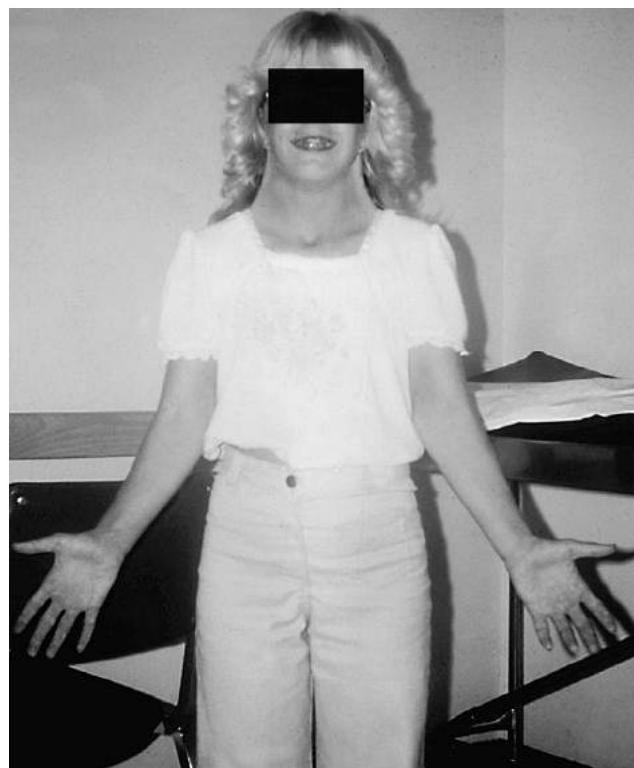
If a female has advanced breast development but no androgen signs, she may have a deficiency of androgen receptors, as occurs in **androgen insensitivity syndrome** (testicular feminization). In females, the androgens come predominantly from the adrenal glands (adrenarche). If the bone age has not passed 8 years, when DHEAS generally increases, adrenarche may simply be delayed (delayed adrenarche). If bone age is advanced, however, there is a deficiency in androgen production. In


FIGURE 42.5 A 16-year-old girl with Turner syndrome (45,XO), characterized by short stature, absence of thelarche, webbed neck, and increased carrying angles.

addition, there may be an inherited problem in androgen synthesis from an enzyme deficiency or the adrenal glands may be damaged secondary to autoimmune, infectious, or hypoxic injury. In these latter conditions, other signs of adrenal insufficiency would be evident.

◆ Diagnostic Approach to Delayed Puberty

A normal growth rate with delayed, but not absent, puberty and a family history of "late blooming" suggests the diagnosis of constitutional delay of growth and puberty, which is the most commonly encountered cause (see Tables 42.11 and 42.12). A bone age that correlates with the patient's pubertal status confirms the clinical impression; no other testing is necessary.

Initial evaluation should include:
- Medical history: trauma, illness, medications (e.g., stimulants, chemotherapy), radiation, infection, malnutrition, autoimmune problems, sickle status, stresses, growth records, galactosemia
- Review of symptoms: vision problems, headache, vomiting, inability to detect odors (hyposmia or anosmia), age at onset of androgen signs, age at onset of estrogen signs, small genitalia at birth, signs of primary adrenal insufficiency such as hyperpigmentation, need for deodorant, need to wash hair more frequently
- Family history: timing of maternal and paternal growth and pubertal development; siblings and cousins with delayed development
- Physical examination: signs of chronic disease, temperature, blood pressure, height, weight, head circumference, dental age, tanning (hyperpigmentation), pubic and axillary hair, adult body odor, skin and hair oils, visual fields, optic discs, ability to detect odors, breast development, vaginal cornification/discharge, penis size, scrotal development, testicular volume, pubic hair stages, neurologic status, affect or mood, intellectual ability, dysmorphic features

Initial laboratory evaluation screens for chronic disease include (complete blood cell count, chemistry profile, sedimentation rate),

hypothyroidism (free thyroxine and thyroid-stimulating hormone), and hyperprolactinemia (prolactin level). If growth is slow, the clinician should measure insulin-like growth factor-1 level (a marker of basal growth hormone activity) and consider growth hormone testing. The clinician should measure testosterone levels in males and estradiol levels in females.

Measurements of random FSH and LH and results of a GnRH stimulation test may differentiate between hypogonadotropic hypogonadism and primary gonadal failure (Figs. 42.6 and 42.7). Elevated gonadotropin levels support a diagnosis of primary gonadal failure. Chromosomal karyotyping is then performed (Klinefelter syndrome in males and Turner syndrome in females). GnRH stimulation testing, with measurement of serum LH levels over 1-2 hours, is often employed. Its rationale is based on the fact that a child in puberty has a significant rise in serum LH over baseline. Unfortunately, the GnRH test is not helpful in distinguishing between constitutional delay and hypogonadotropic hypogonadism because in both cases, the LH

response is blunted secondary to lack of endogenous GnRH priming of the gonadotrophs. However, the child with constitutional delay eventually develops an appropriate pubertal response to GnRH stimulation testing.

If **Kallmann syndrome** is being considered, a magnetic resonance imaging scan may show abnormalities in the olfactory region. If a 46,XX female has unexplained ovarian failure, antiovarian antibodies are obtained and müllerian-inhibiting substance can also be utilized in girls to assess ovarian follicle reserve and potential fertility. An hCG stimulation test to evaluate ability to produce testosterone and a serum level of müllerian-inhibiting substance (secreted by Sertoli cells) are useful for determining whether functional testicular tissue is present.

◆ Treatment of Delayed Puberty

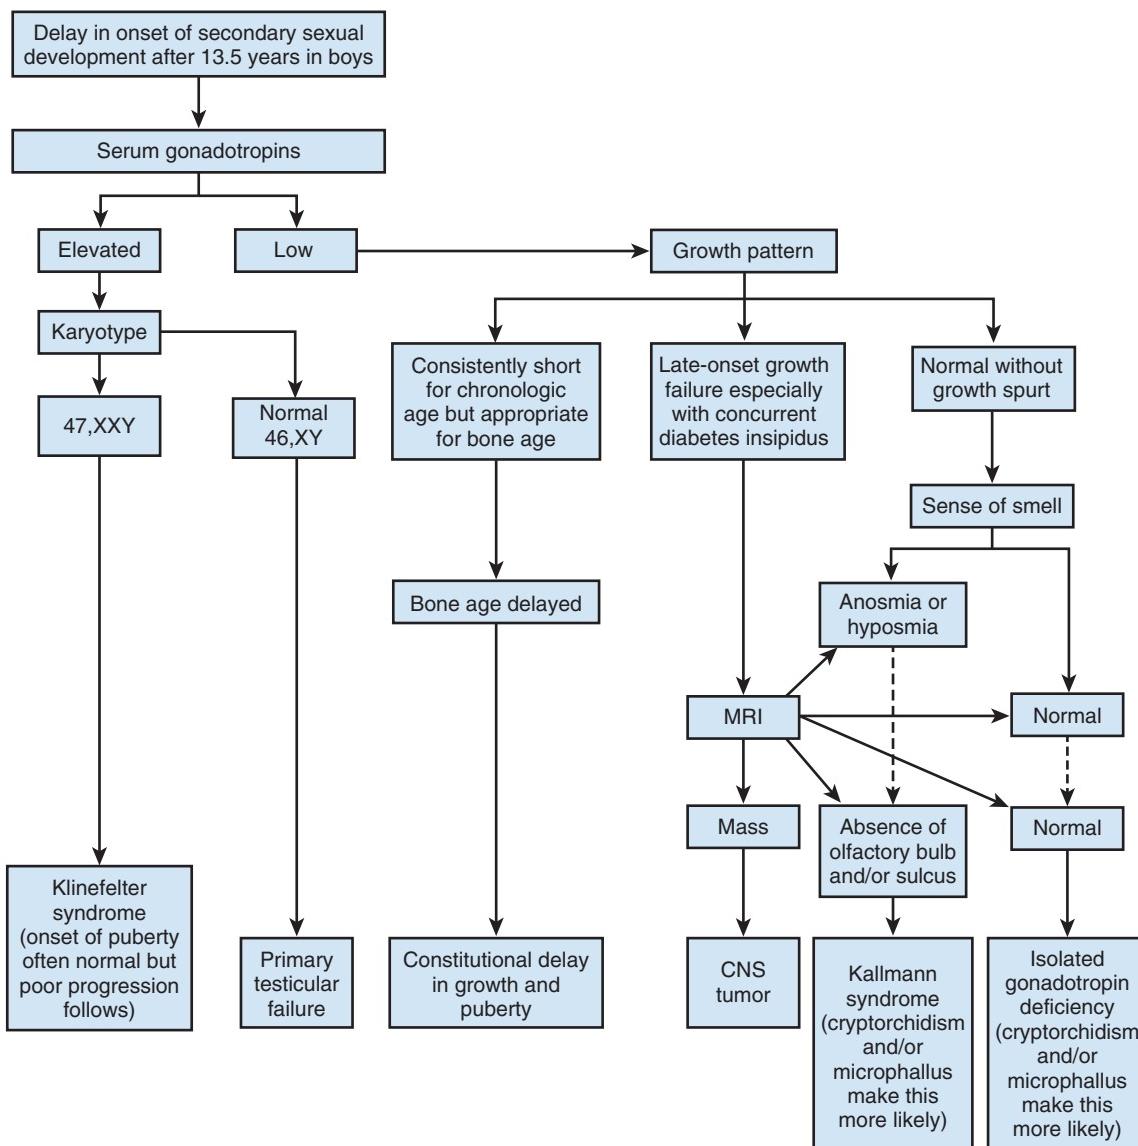
If delayed puberty is **physiologic**, there is no medical necessity for initiating sex steroid replacement. "Watchful waiting" is usually the appropriate course of action. Adolescent males with constitutional


FIGURE 42.6 Flow chart for the evaluation of delayed puberty in males. A brain MRI with absent olfactory bulb and/or sulcus is consistent with Kallman syndrome, while a normal MRI suggests Isolated gonadotropin deficiency. CNS, central nervous system; MRI, magnetic resonance imaging. (From Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, editors. *Williams Textbook of Endocrinology*. 13th ed. Philadelphia: Elsevier; 2016:1156.)
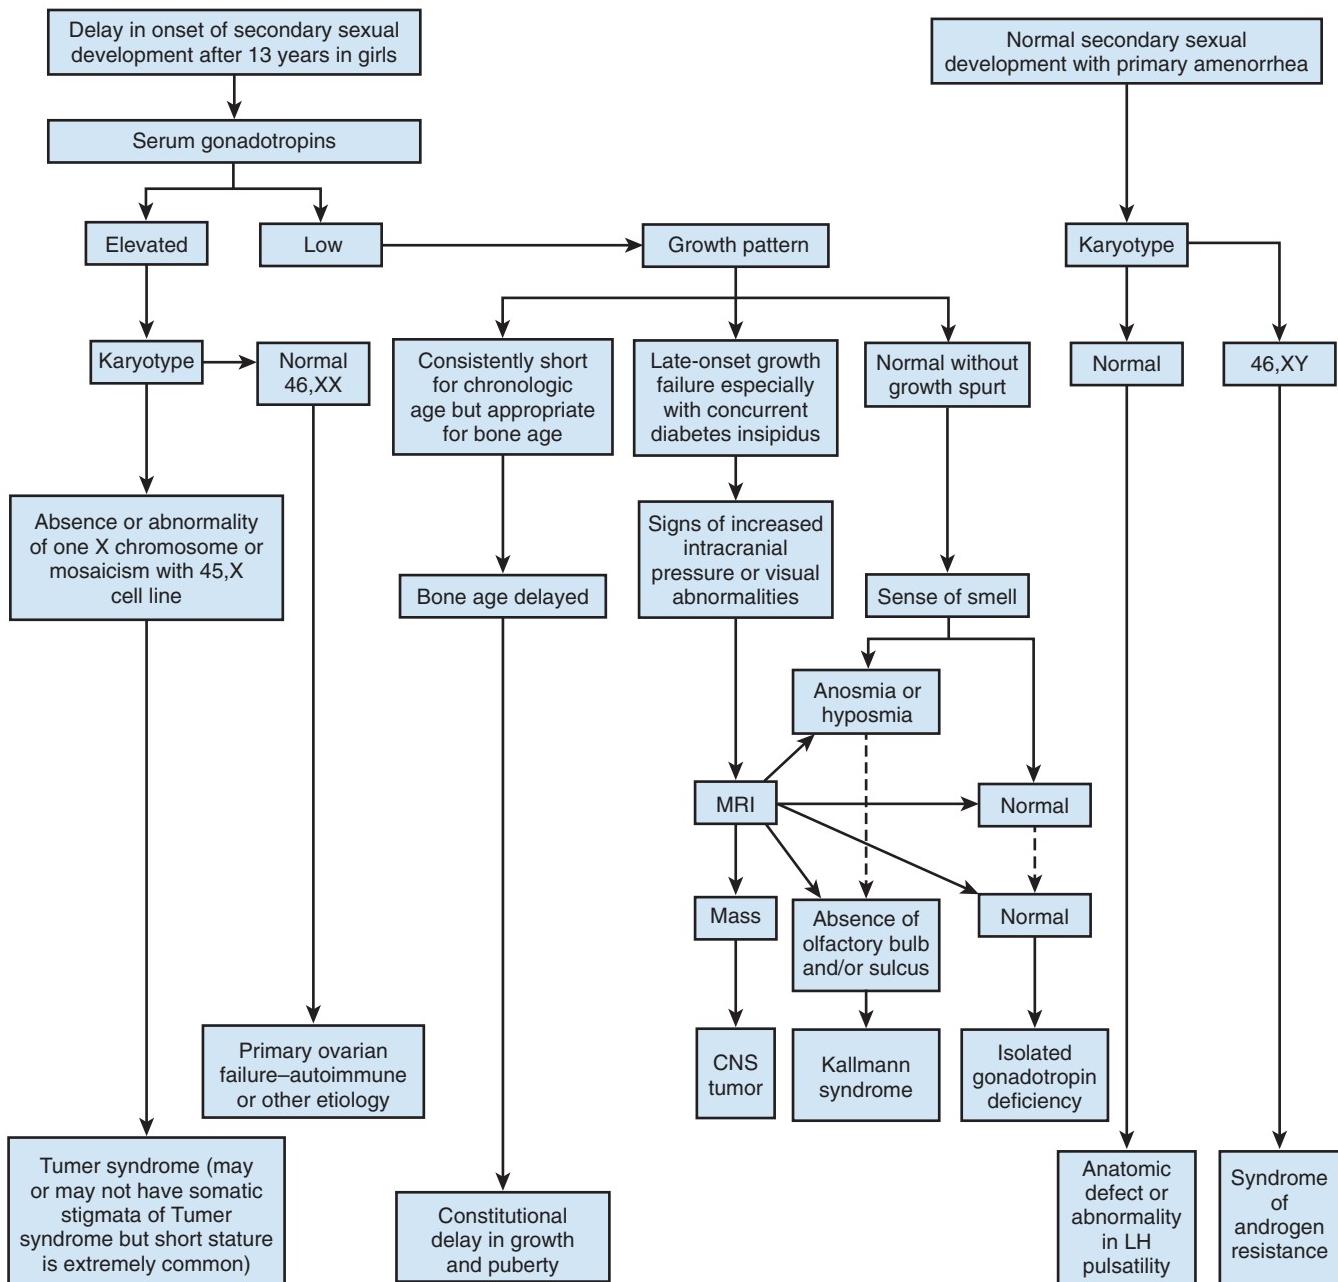

FIGURE 42.7 Flow chart for the evaluation of delayed puberty in females. A brain MRI with absent olfactory bulb and/or sulcus is consistent with Kallman syndrome, while a normal MRI suggests Isolated gonadotropin deficiency. CNS, central nervous system; LH, luteinizing hormone; MRI, magnetic resonance imaging. (From Melmed S, Polonsky KS, Larsen PR, Kronenberg HM, editors. *Williams Textbook of Endocrinology.* 13th ed. Philadelphia: Elsevier; 2016:1157).

delay of growth and puberty who are short, underdeveloped, and psychologically compromised frequently benefit from a short course of testosterone therapy. This is usually given as long-acting intramuscular testosterone at a dosage of 50-100 mg every 3-4 weeks for a course ranging between 3 and 12 months. Treatment is generally begun at about 13 years of age, and if possible, when the testes are about 6-8 mL in volume. These doses stimulate height and weight gain, allow adequate virilization (increased pubic and axillary hair growth and penile enlargement), and do not typically suppress pituitary FSH and LH secretion, thereby allowing simultaneous endogenous pubertal progression (testicular enlargement). This narrows the physical gap between the patient and peers without causing undue advancement of bone age. Acne is the principal side effect and the adult height is not

altered. It is the hope that at the conclusion of treatment, the male will continue to grow and develop rapidly with the testosterone treatment perceived as a "jump starter" of endogenous puberty. A short course of low-dose anabolic steroids, such as oxandrolone or fluoxymesterone, can also be employed in prepubertal and pubertal males, and low-dose estradiol has been used in prepubertal and pubertal females with constitutional delay.

Treatment of **hypogonadism** is aimed at mimicking normal physiology with stepwise replacement of testosterone in males and estrogen and progesterone in females. For males with hypogonadism, low-dose parenteral testosterone is initiated at 50 mg every 3-4 weeks, with increases in 50-mg increments made over a 2- to 3-year period. Most adult men receive 200 mg every 3-4 weeks, which is based on the daily

TABLE 42.13 **Red Flags Related to Puberty**
Pubertal changes in African-American girls beginning before age 6 yr (excluding isolated thelarche from birth to 2 yr of age)
Pubertal changes in white girls beginning before age 7 yr (excluding isolated thelarche from birth to 2 yr of age)
Pubertal changes in all boys beginning before 9 yr of age
Absence of pubertal changes in girls by 13 yr of age
Absence of pubertal changes in boys by 14 yr of age
Neurologic signs and symptoms (headaches, visual disturbances)
Vaginal bleeding before breast development
Significantly asymmetric gonadal size in either sex (boys, by clinical examination; girls, by pelvic ultrasonography)
Testicular underdevelopment
Girls with advancing breast development but no androgen signs
Galactorrhea
Pelvic mass

TABLE 42.14 **Things Not to Miss with Regard to Puberty**

Size of testes in patients with gynecomastia
Other endocrine deficiencies or excesses

adult male testosterone production rate of 6 mg. Some adult men are treated with 300 mg every 2 weeks. Adult men can use testosterone by patch, which is often associated with local irritation, or by gel, but typically in growing adolescents, intramuscular testosterone is prescribed.

For females, daily estrogen therapy is given for 1 year. This can be either in the form of conjugated estrogens (Premarin) at 0.3 mg daily for the 1st 6 months and 0.625 mg daily for the 2nd 6 months, or with an analogous schedule of ethinyl estradiol replacement or through a weekly applied 17β-estradiol patch. This duration does not place the uterus at undue risk for hyperplasia and malignancy, but after 2 years of therapy (or if spotting occurs prior), progesterone should be added. Options to consider when adding progesterone include continuing the purely estrogen-containing pills (conjugated estrogens or ethinyl estradiol) or the 17β-estradiol patches in conjunction with oral medroxyprogesterone acetate (Provera) or switching the patient over to conventional oral contraceptives. If the patient is not put on a conventional oral contraceptive, the estrogen (pill or patch) is prescribed days 1-23 of the calendar month with addition of medroxyprogesterone acetate on days 10-23. With this approach, withdrawal bleeding generally occurs between day 23 and the end of the month, although there can be some variability in the timing between patients.

Patients of either sex with hypogonadotropic hypogonadism are potentially fertile, but sex steroid therapy alone is ordinarily not sufficient to initiate gametogenesis, although there are rare cases in males in which testosterone replacement alone has stimulated spermatogenesis. The general approach to fertility induction in either sex involves the addition of either cyclic gonadotropin therapy or pump-driven GnRH therapy at the age of desired conception. *Finally, if hypogonadotropic hypogonadism is present as 1 component of hypopituitarism, it is critical to adequately replace all deficient hormones.* In contrast, patients with primary hypogonadism have intrinsic gonadal damage and are normally infertile.

SUMMARY AND RED FLAGS

Early, late, or asynchronous puberty can indicate underlying pathology. Red flags related to puberty are listed in Table 42.13. Important findings not to miss are listed in Table 42.14.

Short Stature

Omar Ali

Short stature (usually defined as height >2 standard deviations [SD] below the mean for age) and growth failure (a subnormal height velocity that leads to a decline in growth percentiles, usually a height velocity >1.5 SD below the mean for age) are *symptoms, not diseases*. Of the 2, short stature is more likely to be noticed but growth failure is more likely to be pathologic.

Short stature may represent a normal variant or may be a signal of serious physical or emotional illness. Because linear growth is a crucial component of childhood, growth is in many ways an index of childhood well-being. Illnesses, even those not involving aberrations of growth-regulating hormones, often interfere with growth. Therefore, the measurement and charting of heights sequentially on standardized growth charts constitute a central part of a child's medical evaluation and the finding of short stature, particularly if associated with a subnormal height velocity, deserves close attention and appropriate evaluation.

DEFINITION

Short stature is defined as height more than 2 SD below the mean for age, which is at the 2.3 percentile (Fig. 43.1*A, B*). On growth charts (and in clinical practice) it is more common to define short stature as height below the 3rd percentile for age, which is −1.88 SD. Implicit in this definition is the understanding that height is a normally distributed characteristic; therefore, a proportion of normal individuals have heights >2 SD from the mean. Since height is strongly heritable (i.e., a large proportion of the observed variation between individuals is hereditary), stature that is inappropriately low for the child's genetic endowment may also be a cause for concern.

Growth failure is defined as a subnormal rate of growth, or a height velocity that is below the norm for that age. Since sustained height velocity below the 25th percentile is insufficient to maintain a child's position on the growth chart, growth failure is sometimes defined as a height velocity below the 25th percentile for age. Other authorities prefer to use >1.5 SD below the average height velocity for that age as the cutoff.

Short stature should be distinguished from "failure to thrive." The latter term refers primarily to *poor weight gain* in infants and young children (although linear growth may be secondarily affected), whereas short stature refers primarily to subnormal linear growth in childhood and adolescence.

NORMAL GROWTH

Height is highly heritable, but the genetic program underlying this regulation is not fully understood. The growth of individual organs as well as the growth of the skeleton as a whole is regulated by negative feedback mechanisms that slow and eventually stop growth as organs and the organism reach their final size. This gradual deceleration of growth with age does not appear to be driven primarily by changes in the endocrine system since levels of growth hormone (GH) and the insulin-like growth factors remain elevated even as growth slows in the latter part of puberty. The final height and growth pattern of any given individual are affected by subtle variations in large numbers of many genes, while more significant variants in *individual* genes cause the various genetic forms of short stature and **skeletal dysplasias**.

Fetal Growth and Birth Size

A human being experiences his or her most rapid linear growth in the *prenatal* period (growing from near zero to about 50 cm in length in just 9 months). While genetic factors play a major role in postnatal growth, *fetal* growth and birth size mainly reflect maternal and placental factors, including maternal or uterine size, parity, multiparity, nutrition, and placental function. Many congenital disorders such as Turner syndrome and congenital GH deficiency that markedly stunt postnatal growth have only minimal effects on prenatal growth and birth size. Therefore, birth size is generally a poor predictor of the eventual growth pattern in most children. An exception is the neonate who is small for gestational age (SGA) as a result of **intrauterine growth restriction (IUGR)**. While most infants with IUGR (caused by nutritional problems or poor placental function) show catch-up growth (a period of rapid growth that occurs spontaneously after relief from the adverse intrauterine condition that had suppressed the rate of growth), 10-20% remain shorter than expected beyond infancy and early childhood, making IUGR 1 of the possible causes of childhood short stature.

Postnatal Growth Patterns

Infancy is also a period of relatively rapid growth (faster than at any other time in postnatal life). Growth then gradually slows as the infant gets older, declining to its lowest point just before puberty, before accelerating again during the pubertal growth spurt, and finally ending with the completion of linear growth about 5 years after the onset of puberty (Table 43.1 and Fig. 43.2).

Since birth length is mostly determined by maternal and placental factors, size at birth may not reflect the infant's genetic growth potential. It is during the 1st 2 years of life that infants gradually transition from their birth size to their own genetically determined height potential. Therefore, it is normal for infants to shift linear growth percentiles during this period; 65% of infants will exhibit such shifts, moving up or down on the growth chart. By 24 months, these shifts are complete and most children have entered a specific "growth channel" or linear growth percentile in relation to peers and any significant deviation from this channel should evince concern.

After a period of slow but steady growth during childhood, many children experience a further "prepubertal dip" in height velocity,

TABLE 43.1   Growth Velocity at Various Ages

Age Interval	Average Height Velocity
Prenatal	66 cm/yr
0-1 yr	25 cm/yr
1-2 yr	12 cm/yr
2-3 yr	8 cm/yr
3-5 yr	7 cm/yr
5–onset of puberty	5-6 cm/yr
Pubertal growth spurt	Girls 8-12 cm Boys 10-14 cm

reaching a nadir just before the onset of puberty. Height velocity then accelerates once again as puberty advances. This acceleration of growth during puberty reaches a peak known as the "pubertal growth spurt." The timing of the pubertal growth spurt differs between girls and boys. Females generally begin pubertal development at 10-11 years of age and their pubertal growth spurt starts coincidentally with breast development and peaks before menarche. For females with an average tempo of puberty, peak growth velocity (8-9 cm/yr) is reached at 11-12 years of age. After menarche (which generally occurs 2-2.5 years after

the onset of puberty), the growth rate declines and growth finally stops about 2 years after menarche, with girls gaining an average of 7 cm in height after menarche.

In males, testicular enlargement is generally the 1st sign of puberty and occurs at approximately 11.5 years on average (range, 9-14.3 years). In males with an average tempo of pubertal development, peak growth velocity occurs about 2 years after the onset of puberty (so, later than girls in absolute terms, as well as in terms of the stage of puberty) at approximately 13-14 years, with an average rate of 10.3 cm (4 inches)/yr. It is worth noting that prepubertal males and females grow at very similar rates; the ultimate taller stature of males relative to females is mostly the result of a longer period of growth and a higher peak growth velocity during puberty.

These are the *average* timings of puberty and pubertal growth, but it should be kept in mind that there are large variations in the timing of puberty—and therefore, in growth rates—among individuals of the same age during the period of adolescence.

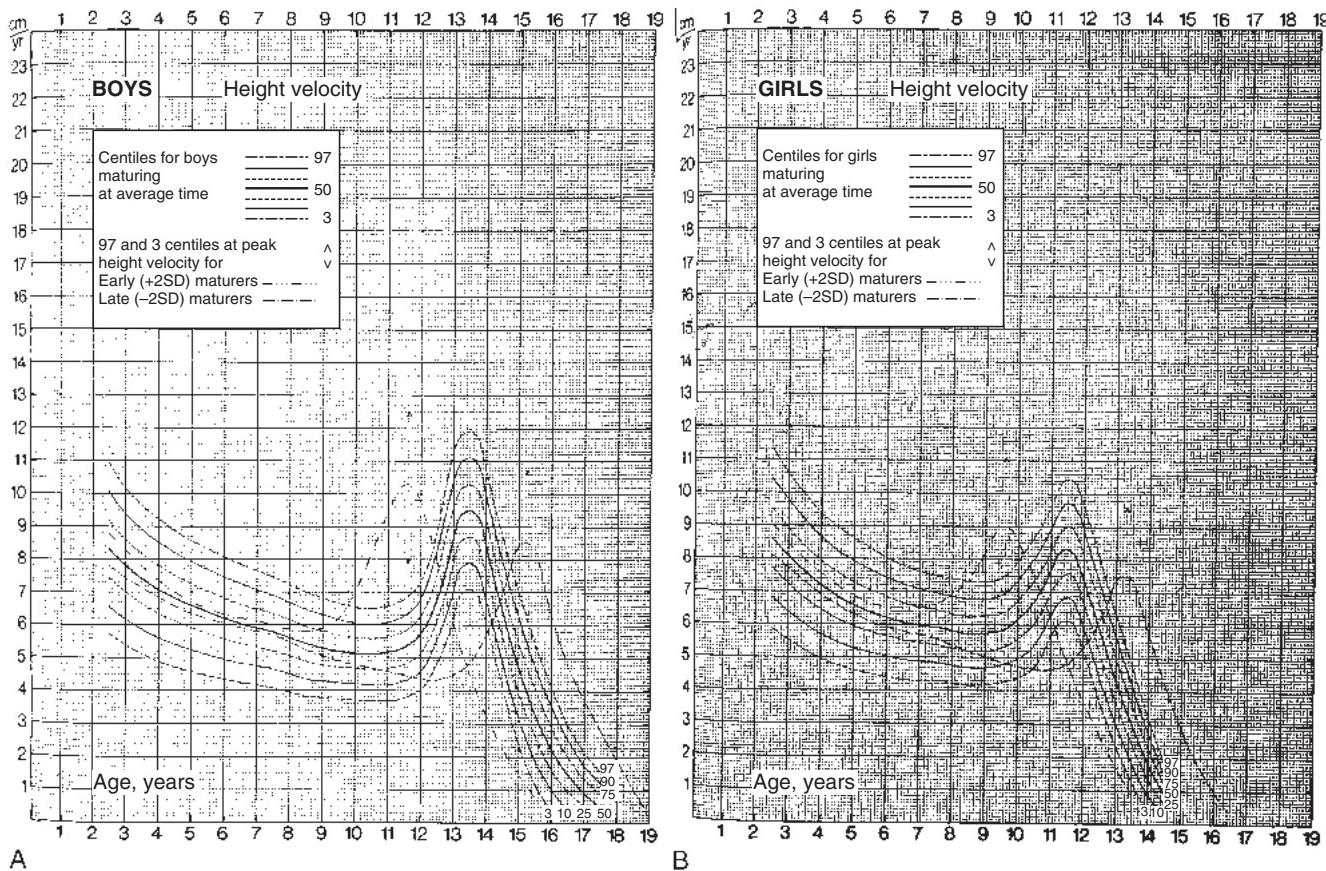
Because of these characteristic patterns of growth during childhood and adolescence, the rate of growth (centimeters per year or inches per year) is a key variable in evaluating a short child. Growth rates may vary somewhat with season and can be affected by transient illness, but a child should maintain a relatively set growth channel on the linear growth percentile charts after 2-3 years of age. A persistently slow rate of growth in relation to age-appropriate norms is alarming and is likely to reflect an underlying medical disorder.


FIGURE 43.2. *A,* Height velocity for American boys. Lines with early velocity refer to the 50th percentile for boys 2 standard deviations (SD) early in growth tempo; lines with late or gradual velocity refer to the 50th percentile for boys 2 SD late in growth tempo. ^ and v, 97th and 3rd percentiles for peak velocities of early and late maturers, respectively. *B,* Height velocity for American girls. Lines with early velocity refer to the 50th percentile for girls 2 SD early in growth tempo; lines with late or gradual velocity refer to the 50th percentile for girls 2 SD late in growth tempo. ^ and v, 97th and 3rd percentiles for peak velocities of early and late maturers, respectively. (Modified from Tanner J, Davies P. Clinical longitudinal standards for height and height velocity in North American children. *J Pediatr.* 1985;107:317-329.)

MEASURING A CHILD

Stature is evaluated as supine length until 2 years of age and as standing height thereafter (Fig. 43.3). For measurement of supine length, an infant lies on an inflexible ruled horizontal surface, at 1 end of which 1 person holds the infant's head in contact with a fixed board; a 2nd person extends the infant's legs as much as possible and brings a movable plate in contact with the infant's heels. Recumbent measurements average 1 cm (0.4 inch) more than standing height.

After 2 years of age, children are measured standing and barefoot with a device such as a Harpenden stadiometer; a vertical metal bar is affixed to an upright board or wall, and height is measured at the top of the head by a sliding perpendicular plate or block. *Measurements of length using pen marks on the examining table at the head and foot of an infant are often grossly inaccurate, as are height measurements using a flexible metal rod atop a standard weight scale.*

With the use of optimal techniques, the variation in measurement among observers is less than 0.3 cm (0.1 inch). It is then possible to determine changes in height over 3- to 4-month intervals to estimate the annualized growth rate. However, because of normal seasonal variations in growth rates, a longer interval between measurements (6-12 months) is more reliable in the calculation of height velocity.

Measurements are then plotted on standard growth charts; it is recommended that World Health Organization (WHO) growth charts be used for infants from birth to 2 years of age and Centers for Disease Control and Prevention (CDC) growth charts for children from ages 2-18 years (see Fig. 43.1). These CDC and WHO growth charts are available at: http://www.cdc.gov/growthcharts/ and http://www.who.int/childgrowth/standards/en/.

Calculated growth rates (centimeters per year or inches per year) should be evaluated in relation to age-related norms with growth velocity charts for North American children for children over 2 years of age (see Fig. 43.2).

Body Proportions

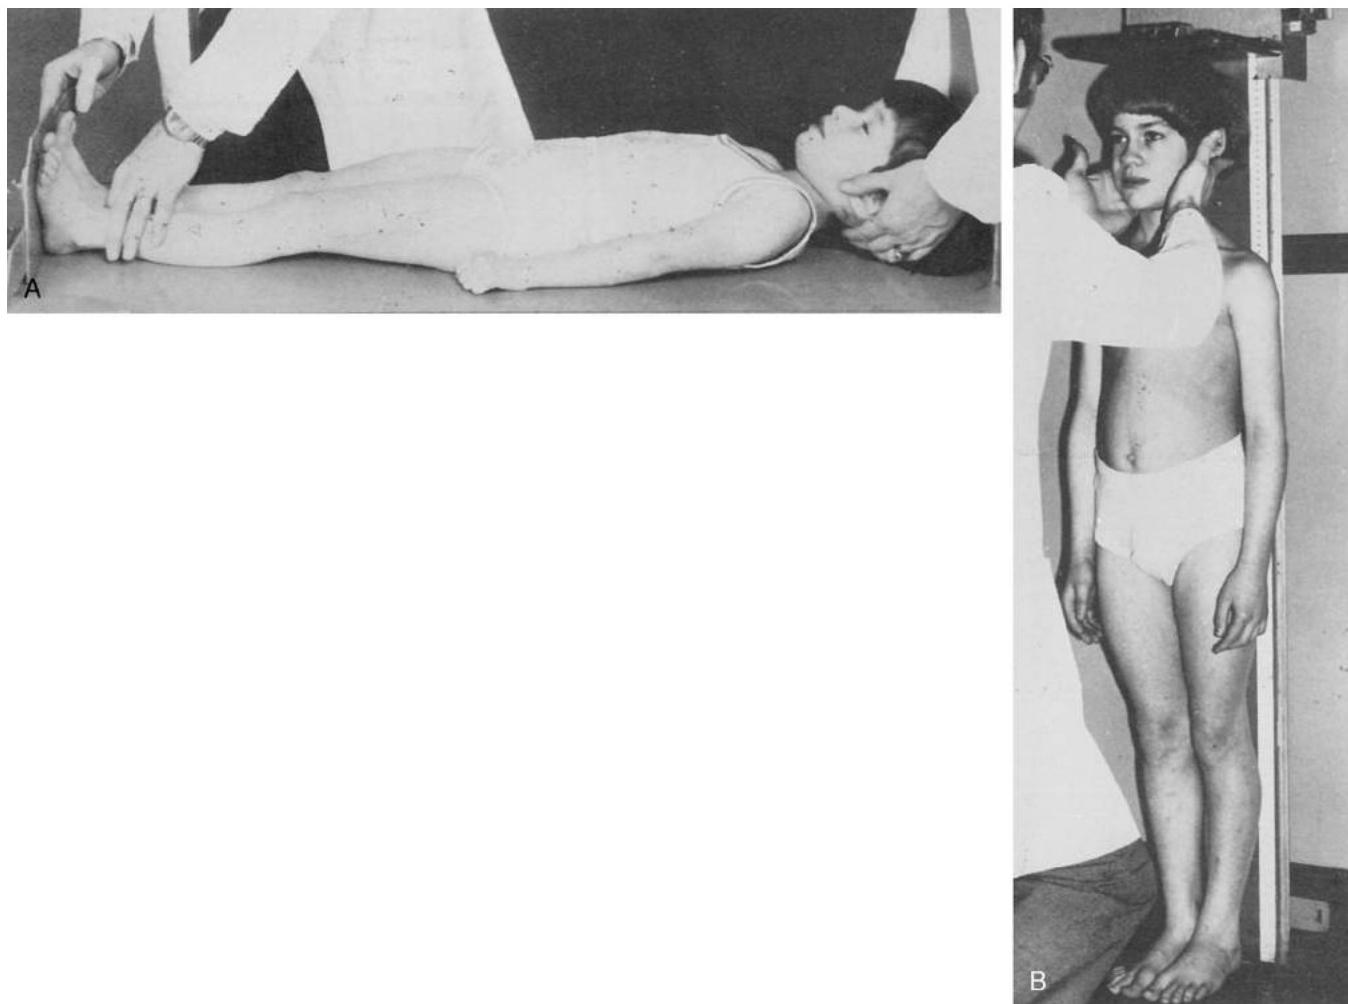
Apart from linear height, it is also useful to assess the upper-to-lower segment ratio (U/L) (Fig. 43.4) and the arm span. The U/L is determined by measuring the lower segment (vertical distance between the symphysis pubis and the floor, with the child standing) and the upper segment (the difference between the lower segment and height). Arm span is the distance between the outstretched middle fingertips with the child standing against a flat board or wall. The U/L and arm span are used to determine whether the child is normally proportioned or not (in Europe, it is more common to assess sitting height versus standing height for the same purpose).


FIGURE 43.3 *A,* Technique for measuring length. *B,* Technique for measuring erect height. (From Wilson JD, Foster DW, eds. *Williams Textbook of Endocrinology.* 8th ed. Philadelphia: WB Saunders; 1992: 1106-1107.)

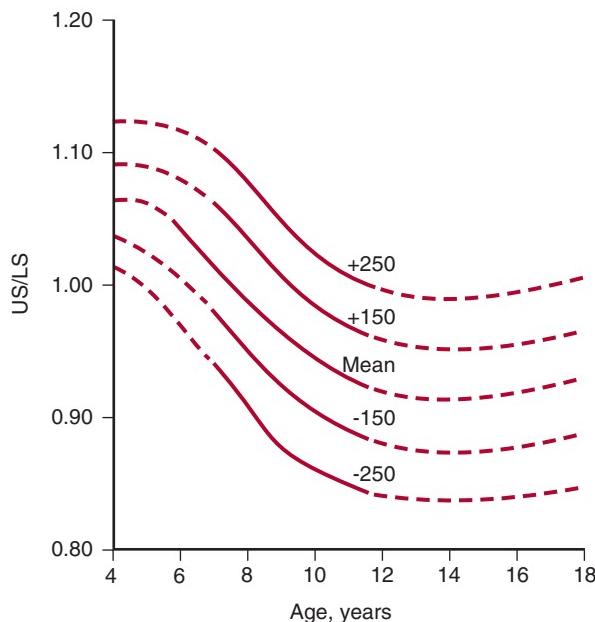

FIGURE 43.4. Normal upper-to-lower segment ratios (US/LS) for white children. (From McKusick V. *Hereditable Disorders of Connective Tissue.* 4th ed. St. Louis: CV Mosby; 1972.)

The U/L gradually declines with age throughout childhood. Since infants have relatively short legs, the U/L is high (an average of 1.7) at birth. It then declines throughout childhood as the legs increase in length relative to the upper body, decreasing to a mean of 0.9 by late puberty (in males; in females, the ratio may be closer to 0.95). The arm span as compared to the height is another measure of body proportions and is normally shorter than the height in younger children and increases to become slightly longer than the height by late puberty (about 5 cm more than height in boys, 1.2 cm more than height in girls). Deviations from the norm in the U/L and the arm span may point to conditions such as skeletal dysplasias, Turner syndrome, or long-standing hypothyroidism (increased U/L segment ratio, i.e., relatively short extremities) and radiation-induced spinal damage or genetic disorders such as Klinefelter or Marfan syndromes and homocystinuria (low U/L segment ratio, due to a relatively short trunk or unusually long extremities).

Weight should also be considered in relation to a child's stature. Undernutrition is generally caused by nonendocrine factors (poor nutritional intake, malabsorption, systemic illness) and typically leads to a decrease in weight before a decrease in linear growth. Obesity in childhood is usually exogenous; exogenous obesity is generally associated with an accelerated growth rate. In contrast, endocrine disorders that cause poor growth and short stature are often associated with weight gain and obesity (Cushing syndrome, hypothyroidism, and in

some instances, GH deficiency). Therefore, the obese child who has a slow growth velocity is more likely to have an endocrine cause of short stature, while the undernourished child with short stature likely has short stature secondary to poor weight gain and is unlikely to have an endocrine disorder.

Familial and Genetic Factors

Both parental height and parental pattern of growth are key determinants of a child's growth pattern. This strong familial influence on height is not detectable at birth but is manifested by 2-3 years of age. Final adult height is strongly heritable with heritability estimates ranging from 0.8-0.95 (i.e., 80-95% of the observed variation is explained by hereditary rather than environmental factors). The mid-parental height (MPH) is used as a measure of the child's genetic growth potential and is an average of the height of both parents *after correcting for sex*. Since the average adult male is taller than the average adult female by 13 cm (5 inches), 13 cm is added to the mother's height in the case of a male child, while 13 cm is subtracted from the father's height in the case of a female child; the parental heights, after correction for sex, are then averaged to obtain the MPH.

Thus MPH is determined in the following manner:
Males: [father's height in cm + (mother's height in cm + 13 cm)]/2
Females: [(father's height in cm − 13 cm) + mother's height in cm]/2

The MPH is a good index of the child's genetic height potential, but tends to become less accurate if 1 parent is unusually tall or short; that is, the offspring of an exceptionally tall parent or exceptionally short parent will be closer to the average height than is predicted by the MPH because of the phenomenon of *regression to the mean*.

In addition to the influence on final adult height, parents' *patterns* of growth are also often repeated in their children. In particular, many men who were "late bloomers" with delayed onset of puberty and delayed but normal growth spurts have sons with similar growth patterns.

Ethnic Factors and Secular Trend

The average height of various populations across the globe is not the same; in the current era, Northern European populations are taller than many (but not all) other ethnic groups, and it therefore seems to make sense to use population-specific standards of growth because a child from a generally short ethnic group may be labeled as "short stature" by Northern European standards, but may be normal for his or her own ethnic group. Two additional observations need to be kept in mind:

1. Migrants from countries where the average height is lower tend to have children who are taller than their parents when they move to a country with a higher standard of living. This indicates that at least some of the observed height difference may be environmental (most likely related to nutrition and childhood disease burden) and that this height difference may shrink or disappear in subsequent generations.
2. The Northern European populations were themselves much shorter in the 18th and 19th centuries and average heights have steadily increased as living standards improved (reflecting improvements in nutrition and other public health measures). This "secular trend" in height slows down and plateaus over time, but is much more marked in populations that have recently seen an improvement in living standards.

Thus practitioners should make allowances for ethnic differences in height when evaluating children from different ethnic backgrounds, but should not automatically assume such differences as the sole explanation for short stature in children from historically shorter populations. Growth velocity in particular should not be abnormal even in historically shorter populations, and a subnormal growth velocity should trigger an evaluation in the same way as it would in children from a Northern European background.

General Well-Being

Because growth is a barometer of a child's health, general well-being and freedom from serious illness are necessary for a child to achieve his or her genetic growth potential. Chronic illnesses that are not primarily problems of stature often interfere with growth secondarily, and short stature may be the presenting feature of such conditions as inflammatory bowel disease, celiac disease, and renal disease.

Psychologic Factors

Under normal circumstances, emotional and psychologic factors do not have a great effect on growth. However, in certain cases, emotional deprivation can lead to very significant growth failure (sometimes labeled "deprivation dwarfism" or "psychosocial dwarfism") via mechanisms that are still poorly understood.

Endocrine Regulation of Growth

GH is produced by the anterior pituitary under the control of GH-releasing hormone (GHRH) from the hypothalamus, and is essential for normal growth in childhood and adolescence (though it appears to play a relatively small role in prenatal growth). GH is secreted in brief pulses and peak secretion occurs during sleep, so random serum levels have little utility in the evaluation of GH deficiency except in the newborn period (when random GH levels are usually elevated, and a level below 7 ng/mL is very likely to reflect GH deficiency).

GH exerts its growth-promoting effect through stimulating the production of **insulin-like growth factor 1 (IGF-1)** (primarily in the liver, but also in some target tissues) as well as via direct actions of GH on bone. Most circulating IGF-1 is bound to IGF-binding proteins, with the largest proportion being bound in a ternary complex with **IGF-binding protein-3 (IGFBP-3)** and a protein named the acid-labile subunit (ALS). Because IGF-1 levels in the blood are stable throughout the day and reflect the integrated effect of GH secretion, measurement of IGF-1 is often used as a surrogate measure of GH secretion.

Thyroid hormone also has a relatively limited role in prenatal growth, but is absolutely essential for normal postnatal linear growth, both via direct actions on the epiphyseal growth plate and via a permissive effect on GH secretion. **Hypothyroidism** can therefore lead to very profound growth failure and an evaluation of thyroid hormone status is essential in the investigation of growth failure.

Glucocorticoids do not play any significant role in promoting growth, but are powerful inhibitors of growth when present in excess. Persistent exposure to excess corticosteroids (whether endogenous or exogenous) can lead to very severe growth failure (along with significant weight gain). Deficiency of glucocorticoids generally does not adversely affect growth if the child is otherwise healthy.

Sex steroids mediate the pubertal growth spurt (see Chapter 42). This involves direct effects of sex steroids on bone growth as well as steroid-induced amplification of GH secretion. Most of the bone-maturing action of sex steroids is mediated by estrogen in *both* sexes; while testosterone has some direct effects on bone strength and thickness, most of the effects of testosterone on linear growth and the maturation of growth plates in males occur via the action of estrogen produced by the peripheral conversion of testosterone. Consequently, even in males, bone maturation can be affected by genetic defects in the production or action of estrogen, as well as by pharmacologic inhibition of this pathway (e.g., by using aromatase inhibitors that block the conversion of testosterone to estrogen). **Sexual precocity** (true precocious puberty, exogenous exposure, or congenital adrenal

hyperplasia) tends to accelerate linear growth transiently as a result of premature or excessive production of sex steroids (or both) (see Chapter 42). But if left untreated, these conditions advance osseous maturation, leading to premature epiphyseal fusion and a short final adult height. The absence of sex steroids (hypogonadism) in the absence of other abnormalities blunts the pubertal growth spurt, but tends not to limit final height, as bone maturation and epiphyseal fusion are also delayed by the lack of estrogen in these patients.

Bone Age

Osseous maturation follows a very predictable pattern during the growth and development of the child, and a radiograph of the *non-dominant hand* can be used to assess bone age (i.e., the degree of maturation of the bones compared to age-matched standards). Bone age is usually estimated by comparing the child's radiologic findings with a standard set of radiologic images, or by using various scoring algorithms. These readings are subject to observer bias and error but are still useful as long as this inherent subjectivity is kept in mind. Bone age is very closely correlated with pubertal maturation and an assessment of bone age can be especially useful in cases of precocious puberty, delayed puberty, and constitutional growth delay. Except in cases of precocious puberty, bone age is rarely useful in the evaluation of short stature in a child less than 5 years of age.

CAUSES OF SHORT STATURE

Understanding the factors that influence childhood growth leads directly to an understanding of the causes of short stature and to the differential diagnosis of short stature for an individual child (Tables 43.2, 43.3, 43.4, 43.5, and 43.6). While a very large number of conditions can potentially lead to short stature and growth failure, the vast majority of children with short statures are either normal variants (familial short stature, constitutional delay of growth and puberty) or have no discernible cause (idiopathic short stature [ISS]). It is also important to remember that the child with *growth failure* is far more likely to have an underlying pathology than a child who happens to be short but has a normal growth velocity.

Normal Variants

The 2 most frequent causes of short stature in children are **familial short stature** and **constitutional delay of growth and puberty**. These are considered normal variants and their recognition can help avoid expensive and unnecessary testing and interventions.

Familial Short Stature

The term "familial short stature" is usually reserved for familial forms of mild-to-moderate short stature that do not have a specific identifiable genetic defect; since hundreds of genes play a role in growth, this height potential likely reflects the influence of multiple loci of small effect or a few loci of relatively moderate effect. Genetic disorders that result in severe short stature, or that are associated with other abnormal physical findings (syndromes), or that are caused by known genetic defects, are conventionally treated separately from familial short stature.

The child's height is in keeping with the genetic endowment, and the child is otherwise healthy. Typically, 1 or both parents (and often other family members) are about 1.5-2 SD below the mean in height. This relatively short genetic potential is reflected in the short MPH, and if the child continues to grow along his or her current percentile, he or she would fall within 9 cm of this height (approximately within 2 SD of the MPH); by age 2, the child is usually noted to be small in relation to peers. Although the growth channel is low, it should *parallel*

the normal growth curve from that point onward. Continued deviation away from the normal growth curve (indicating a subnormal growth velocity) is *not* typical and should raise concerns about a disorder other than familial short stature. Stature that is extremely low (2.5-3 or more SD below the mean) raises concerns even if the parents are short, since this degree of short stature may reflect a specific genetic cause of short stature (e.g., a mild defect in GH secretion or action, or a form of hypochondroplasia) in the parents as well as the child.

The review of systems is generally negative in the otherwise healthy child, as are the physical examination findings (aside from short stature). The height-to-weight ratio, body proportions, muscularity,

TABLE 43.4 Established Genetic Defects of the GH-IGF Axis Resulting in IGF Deficiency

Mutant Gene	Inheritance	Phenotype
HPA		Developmental abnormalities
HESX1	AR	Septo-optic dysplasia; variable involvement of pituitary hormones
PROP1	AR	GH, PRL, TSH, LH, FSH deficiencies; variable ACTH deficiency
POU1F1 (Pit1)	AR, AD	GH, PRL deficiency; variable degree of TSH deficiency

and pubertal development are normal for age. Abnormalities found on review of systems or physical examination should prompt consideration of other diagnoses.

Laboratory studies are not mandatory, but if done are all normal. The bone age is also normal, and this suggests that the short child's "room for growth" is not greater than that of other children of the same age. Prediction of adult height can be made on the basis of bone age, but the accuracy is variable; the predicted height is within 9 cm of the MPH.

Constitutional Delay of Growth and Puberty

Constitutional delay of growth and puberty is a growth pattern that is also considered a variant of normal. These children appear to have a

slowed maturational pattern and their bone age is delayed relative to their peers. As part of this slowed maturation, they also enter puberty later than their peers. This variant occurs in both sexes but is more common in males and is recognized predominantly in them for this reason, as well as for cultural reasons.

These children often begin to show moderate short stature (height, −1.5 to −2.5 SD) during early-to-middle childhood but are otherwise healthy. They have delayed onset of puberty and therefore a delayed growth spurt. One or both parents (or other family members) may have a history of delayed puberty and a late adolescent growth spurt, with eventual cessation of growth during late adolescence or even into the 3rd decade of life. The affected parent usually is of normal adult stature. Otherwise, the history and review of systems are negative. The physical examination findings are normal except for delayed onset of puberty in children of an appropriate age.

Laboratory tests are not mandatory but are normal if performed, with the important exception of a delayed bone age (bone age < chronologic age). It is important to note that IGF-1 levels normally increase with onset of puberty and should be compared with standards for the child's pubertal stage and bone age rather than his or her chronologic age. A delayed bone age suggests that the child has more "room to grow" than the average age-matched child and that the child is likely to reach an adult height taller than that suggested by the current height percentile. Some children have *mixed* familial short stature and constitutional delay in growth and development; they tend to have both delayed puberty and a short predicted adult height.

Chronic illness may mimic constitutional delay in growth and development and should be considered in the differential diagnosis. It is sometimes difficult to distinguish children with constitutional delay in growth and development from the more unusual condition of central (hypothalamic/pituitary) hypogonadism; a positive family history of delayed but normal puberty and growth, a normal sense of smell (to exclude Kallmann syndrome), and normal neurologic findings favor constitutional delay. Evaluation for permanent **central hypogonadism** is indicated if puberty fails to begin by the age of 13 years in females or 14 years in males, particularly if there is no family history of constitutional growth delay.

Females with delayed puberty are more likely to have an underlying pathologic cause, so the threshold for investigation is lower in females. On the other hand, benign constitutional delay is common in males,

---

TABLE 43.5 Proposed Classification of Growth Hormone (GH) Insensitivity

Primary GH Insensitivity (Hereditary Defects)
1. GH receptor defect (may be positive or negative for GH-binding protein)
   - Extracellular mutation (e.g., Laron syndrome)
   - Cytoplasmic mutation
   - Intracellular mutation
2. GH signal transduction defects (distal to the cytoplasmic domain of the GH receptor)
   - STAT5B mutations
3. Insulin-like growth factor-1 defects
   - IGF-1 gene deletion
   - IGF-1 transport defect (acid labile subunit [ALS] mutation)
   - IGF-1 receptor defect
4. Bioinactive GH molecule (responds to exogenous GH)

Secondary GH Insensitivity (Acquired Defects)
   - Circulating antibodies to GH that inhibit GH action
   - Antibodies to the GH receptor
   - GH insensitivity caused by malnutrition, liver disease, catabolic states, diabetes mellitus
   - Other conditions that cause GH insensitivity

TABLE 43.6 Genetic Syndromes Associated with Short Stature

Selected Genetic Disorders Associated with Short Stature		
Condition	**Genetics**	**Features (Not All Are Present in Every Case)**
Turner syndrome	45,XO and variants	Short stature, lymphedema of hands and feet at birth, low posterior hairline, webbed neck, shield chest, cubitus valgus, clinodactyly, short 4th metacarpal, Madelung deformity
Noonan syndrome	*PTPN11, SOS1, RAF1, KRAS, SHOC2, BRAF, NRAS, RIT1, CBL, KATB6, LZTR1, SOS2*	Short stature, hypertelorism, downslanting eyes, low-set ears, webbed neck, chest deformity (pectus excavatum), cryptorchidism, intellectual disability, lymphedema
Prader–Willi syndrome	Paternal chromosome 15 (15q11.2-13) defects	Initial hypotonia and failure to thrive, then marked hyperphagia and obesity, hypogonadism, small hands and feet, thick saliva, intellectual disability
SHOX haploinsufficiency	SHOX gene mutations	Short stature, Madelung deformity, mesomelia, cubitus valgus, dislocation of the ulna
Russell–Silver syndrome	Imprinting control region on paternal chromosome 11p15.5; maternal uniparental disomy of chromosome 7	IUGR, age appropriate head circumference with short stature, triangular facies, downturned corners of the mouth, prominent forehead, 5th finger clinodactyly, limb length asymmetry

SHOX, Short Stature HomeoboX gene; IUGR, intra-uterine growth restriction; PTNP11. Protein Tyrosine Phosphatase Nor-receptor type 11.

and in the presence of a positive family history, further evaluation may be delayed even beyond the age of 14 years. The possibility of **central hypogonadism** becomes stronger the longer the onset of puberty is delayed, but it should be noted that cases of spontaneous development of normal puberty can occur up to and even beyond the age of 18.

In most cases, only reassurance and an explanation of the growth pattern are required, but if the parents *and* the child are eager to hasten pubertal development (usually because of involvement in sports or because of bullying and other psychosocial considerations), then a short course of low-dose sex steroids can accelerate the onset of puberty. Intervention does not change the final height but hastens the child's progression to that height. Treatment options are discussed in detail later in this chapter.

Idiopathic Short Stature

ISS is a clinical description rather than a disease. ISS is generally considered a normal variant of growth (since pathologic causes are excluded by definition). The exact definition varies from country to country; in the United States, the Food and Drug Administration (FDA) uses a definition of height >2.25 SD below the age mean (which is the 1st percentile for height) for children in whom no specific cause of short stature has been identified after a thorough evaluation. This corresponds to an adult height <160 cm (5 feet 3 inches) for males and <150 cm (4 feet 11 inches) for females.

In many cases, these children have familial short stature and their height is not inappropriate for parental height. But in most definitions, they are included in the category of ISS because the purpose of the definition was to identify children who may not have any pathology, but whose short stature per se constitutes a possible reason to treat them with GH. This notion remains controversial because there is no universal agreement about the possible psychosocial or economic impact of ISS. Those who support treatment of these children argue that such a degree of short stature may have adverse psychologic, social, and economic consequences and deserves to be treated even if no underlying pathology is identified. Opponents argue that there is no convincing evidence that short stature of this degree itself leads to any significant handicaps that would justify prolonged invasive therapy with an extremely expensive medication that may itself have future adverse health consequences. Third-party payers often regard such treatment as cosmetic and may not approve requests for therapy. It should be noted that in most cases, there are no consistent adverse effects of short stature on quality of life in children at or just below the 1st percentile; however, some studies do indicate that practical and psychosocial difficulties increase in those with extreme degrees of short stature.

ISS is a diagnosis of exclusion; history, physical examination, laboratory studies, and imaging studies do not reveal any specific cause of short stature in an otherwise normal child. How much investigation is needed before a child can be labeled ISS remains a matter of controversy and clinical practice can vary significantly within and between different countries. Treatment with GH was approved by the FDA in 2003 but remains controversial and may not be approved by third party payers. Treatment is more likely to be beneficial in those with more extreme degrees of short stature. A predicted adult height less than 136 cm (about 4 feet 6 inches) in females and less than 149 cm (about 4 feet 11 inches) in males is *very* likely to be associated with quality of life issues and certainly deserves treatment even in the absence of any underlying cause.

Small for Gestational Age

Children who are born SGA usually catch up with their peers by 2-3 years of age, but 10-20% of children born SGA will fail to catch up and will continue to be below the 3rd percentile. This is more likely in children who are born premature as well as SGA and in those most severely affected at birth. The mechanism underlying this failure of catch-up growth is not well understood. Children with IUGR also have an increased future risk of metabolic disorders such as type 2 diabetes. Children who were SGA typically have normal proportions and no other physical findings; in some cases, the IUGR is 1 component of a genetic syndrome (see Tables 43.2 and 43.6) and other features of the syndrome are present.

Children who were born SGA with poor postnatal growth typically have normal or even elevated GH levels but lower average values of IGF-1 and IGFBP-3 (though most are still in the normal range), indicating some degree of GH resistance in at least some of these children. GH treatment increases final height by about 1 SD on average (about 6 cm) if started early in life and continued for at least 7 years. In the United States, treatment is approved by the FDA for children who were born SGA and whose height remains >2 SD below the mean at age 2. In Europe, treatment is approved for children whose height is >2.5 SD below the mean by age 4. These children can be mildly GH-resistant and may therefore require GH doses at the higher end of the dose range. Since individual response varies, GH treatment can be started at the usual dose (30-50 µg/kg/day) and then increased if needed based on growth response and IGF-1 levels.

Endocrine Disorders

Growth Hormone Deficiency

GH is essential for postnatal growth, and children who lack it are extremely stunted. GH deficiency may be congenital or acquired. The **congenital** form may be associated with other pituitary hormone deficiencies (multiple pituitary hormone deficiency [MPHD]) and may be associated with **midline craniofacial defects** (absence of the septum pellucidum and optic nerve hypoplasia [septo-optic dysplasia], cleft palate, holoprosencephaly, single central incisor). Genetic testing has revealed underlying genetic mutations in transcription factors involved in the development of the anterior pituitary in many (but not all) of these cases (see Table 43.4). Isolated congenital GH deficiency is relatively rare (i.e., it is more common to see congenital GH deficiency as a component of MPHDs). Some of these isolated cases are related to genetic abnormalities in the GH-releasing hormone receptor (GHRHR mutations) and others to mutations in the GH gene itself. Mutations in the GH receptor or in downstream signaling molecules lead to various rare forms of GH resistance. Mutations in the IGF-1 gene, in the ALS protein (a component of the IGF–IGFBP-3–ALS ternary complex), and in the IGF-1 receptor can lead to growth failure on rare occasions. But most cases of GH deficiency discovered in the course of evaluation of short stature are not due to known genetic mutations in the GH-IGF axis and are regarded as **idiopathic**.

GH deficiency may also be **acquired** secondary to birth injury, head injury, midline tumors (most commonly craniopharyngioma), and cranial irradiation. Most such cases are associated with deficiencies of other pituitary hormones, but isolated GH deficiency may also occur after such insults. Injury to the anterior pituitary during childhood most likely affects GH secretion, followed by gonadotropins, thyroid-stimulating hormone (TSH), and adrenocorticotropic hormone (ACTH) in that order (in adults, gonadotropins may be affected more than GH). It is therefore possible to see isolated GH deficiency after a cranial injury, while it is very unusual to see central hypothyroidism or adrenal insufficiency in the absence of GH deficiency.

Growth Hormone Deficiency Presenting in the Neonatal Period

Isolated congenital GH deficiency that *presents* in the newborn period is uncommon. If GH deficiency presents in the newborn period, it

(See *Nelson Textbook of Pediatrics,* p. 2640.)

usually does so in the setting of MPHD. It may be associated with midline defects (central incisor, septo-optic dysplasia, holoprosencephaly, cleft palate). Affected infants are often normal in birth size, although statistical analysis suggests that as a group, they are somewhat small. These newborns have an increased incidence of **hypoglycemia** and may also have **jaundice** with a hepatitis-type picture. Males frequently have **micropenis**; cryptorchidism may be seen in cases with concomitant gonadotropin deficiency. Hypoglycemia may be worsened by associated ACTH deficiency, which may also lead to hypotension and hypothermia. Associated central **hypothyroidism** may also cause hypothermia, poor growth, poor feeding, and prolonged jaundice.

Laboratory testing reveals a low random GH level (this is the only stage in life at which a random GH level is useful; levels less than 7 ng/mL in the 1st week of life are considered abnormal), as well as low levels of IGF-1 (not very useful because the normal range overlaps with the deficient range) and low IGFBP-3. Associated central hypothyroidism, if present, is suggested by a low T_4 and an *inappropriately normal* (or even slightly elevated) TSH level; one would have expected the TSH level to be markedly elevated in a baby with low T_4, but instead it is either normal or just minimally elevated. A low cortisol level (especially in the face of hypoglycemia or other stressful situations) and low or low-normal ACTH level may hint at central ACTH deficiency; an ACTH stimulation test may be required to confirm the diagnosis. Gonadotropin levels may be affected, and if so, will remain low instead of rising in the 1st 2-3 months of life as they normally do in infants. GH stimulation testing is *not* required for the diagnosis of GH deficiency in the newborn period. Genetic testing may show mutations in 1 of several genes involved in the normal development of the pituitary and the GH-producing cells of the pituitary *(POUF1, PROP1, HESX1, LXH3, LHX4, SOX3)* (see Table 43.4). Treatment with GH (*and* with other pituitary hormones that are frequently deficient in these neonates) will permit normal growth and development and prevent hypoglycemia and other complications.

Growth Hormone Deficiency in Childhood

Most male children who are diagnosed with GH deficiency in childhood demonstrate no manifestations in the neonatal period. A very small proportion has specific genetic defects in GH secretion or action that did not present (or were not obvious) in the newborn period; these children will usually exhibit very profound growth failure by the 2nd or 3rd year of life. They typically look younger than their actual age and are classically described as chubby or cherubic; their heights are depressed more than their weights. They may have high-pitched voices, delayed dentition, and poor musculature. On testing, they are found to have very low IGF-1 and IGFBP-3 levels; GH stimulation testing reveals peak GH levels that are usually lower than 5 ng/mL. Bone age is typically delayed and an MRI of the brain may show a hypoplastic pituitary gland, an empty sella, or an abnormal pituitary bright spot. Genetic testing may show defects in the GHRH receptor gene or the GH gene. Defects in other genes involved in regulating GH secretion may be seen, but all are extremely rare. These children typically respond very dramatically to GH replacement therapy and will grow very poorly in the absence of such therapy.

Much more common is the phenomenon of the child who presents with short stature in childhood but does not have any known genetic or acquired cause of GH deficiency. These children are diagnosed as GH deficient based on a combination of auxologic and laboratory criteria and are candidates for GH therapy. But unlike children with neonatally apparent GH deficiency, or children with obvious causes of acquired GH deficiency (tumors, trauma, radiation), these children are frequently not GH-deficient when retested after puberty. This

idiopathic GH deficiency may be due to multiple genetic loci of small effect or a few loci of moderate effect, but the exact cause remains unknown. Poor linear growth usually becomes evident by age 3 years, but many cases are not brought to the attention of physicians until later in childhood.

Diagnosis and treatment of children with idiopathic GH deficiency are based on consensus guidelines and expert opinion and may vary from country to country. In most cases, children are investigated for idiopathic GH deficiency if they are below the normal range for height (>2 SD below the mean, or <3rd percentile) or are extremely short for their genetic target height (projected adult height more than 9 cm below the MPH). A subnormal growth velocity (growth velocity <25th percentile or >1.5 SD below the mean) is seen and no other obvious cause of short stature can be found.

No single test can be regarded as the gold standard for making this diagnosis. Most children will have an IGF-1 level that is low for age (and in older children, for pubertal stage and bone age), but occasionally a child who meets all other criteria for GH deficiency will have a normal IGF-1 level, while in other cases the IGF-1 level may be low because of malnutrition or chronic disease in a child who is not GH deficient. IGFBP-3 level is also frequently used as a measure of GH secretion but is less sensitive than the IGF-1 level and may not be helpful in most cases. **Bone age is almost always delayed**. If the diagnosis is suspected as a result of auxologic findings (short stature, subnormal growth velocity), a delayed bone age, and low IGF-1 and/or IGFBP-3 levels, then most authorities recommend performing 2 GH stimulation tests. In these tests, GH secretion is provoked by 1 of several pharmacologic agents and multiple GH levels are drawn over the next 2-3 hours. Glucagon, arginine, L-dopa, and clonidine are the most commonly used agents in children; insulin-induced hypoglycemia is considered by many to be the gold standard test in adults, but is associated with the risk of life-threatening hypoglycemia and is not recommended in children. If all levels remain below an arbitrary cutoff (10 ng/mL in the United States), then the child is considered GH deficient. It should be noted that provocative testing is known to have both false-positive as well as false-negative results and should only be interpreted in the context of all available auxologic, laboratory, and imaging information. Because of these issues, some authorities recommend using auxologic criteria and growth factor levels to make the diagnosis of GH deficiency without performing any provocative tests of GH secretion.

Any child diagnosed as having GH deficiency should have cranial imaging performed to rule out intracranial pathology before treatment is started. Once imaging (usually an MRI of the brain with fine cuts through the pituitary region) has been performed, treatment can be started with GH. The usual starting dose ranges from 30-50 µg/kg/day, and this can then be increased in the case of poor response. Doses of 70 µg/kg/day or higher may be needed in some cases. IGF-1 levels can be used to assess the biochemical response and to see if there is room to increase the GH dose any further. Some authorities have recommended IGF-based dosing (adjusting the GH dose to keep the IGF-1 level in the high-normal range), but very high doses of GH may be required in some children to achieve such levels, and because of safety concerns this method has not been widely adopted.

Acquired Growth Hormone Deficiency

In acquired forms of GH deficiency, there may be a history of a precipitating event (cranial irradiation, head trauma) or a history suggestive of an intracranial lesion (headaches, vomiting, visual disturbances). Affected children often have normal growth until the onset of the disorder; thereafter, their growth is attenuated.

On physical examination, there may be evidence of the underlying disturbance (bitemporal hemianopsia, optic atrophy, or papilledema in midline tumors such as craniopharyngioma; dermatitis, scalp lesions, hepatosplenomegaly in Langerhans cell histiocytosis). The typical case will either be a child with a known history of conditions that can affect the anterior pituitary (head injury, irradiation, tumor) who shows deceleration of growth, or a child who was growing normally and then has an obvious growth failure. Laboratory tests will show decreased IGF-1 levels (and in some cases, abnormal levels of other pituitary hormones); cranial imaging (usually an MRI with and without contrast) should then be done in all such cases. Bone age may not be delayed if the onset of GH deficiency was relatively recent. The diagnosis of GH deficiency is usually confirmed by provocative testing and treatment can then be started with usual doses of GH. In patients with brain tumors, treatment is usually delayed for at least 1 year after completion of therapy because of the theoretical risk that GH therapy may increase the size of any tumor that is present.

Traditionally, GH therapy for GH deficiency was continued until linear growth was completed (i.e., until the closure of epiphyses), though it could be stopped at any point before that if the child is satisfied with his or her attained height. Because of the extremely high cost of GH therapy (50-100,000 dollars/year in the United States), many 3rd party payers require cessation of therapy once a reasonable adult height has been reached (exact targets vary depending on the plan).

Growth Hormone Insensitivity

GH action may be impaired due to mutations of the GH receptor (**Laron syndrome**), defects in postreceptor signaling, mutations in the IGF-1 gene, deficiency of the ALS protein, and defects in IGF-1 action (Table 43.7; see also Tables 43.2 and 43.5). All of these conditions are very rare and constitute only a tiny fraction of the cases of short stature and growth failure seen in clinical practice.

The GH receptor consists of an extracellular ligand-binding domain, a single membrane-spanning domain, and a cytoplasmic signaling component. Circulating GH-binding protein (GHBP) is just the extracellular domain of the GH receptor protein. Mutations in this receptor lead to various forms of **Laron syndrome**, characterized by GH resistance (hence elevated GH levels), low IGF-1 and IGFBP-3, and extreme degrees of growth failure. In some (but not all) cases, the extracellular domain of the receptor is involved, so GHBP level is also low.

Other clinical features of Laron syndrome include small head circumference, characteristic facies with saddle nose and prominent forehead, delayed skeletal maturation, small genitalia and testes, short limb length compared to trunk length, and abnormal body composition with osteopenia and obesity. Intellectual development is normal or only modestly impaired. Prenatal growth is near normal, but postnatal growth is profoundly affected, with heights as low as −10 SD.

It is worth noting that *untreated* children do not have a shortened life span and have a *lower* than average risk for cancer.

Defects in the post-GH receptor signaling pathway can also cause short stature. Several patients have been described as GH insensitivity caused by a homozygous missense mutation in the gene encoding the STAT5B protein, which is an essential component of the JAK-STAT signaling pathway that is activated by the GH receptor. These patients have severe postnatal growth failure as well as immune dysregulation related to the role of STAT5B in the immune system.

Mutations in the gene encoding IGF-1 cause profound prenatal as well as postnatal growth failure. A complete absence of IGF-1 is probably lethal in humans, but individuals have been described with deletions in the IGF-1 gene causing partial loss of function. These

TABLE 43.7	**Clinical Features of Growth Hormone Insensitivity**
Growth and Development
• Birth weight: near normal
• Birth length: may be slightly decreased
• Bone age: delayed, but may be advanced relative to height age
• Genitalia: micropenis in childhood; normal for body size in adulthood
• Puberty: delayed 3-7 yr
• Sexual function and fertility: normal
Craniofacies
• Hair: sparse before the age of 7 yr
• Forehead: prominent; frontal bossing
• Skull: normal head circumference; craniofacial disproportion due to small facies
• Facies: small
• Nasal bridge: hypoplastic
• Orbits: shallow
• Dentition: delayed eruption
• Sclerae: blue
• Voice: high-pitched
Musculoskeletal/Metabolic/Miscellaneous
• Hypoglycemia: in infants and children; fasting symptoms in some adults
• Walking and motor milestones: delayed
• Hips: dysplasia; avascular necrosis of femoral head
• Elbow: limited extensibility
• Skin: thin, prematurely aged
• Osteopenia

From Sperling MA. *Pediatric Endocrinology*. 4th ed. Philadelphia: Elsevier; 2014:355.

patients also have microcephaly, significant developmental delay, and hearing loss.

IGF-1 is carried in the bloodstream primarily as part of a ternary complex with IGFBP-3 and the ALS. **ALS deficiency** leads to low circulating IGF-1 levels (probably via accelerated IGF-1 metabolism) and leads to mild short stature and pubertal delay.

IGF-1 receptor mutations are extremely rare in liveborn babies and present with profound prenatal and postnatal growth failure. These children may have normal or only mildly abnormal cognitive development. Unlike the other GH insensitivity syndromes, circulating levels of IGF-1 are normal or elevated in these patients.

All forms of GH insensitivity (except rare IGF-1 receptor defects) lead to IGF-1 deficiency. The FDA has approved treatment of these disorders with recombinant IGF-1 in cases where height *and* IGF-1 levels are >3 SD below the mean with elevated or normal GH levels and no response to GH therapy. Commercial availability of this product has varied, and obtaining supplies for therapy may sometimes be a problem.

Hypothyroidism

Hypothyroidism impairs linear growth (Fig. 43.5). Thyroid deficiency may be congenital or acquired (Fig. 43.6). In view of the usefulness of neonatal thyroid screening programs, it is very uncommon for congenital hypothyroidism to go untreated and cause short stature.

Acquired hypothyroidism in children usually results from **autoimmune thyroiditis**. Children with Turner syndrome, Down syndrome, Klinefelter syndrome, celiac disease, or diabetes mellitus are at increased risk for autoimmune hypothyroidism, as are children with a family history of autoimmune disease. Acquired hypothyroidism tends

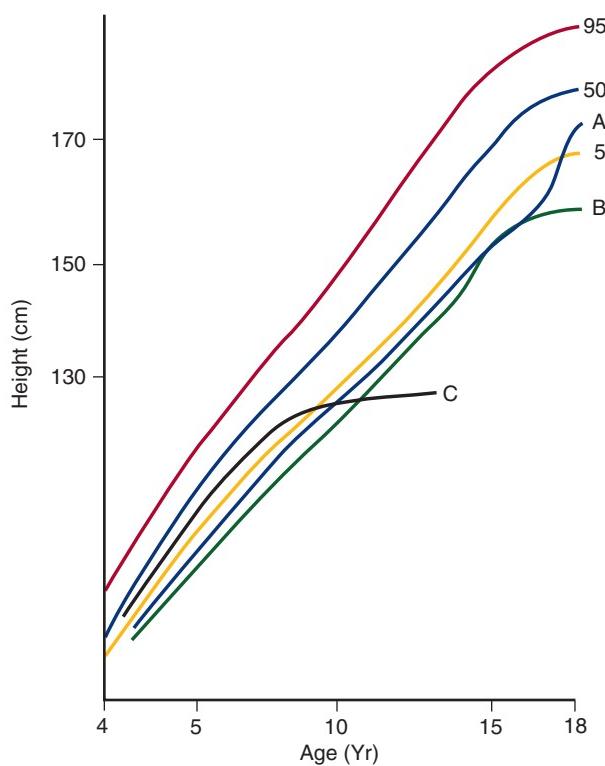
(See *Nelson Textbook of Pediatrics,* p. 2665.)


FIGURE 43.5 Patterns of linear growth. Normal growth percentiles (5th, 50th, 95th) are shown along with typical growth curves for constitutional delay of growth and adolescence *(A),* familial short stature *(B),* and acquired pathologic growth failure *(C)* (e.g., acquired primary hypothyroidism). (From Styne DM. Endocrine disorders. In: Behrman RE, Kliegman RM, eds. *Nelson Essentials of Pediatrics.* 2nd ed. Philadelphia: WB Saunders; 1994:616.)

to manifest most commonly in older children and teenagers. Often there are few complaints except for slow growth (after previously normal growth), weight gain, a goiter, or a combination of these. Other symptoms (dry hair or skin, constipation, cold intolerance) are less common. Postmenarchal females may have amenorrhea, or in rare cases, galactorrhea. School performance is generally not impaired. On physical examination, the major features are a height suggestive of deceleration from the previous growth curve, a goiter, and relative obesity (weight age > height age). The physical examination may also reveal bradycardia, dry hair or skin, and delayed reflexes.

In acquired hypothyroidism, the laboratory test results include a high level of TSH and a low or low-normal thyroxine (T_4) level or free thyroxine level (FT_4). The presence of positive thyroid antibodies (antithyroperoxidase and antithyroglobulin antibodies) is consistent with autoimmune thyroiditis. The bone age is often significantly delayed in hypothyroidism.

Central hypothyroidism is uncommon. In the newborn period, it usually (but not always) presents as a component of MPHD with TSH levels that are normal or even mildly elevated but that are inappropriately low for the decreased thyroxine level. Acquired central hypothyroidism is usually due to known injury to the anterior pituitary (e.g., central nervous system tumors, granulomas, irradiation, head trauma) and is associated with other pituitary hormone deficiencies. In practice, it is much more common to see low T_4 and normal or mildly elevated TSH levels in children who have another illness and have the syndrome of **nonthyroidal illness (NTI)** leading to temporarily abnormal thyroid function tests (previously known as euthyroid sick syndrome).

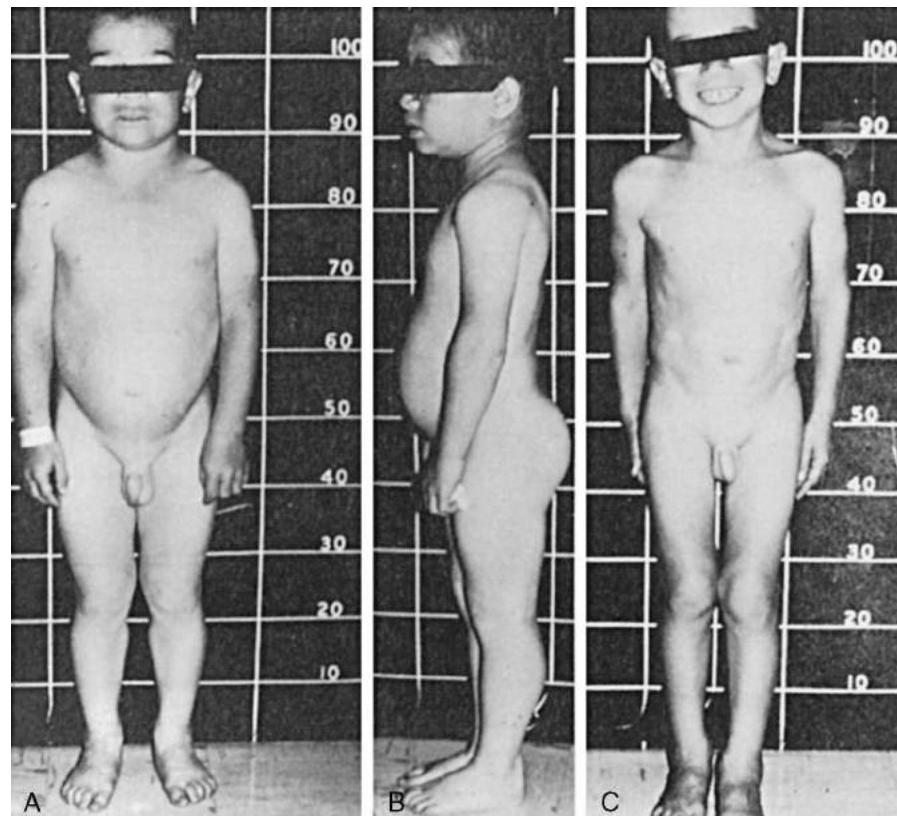
The treatment of hypothyroidism is thyroid replacement therapy (L-thyroxine).


FIGURE 43.6 *A* and *B,* A 10-year-old boy with acquired hypothyroidism before treatment. Note the short stature, immature body proportions, sleepy expression, generalized myxedema, and protuberant abdomen. *C,* After 4 months of thyroid hormone therapy, the child has grown, has lost myxedema, and has a bright facial expression. (From Kaplan SA, ed. *Clinical Pediatric and Adolescent Endocrinology.* Philadelphia: WB Saunders; 1982:93.)

Glucocorticoid Excess (Cushing Syndrome)

Cushing syndrome results from excessive levels of glucocorticoids. Whether endogenous or exogenous, glucocorticoids markedly stunt growth. In general, because such conditions are acquired, the history reveals a child previously growing well whose growth velocity slows. The child typically continues to gain weight at a rapid rate, even though linear growth is attenuated. This is in contrast to exogenous obesity, in which affected children tend to grow at normal or rapid rates. The history may indicate that the child was treated with oral, topical (especially with occlusive dressings), or intradermal glucocorticoids at high doses or for long durations. Alternate-day oral glucocorticoids are much less likely to attenuate growth than are daily doses. Cushing syndrome is very unlikely with inhaled corticosteroids (ICS), but a small effect on linear growth may be seen with the use of high-potency ICS.

Physical findings in endogenous Cushing syndrome may include acne, virilization, and increased appetite. Hyperpigmentation may occur when Cushing syndrome is secondary to excessive ACTH levels. This may be caused by ACTH from a pituitary tumor (Cushing disease) or (less commonly) from a nonpituitary source (ectopic ACTH syndrome).

The physical examination usually reveals short stature with relative obesity. Many affected children have the moon face and plethora characteristic of Cushing syndrome. A buffalo hump, large purple striae, acne, and hypertension may also be present. Marked virilization is worrisome because it may indicate an adrenal tumor.

The diagnosis of endogenous Cushing syndrome is based on demonstrating abnormally high glucocorticoid production (on a 24-hour urine sample for free cortisol, normalized to creatinine) and failure to suppress cortisol production adequately in response to exogenous glucocorticoid. A screening test for capacity to suppress cortisol secretion in response to exogenous glucocorticoid is the overnight dexamethasone suppression test. This involves the child taking 0.3 mg/m^2 of dexamethasone at 11:00 P.M. (the standard dose of dexamethasone in adults is 1 mg), followed by a measurement of circulating cortisol the following morning; a normal cortisol level after dexamethasone suppression is less than 5 ng/mL. False-positive results may occur in the setting of obesity, chronic illness, or stress. If the child shows biochemical evidence of Cushing syndrome, further investigations including computed tomography, magnetic resonance imaging, and measurement of ACTH levels are needed to determine whether a pituitary tumor (the commonest cause), an adrenal tumor, or ectopic ACTH production is present. Exogenous Cushing syndrome is usually evident from the history and physical examination results.

Treatment involves the removal of excess glucocorticoids either by reducing or discontinuing exogenous steroids if medically feasible, or in the case of endogenous hypercortisolism caused by a pituitary or adrenal tumor, by surgery.

Other Endocrine Disorders

Diabetes mellitus, when poorly controlled, can lead to slow linear growth. The diagnosis should be apparent from the history. However, because of the risk of autoimmune thyroiditis and celiac disease, slow-growing children with diabetes should also be checked for hypothyroidism and celiac disease.

Diabetes insipidus, when poorly controlled or untreated, may lead to slow growth. High fluid intake in central diabetes insipidus is dramatically decreased with vasopressin; treatment of nephrogenic diabetes insipidus is more challenging (see Chapter 45).

Vitamin D deficiency rickets, hypophosphatemic rickets, and **pseudohypoparathyroidism** are also associated with short stature, but bony abnormalities and disorders of calcium and phosphate metabolism, rather than short stature, are the usual presenting features of these disorders.

Genetic Causes of Short Stature

Several chromosomal abnormalities, copy-number variants (microdeletions, duplications), and single-nucleotide variants that are associated with significant short stature are well described and more are being discovered, but apart from Turner syndrome, these are uncommon causes of short stature. Because of the relatively high prevalence of Turner syndrome, **a karyotype is indicated in the evaluation of all prepubertal girls with significant short stature**.

Turner syndrome. Turner syndrome is relatively common, with an incidence of 1/2500 liveborn females, and is caused by the absence or abnormality of an X chromosome. Short stature is the *single most common physical finding* in Turner syndrome and may occur in the absence of any other physical finding (Fig. 43.7). The mechanism by which short stature occurs in Turner syndrome is multifactorial, but haploinsufficiency (absence of 1 copy) of the **S**hort **S**tature **H**omeobo**X** gene *(SHOX)* is believed to play a major role. This gene is located within the pseudoautosomal region of the X chromosome, which escapes X-inactivation and is therefore normally expressed from both copies of the X chromosome. It is highly active in skeletal tissues, and its absence in Turner syndrome (where only 1 X chromosome is present, or if present, the 2nd X chromosome is abnormal) leads to haploinsufficiency and causes severe short stature.

Linear growth is only mildly affected in utero and birth size is normal or near normal. By early childhood, marked short stature is usually noted and there is progressive deviation of height away from the normal growth curve. Linear growth is further attenuated during the teenage years and the mean adult height ranges from 142-146 cm in various populations. Even in females with Turner syndrome, adult height is influenced by the height of the parents, and girls with Turner syndrome who are born to tall parents tend to be taller. Breast enlargement and menses generally fail to occur as a result of ovarian failure. However, the presence of pubertal development should not deter consideration of the diagnosis because approximately 10% of patients have some residual ovarian tissue rather than streak gonads. In a few cases, even fertility has been reported.

In addition to short stature and ovarian failure, there may be various dysmorphic features, including a webbed neck, low posterior hairline, lymphedema beginning in the neonatal period (manifesting mainly as puffy hands and feet), increased carrying angle of the arm, pigmented nevi, short 4th metacarpals, nail abnormalities, and renal and cardiac anomalies (coarctation of the aorta). But any or all of these may be absent, and short stature may be the only abnormality in some females with Turner syndrome (particularly in those with chromosomal mosaicism). Therefore, the absence of dysmorphic features should not preclude consideration of Turner syndrome in short females.

A karyotype analysis is necessary to confirm or rule out the diagnosis of Turner syndrome in any female with short stature of unknown origin. If 45,X0 is confirmed, additional screening in the laboratory should include a fluorescence in situ hybridization (FISH) probe for the Y chromosome as these individuals require removal of their streak gonads to reduce the risk for gonadoblastoma in the dysgenic gonadal tissue. Additional laboratory features may include abnormally high levels of the gonadotropins, luteinizing hormone, and follicle-stimulating hormone (FSH), which are indicative of ovarian failure; however, levels may be normal in middle childhood because of normal central nervous system suppression of gonadotropin secretion at that time.

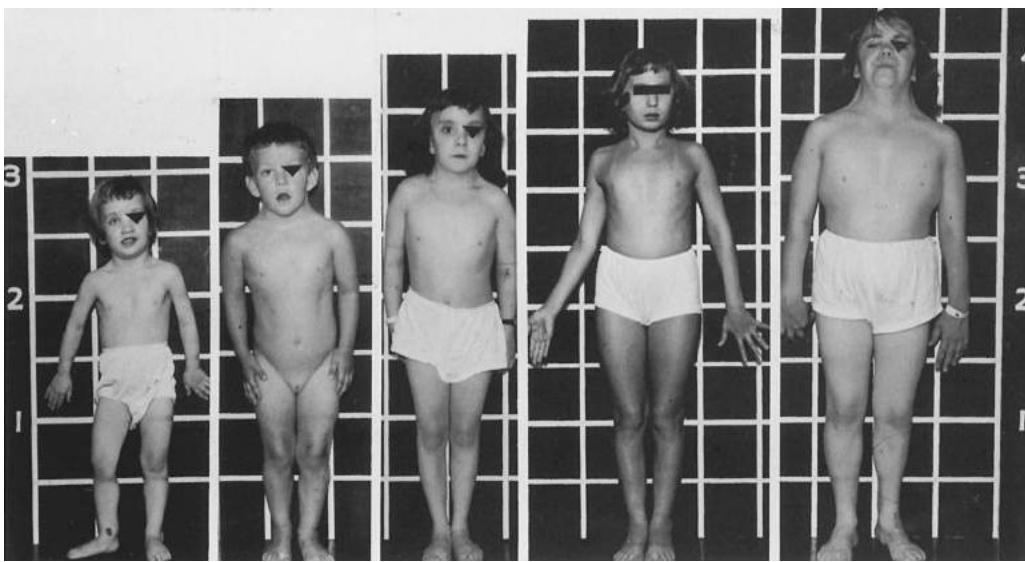
(See *Nelson Textbook of Pediatrics,* p. 2723.)


FIGURE 43.7 Five girls with 45,X0 syndrome illustrating the variability of features such as a webbed neck and broad chest. (From Lemli L, Smith D. The X0 syndrome. A study of the differentiated phenotype in 25 patients. *J Pediatr*. 1963;63:577-588.)

Although short stature in Turner syndrome is not believed to result from GH deficiency, treatment of Turner syndrome with GH therapy (typically in higher doses than those required for classic GH deficiency) increases final height and is recommended. The addition of low-dose oxandrolone may further increase the growth of females with Turner syndrome and is a useful adjunct in females who are diagnosed relatively late and who may not reach a normal height with GH therapy alone.

Down syndrome. Short stature is a prominent feature in Down syndrome, but the mechanism by which trisomy 21 causes impaired growth is not known. It is independent of the hypothyroidism that may also occur in this condition. Specific treatment for short stature is typically not recommended in this condition.

Prader–Willi syndrome (PWS). PWS is characterized by hypotonia, failure to thrive with poor sucking during infancy, hypogonadism (manifested as cryptorchidism in males), short stature with small hands and feet, hyperphagia leading to morbid obesity beginning in early childhood, developmental delay/intellectual disability, and behavioral concerns including obsessive-compulsive disorder. The average adult height is 147 cm (4 feet 9 inches) in females and 155 cm (5 feet 1 inch) in males. PWS is caused by the absence or inactivity of a segment of the paternally inherited chromosome 15 (15q11.2-13), whereas deletion of the same chromosomal segment in the maternally inherited chromosome causes **Angelman syndrome**. It is thus the classic example of genomic imprinting; a phenomenon in which the expression of a gene or genomic region differs depending on the chromosome's parent of origin.

PWS may be due to a deletion of the PWS region of the paternal chromosome (about 65% of cases), or the inheritance of 2 complete copies of the maternal chromosome 15 and the absence of the paternal chromosome (a condition labeled maternal uniparental disomy, responsible for 30-35% of the cases). In about 2% of the cases, it appears to be due to a defect in the imprinting center rather than the absence of the paternal genes. DNA methylation probes will detect almost all cases by revealing whether the patient has maternal and paternal methylation patterns (normal), absence of the paternal pattern (causing PWS), or absence of the maternal pattern (causing Angelman syndrome). Further genetic testing is then needed to determine whether the cause is a deletion, a disomy, or an imprinting center defect.

Early treatment with GH increases final height, but also improves body composition and the achievement of developmental milestones. It may also decrease the incidence of morbid obesity. Because of these reasons, most authorities consider early treatment with GH (starting between 4 months and 2 years of age) to be the standard of care in PWS. Because of some reports of a possible increase in the rate of sudden death from upper airway obstruction in the 1st months of treatment, a sleep study and/or an ears, nose, and throat (ENT) consult may be recommended before initiating treatment, with the sleep study repeated 6-12 weeks after starting treatment and annually thereafter.

Russell–Silver syndrome. Russell–Silver syndrome (RSS) is characterized by severe IUGR that persists in postnatal life. These children have proportionate short stature, a normal head circumference, triangular facies, downturned corners of the mouth, and a prominent forehead. Other features may include 5th finger clinodactyly and undergrowth of 1 or more limbs of the body (hemihypotrophy), leading to limb length discrepancy. These children usually have feeding difficulties and may exhibit mild developmental delay.

RSS is associated with methylation abnormalities in an imprinting control region on the paternal chromosome 11p15.5 in about 60% of subjects. In another 10%, it is caused by maternal uniparental disomy of chromosome 7 (absence of the paternal chromosome 7). No genetic cause is identified in the remaining children and the diagnosis is based on clinical criteria. Treatment with GH increases height, but the doses required may be higher than average because of some element of GH resistance.

Short stature HomeoboX gene mutations. The *SHOX* gene is located within the pseudoautosomal regions of the X and Y chromosomes. This region escapes X-inactivation and so it is normally expressed from both X chromosomes in females. In males, the gene is expressed from the X as well as the Y chromosomes. Haploinsufficiency of the *SHOX* gene (mutations affecting 1 copy of the gene) leads to short stature that may be associated with other skeletal findings such as the Madelung deformity (a dinner fork deformity of the distal forearm and wrist), mesomelia (shortening of the forearm and leg), cubitus valgus, and dislocation of the ulna. The combination of short stature and several of the above significant skeletal abnormalities is labeled **Léri-Weill-dyschondrosteosis** and is more common in females.

In other cases, the skeletal abnormalities may be relatively subtle and isolated short stature may be the only notable finding.

Screening for *SHOX* gene mutations is reserved for children with any combination of the following physical findings: increased U/L, reduced arm span/height ratio, increased sitting height/height ratio, above-average body mass index, Madelung deformity, cubitus valgus, short or bowed forearm, dislocation of the ulna at the elbow, or the appearance of muscular hypertrophy. In otherwise short children who do not have any of these associated findings, the yield from testing for *SHOX* mutations is very low. Treatment with GH can increase final height, though higher than average doses may be required.

Noonan syndrome. Noonan syndrome has an incidence of 1 in 1000-2500 live births. Approximately 50% of children with Noonan syndrome have a pathogenic variant in the *PTPN11* gene. There are currently 12 genes that have been identified in which pathogenic variants result in Noonan syndrome; these are much less common than *PTPN11* and include the genes: *SOS1, RAF1, KRAS, SHOC2, BRAF, NRAS, RIT1, CBL, KATB6, LZTR1,* and *SOS2*. The syndrome is characterized by minor facial dysmorphism (hypertelorism, downward eye slant, and low-set ears), proportionate short stature, and right-sided heart disease, most often pulmonic stenosis and hypertrophic cardiomyopathy. Other common findings include a short webbed neck, chest deformity (pectus excavatum), cryptorchidism, intellectual disability, bleeding diathesis, and lymphedema. Since some of these findings overlap with the findings seen in Turner syndrome, this syndrome was sometimes described as "pseudo-Turner," though Noonan syndrome occurs in both females and males and has its own specific phenotypic features and genetic etiology. GH therapy is recommended to treat short stature associated with Noonan syndrome and is an FDA-approved indication for the use of GH.

Malnutrition

Worldwide, malnutrition resulting from poverty is still the commonest cause of short stature. In North America, malnutrition may arise from inadequate intake secondary to poverty or deprivation, poor intake secondary to overt or occult chronic illness (e.g., inflammatory bowel disease, renal failure), or inability to utilize food intake (malabsorption). In all these conditions, weight tends to be depressed to a greater degree than height. The history should include a review of the child's food intake (often best obtained by a 3-day diet record), appetite, and detailed review of systems. Specific nutritional disorders, such as rickets, may also lead to short stature. Appropriate treatment leads to acceleration of linear growth, typically lagging a few weeks or months behind weight gain. Catch-up growth occurs, but may not compensate for all of the lost height potential in long-standing cases, leading to a permanent height deficit.

Chronic Illness

Chronic illnesses, such as inflammatory bowel disease, celiac disease, renal dysfunction, and chronic inflammation, can lead to short stature. The mechanisms of impaired growth include poor appetite or poor intake (e.g., inflammatory bowel disease, renal dysfunction), malabsorption (e.g., celiac disease), medications (e.g., chronic glucocorticoids for severe asthma), chronic acidosis (e.g., renal tubular acidosis), and secondary endocrine dysfunction (e.g., GH resistance associated with systemic inflammation). Although the primary disorder is evident in many cases, short stature is sometimes the presenting feature of the chronic disease. This occurs notably in inflammatory bowel disease, celiac disease, and renal dysfunction.

Gastrointestinal disease—Children usually have a greater deficit in weight than height. Gastrointestinal symptoms are frequently present, but short stature alone may be the initial presentations of celiac disease and inflammatory bowel syndrome. The growth failure in inflammatory bowel disease is due to a combination of decreased food intake, malabsorption, and the inflammatory process (mediated by proinflammatory cytokines). This may be further aggravated by the use of high-dose glucocorticoids for treatment. GH therapy has been shown to increase height velocity in some small trials in inflammatory bowel disease, but no consensus exists yet about its role in these children. Celiac disease responds to a gluten-free diet and height velocity normalizes with adequate treatment.

Renal disease—Children with chronic kidney disease may develop growth failure due to chronic metabolic acidosis, uremia, poor nutrition, anorexia, anemia, calcium and phosphorus imbalance, renal osteodystrophy, and impairment of GH action. It may also be aggravated by the use of high-dose glucocorticoids. GH therapy is recommended for children with profound growth failure and is typically continued until renal transplantation.

Pulmonary disease—Growth failure in cystic fibrosis is secondary to both its pulmonary and gastrointestinal manifestations. Chronic infection and systemic inflammation contribute to short stature.

Severe asthma may interfere with growth directly as well as via the effect of glucocorticoid therapy. Daily use of systemic glucocorticoids for any significant length of time will lead to growth suppression, but potent ICS may also have noticeable systemic effects in some cases (probably due to individual differences in technique and sensitivity). Alternate-day dosing and drug holidays can reduce this risk of growth suppression from oral corticosteroids. In the case of ICS, the use of the minimum effective potency and dose may help ameliorate systemic effects in children who exhibit signs of growth failure.

Cardiac disease—All forms of severe heart disease in childhood can be associated with growth failure. The underlying mechanism may be an increase in energy requirements, as well as anorexia and poor oral intake.

Immunodeficiencies—Both congenital and acquired immunodeficiencies (such as, human immunodeficiency virus [HIV] infection) are associated with growth failure. Mechanisms include anorexia, malabsorption, diarrhea, chronic infection, and systemic inflammation. The diagnosis is usually evident, but an occasional child with common variable immune deficiency may present with growth failure before clues in the history and physical examination lead to an evaluation of immune status. Successful treatment of the underlying disease will usually lead to an improvement in growth.

Other diseases—Childhood rheumatologic diseases, especially systemic juvenile idiopathic arthritis (JIA), are frequently associated with growth retardation. Children with childhood cancers may have poor weight gain and growth failure because of anorexia, gastrointestinal disturbances, and increased energy utilization. After diagnosis, chemotherapy and radiation may lead to poor growth, and radiation to the spine can lead to a permanent growth deficit and disproportionate growth failure (with short truncal height and longer limbs). Late growth failure may be the result of hypothalamic damage leading to GH and thyroid hormone deficiencies.

In most of these systemic illnesses, the history typically reveals that the child had been growing normally until some point. Then, the growth rate slowed, which is suggestive of the onset of an illness. The history may reveal a clear earlier diagnosis of chronic illness or may include symptoms suggestive of the underlying disorder (e.g., loss of appetite, diarrhea, mouth sores, fevers). The physical examination typically shows that the weight is more depressed than the height. There may also be features indicative of the underlying disorder (e.g., pallor in anemia, perianal findings in Crohn disease).

Laboratory studies that screen for chronic illness (complete blood cell count, erythrocyte sedimentation rate, chemistry profile,

urinalysis) may at times provide clues to the diagnosis. Screening for celiac disease with tissue transglutaminase immunoglobulin (Ig)A antibody testing may be indicated, especially if failure to thrive appears after a period of normal growth or if weight is affected more than height. If indicated by the clinical features and/or screening laboratory studies, definitive diagnosis requires directed tests (e.g., endoscopy and biopsy for inflammatory bowel disease or celiac disease, sweat chloride test for cystic fibrosis).

The management of these conditions rests on a specific therapy directed at the underlying condition (e.g., a gluten-free diet for celiac disease). When the disease is adequately treated, the growth rate often improves, but catch-up growth may not compensate for all of the lost height potential in long-standing cases, leading to a permanent height deficit. GH therapy may be indicated if the height deficit is severe and is unlikely to correct with treatment of the underlying disease alone. GH is specifically approved for the treatment of short stature in children with renal insufficiency.

Emotional Deprivation

Deprivation can stunt growth in 2 ways. First, a child may be deprived of food (an example of malnutrition); in this case, the child's weight is generally depressed more than the height. Second (and more rarely), a child who is emotionally deprived (and emotional deprivation, rather than actual physical abuse, seems to be key) may have profound short stature without apparent malnutrition (psychosocial dwarfism). In this case, the height is depressed more than the weight (Fig. 43.8). Such a child may (in some, but not all cases) have the clinical features of GH deficiency and may in fact show laboratory evidence of

FIGURE 43.8 A growth chart of a boy with deprivation dwarfism (psychosocial dwarfism). Between the ages 6 and 8$\frac{7}{12}$ years, he had chemical evidence of growth hormone (GH) deficiency. After placement in a chronic care facility *(arrow),* his growth rate improved markedly, and his GH levels reverted to normal. NCHS, National Center for Health Statistics. (Data from the Centers for Disease Control and Prevention. Published May 30, 2000, and modified November 21, 2000. http: www.cdc.gov/growthcharts.)

hypopituitarism, but when placed in a more nurturing environment, the child grows markedly, and the GH levels revert to normal. This disorder may be difficult to diagnose, and the social history is critical. The diagnosis ultimately rests on significant improvement of growth once the environment improves.

Iatrogenic Causes

Treatments for medical conditions may secondarily impair growth. The classic example is **glucocorticoids.** This is obviously a risk with prolonged systemic steroid use, but even inhaled or topical steroids (especially if used over a wide area or under an occlusive cover) may suppress growth. A significant proportion of the dose of ICS is deposited in the oral cavity and oropharynx and after being swallowed is absorbed via the GI tract. Much of this is metabolized to inactive metabolites in the liver (1st-pass metabolism) but some still escapes inactivation and may have systemic effects. Systemic effects are generally mild, but long-term studies show that high-potency ICS (e.g., budesonide and fluticasone) do have a small but measurable impact on linear growth. The final adult height may be decreased by 1-2 cm in long-term users of ICS. Since poorly controlled asthma is a serious condition and may have an even bigger impact on growth, this relatively small effect should not prevent the use of ICS in asthma patients who need it. But an occasional child may have more significant slowing of growth based on individual differences in sensitivity, metabolism, and technique, and this possibility should be kept in mind as a possible cause of slow growth.

Spinal irradiation for treatment of malignancies may stunt growth by limiting further spinal growth; this is associated with a high U/L. Treatments for hyperactivity (**sympathomimetic agents** suppress appetite) may interfere with growth and cause a small but measurable decrease in final height in some children.

Bone Dysplasias

Skeletal dysplasias constitute a group of disorders in which there is an innate failure of the bone or cartilage to grow normally (see Table 43.3). Abnormal body proportions are characteristic of these conditions (disproportionate short stature), although there are some exceptions. Skeletal dysplasias are inherited disorders which, most often, impact the regulation of normal bone growth. Bone age is not a reliable indicator of osseous maturity in these conditions.

Achondroplasia

Achondroplasia is the classic example of an **autosomal dominant chondrodysplasia** (Fig. 43.9). The incidence is approximately 1/20,000. This condition is relatively unique in that near all affected individuals have a gain of function mutation in the fibroblast growth factor receptor 3 *(FGFR3)* gene at position 1138, which results in a glycine to arginine amino acid substitution in the protein (p.Gly380Arg). An estimated 80% of the cases are due to de novo mutations (i.e., the parents do not have the mutation). Short stature, body disproportion with short limbs, hypotonia, and a relatively large head with midface hypoplasia are often noted at birth. A progressive deceleration of growth rate begins in infancy, and the humerus and femur are particularly shortened (rhizomelia; i.e., proximal shortening of the limbs). The hands may show a 3-pronged configuration (trident hand). In addition, there may be hydrocephalus as a result of narrowing of the foramen magnum, kyphosis, stenosis of the spinal canal, and vertebral disk lesions. The diagnosis is clinical and is supported by characteristic radiologic features that include small cuboid vertebral bodies and anterior beaking of the 1st or 2nd lumbar vertebra. The average adult height is 125 cm (4 feet 1 inch) in girls and 131 cm (4 feet 3 inches) in boys. There is no effective treatment for short stature in this condition.

FIGURE 43.9 Achondroplasia. *A,* One-year-old boy with height age of 4 months. *B,* Four-year-old girl with a height age of 20 months. (*A,* from Smith DW. Compendium on shortness of stature. *J Pediatr.* 1967;70:504; *B,* from Jones KL, ed. *Smith's Recognizable Patterns of Human Malformation.* 4th ed. Philadelphia: WB Saunders; 1988.)

Hypochondroplasia

Hypochondroplasia is an allelic variant of achondroplasia and manifests with short stature and dysmorphic features that are often milder than in achondroplasia. In particular, there are few craniofacial abnormalities, and body disproportion may be subtle. Newborns may be slightly small, but short stature generally becomes apparent by age 3 years. The short stature is minimally disproportionate with relatively short limbs. The hands and feet are usually noted to show brachydactyly (shortening of the tubular bones). Genu varum may occur. Radiologic hallmarks include metaphyseal indentation and flaring as well as hypoplasia of the ilia with small greater sciatic notches. Some reports suggested a beneficial effect of GH, but this remains a nonstandard indication for GH treatment.

Spondyloepiphyseal dysplasias are a heterogeneous group of dysplasias that primarily affect the epiphyses and the vertebral bodies. Most forms are characterized by a shortened trunk and vertebral anomalies. These conditions may lead to spinal cord compression due to subluxation of the cervical spine. GH therapy is not recommended.

Osteogenesis Imperfecta

Moderate and severe forms of osteogenesis imperfecta are associated with proportional short stature. The diagnosis is usually evident and short stature is not a presenting feature.

EVALUATING THE CHILD WITH SHORT STATURE

Statistically, most children with short stature will turn out to have 1 of the normal variant causes of short stature (familial short stature or constitutional delay) or will have ISS. An extensive evaluation will *not* reveal a specific cause in most patients. On the other hand, short stature in general, and growth failure in particular, may the 1st sign of a serious systemic disease or endocrine disorder and appropriate evaluation is essential to make the correct diagnosis. It is best to start the evaluation with a thorough history (including a family history and direct measurement of the heights of both parents if possible) and physical examination (including careful measurement and plotting of height on appropriate growth charts) and then order laboratory tests and imaging studies based on this evaluation and specifically tailored to the particular child instead of simply ordering a certain panel of tests for every child with short stature.

At the 1st contact with a short child, the physician usually does not know if the height velocity is also abnormal. If the initial history and examination do not indicate that a specific cause may be present, it is best to schedule a 2nd visit in 4-6 months to reassess the height and to accurately measure the height velocity. But if the initial history and examination indicate possible pathology, or if the short stature is unusually severe (>2.5 SD below the mean is a good cutoff), then some immediate laboratory tests and a bone age radiograph may be performed at the 1st visit.

At any stage, the finding of a subnormal growth velocity is more concerning than the finding of short stature. Normal variants are not characterized by a subnormal growth velocity, and barring mismeasurement, a growth rate below the normal range is a cause of concern and should trigger an evaluation. A figure of 5 cm/yr is frequently used as a rough measure of the minimum height velocity in childhood (after age 3), though strictly speaking a normal height velocity may be as low as 4 cm/yr for males and 4.5 cm/yr for females in children between the age of 6 years and puberty.

Initial screening labs should include an IGF-1 level (to assess GH secretion), a TSH (to evaluate the thyroid gland), and a bone

age radiograph to assess bone maturation and obtain an estimate of the final adult height. A complete blood count (to rule out anemia) and a creatinine level (to assess renal function) as well as an erythrocyte sedimentation rate or C-reactive protein to identify systemic inflammation may be indicated. *A karyotype is mandatory in any female with significant short stature* because of the possibility of Turner syndrome. Beyond that, the testing will be guided by the history, the physical examination, and the results of initial screening labs.

◆ Important Considerations in the History

Pregnancy and Birth History

- Did the mother have illnesses or take medication during the pregnancy? Maternal illness or use of certain drugs can cause poor fetal growth.
- What was the birth weight and length? IUGR may lead to continuing small stature.
- Did the baby have perinatal problems such as unexplained hypoglycemia, prolonged jaundice, or in males, a small phallus? These are all suggestive of congenital GH deficiency.
- Did the neonate have other perinatal problems (birth asphyxia, puffy extremities)? These may provide clues to the underlying cause of short stature (significant hypoxia may lead to hypopituitarism; puffy extremities in a female are suggestive of Turner syndrome).

Infancy and Childhood

What was the child's growth pattern? The child who is short but growing at a normal rate and paralleling the 3rd percentile is more likely to have familial or constitutional short stature. The child whose height deviates progressively away from the normal curve (especially after 24 months of age) is much more likely to have an underlying medical disorder. When this progressive deviation occurs from early childhood and continues, it often represents a congenital disorder (e.g., Turner syndrome, congenital GH deficiency). However, growth attenuation that occurs after a sustained period of normal growth suggests that a disorder has been acquired (e.g., acquired GH deficiency, inflammatory bowel disease).

What were the child's developmental milestones? How is the school performance? Slow development or poor school performance may indicate a central disorder or may represent part of a syndrome (e.g., PWS). Hypothyroidism acquired after age 3 years usually does not interfere with school performance, although inadequately treated congenital hypothyroidism often leads to intellectual impairment. This question may also elicit a history of emotional problems.

Has the child had any serious illnesses or been on medication? Chronic illness often impedes growth, as do certain medications (glucocorticoids). A history of nonendocrine medical problems may also provide clues to the underlying disorder (e.g., the presence of aortic coarctation may be suggestive of Turner syndrome).

Review of Systems

How is the child's appetite? What does the child eat in a typical 3-day period (often best described by a formal diet record)? Adequate caloric intake is needed for growth. Inadequate intake may be a symptom of underlying chronic disease.

Does the child have abdominal pain, diarrhea, unexplained fevers, mouth or anal sores, or joint pain? These symptoms suggest occult inflammatory bowel disease.

Does the child have neck swelling, lethargy, constipation, cold intolerance, or weight gain without much increase in height? These are among the symptoms of acquired hypothyroidism.

Does the child have headaches, vomiting, or visual disturbances? Symptoms of central nervous system dysfunction, raised intracranial pressure, or both suggest the possibility of acquired hypopituitarism in association with a central lesion such as a tumor or hydrocephalus.

Has the child begun pubertal development? Puberty influences growth. Children with constitutional delay in growth and development have delayed puberty and often have an exaggerated nadir of growth velocity before puberty begins. However, the more puberty is delayed, the greater the likelihood of a medical disorder such as hypogonadism. Delayed puberty may also be a manifestation of hypogonadism (Turner syndrome), or it may be secondary to a growth-impeding disorder (hypothyroidism, malnutrition, chronic illness). Precocious puberty is not a cause of growth failure (it should accelerate growth), but it may lead to a short final adult height because of premature fusion of the epiphyses.

◆ Family History

What were the heights of the parents and other family members at the child's age, and when did they undergo puberty? What are the current heights of the parents and family members? The most frequent causes of short stature are familial short stature and constitutional delay in growth and development. In the former, a family history of short stature is elicited. In the latter, a family history of delayed puberty is elicited.

◆ Physical Examination

Height and weight should each be plotted carefully on growth charts. The degree of short stature in relation to peers is ascertained. Previous height measurements provide an index of the child's pattern of growth. Weight that is depressed more than height in a short child is suggestive of chronic illness or malnutrition. In contrast, a child who is short but chubby is more likely to have an endocrine disorder or syndrome (e.g., GH deficiency, hypothyroidism, Cushing syndrome, PWS).

Exogenous obesity is usually associated with a relatively tall stature. Disproportionate short stature is characteristic of skeletal dysplasias (short limbs in the case of achondroplasia and hypochondroplasia, short trunk in some rare forms of skeletal dysplasia) and may also be seen in long-standing hypothyroidism.

The presence of dysmorphic features is often suggestive of a syndrome or genetic disorder (e.g., Turner syndrome, Noonan syndrome). Midline craniofacial defects are suggestive of hypopituitarism.

Goiter, delayed dentition, bradycardia, dry hair or skin, or delayed reflexes may be suggestive of hypothyroidism.

A cherubic or doll-like appearance, high-pitched voice, delayed dentition, poor musculature, or relative adiposity may be suggestive of GH deficiency.

Bitemporal hemianopsia, papilledema, optic atrophy, or accelerating head circumference in a young child is suggestive of a central nervous system abnormality (craniopharyngioma) causing hypopituitarism.

The stage of puberty is noted. Delayed puberty is compatible with constitutional delay in growth and development, hypogonadism, panhypopituitarism, severe hypothyroidism, or chronic illness.

THERAPEUTIC OPTIONS

◆ Specific Treatment of the Primary Disorder

If a child is found to have a clear medical condition causing short stature and for which treatment is available (e.g., hypothyroidism, GH deficiency), the appropriate treatment (thyroid replacement therapy or GH therapy, respectively) improves growth markedly as long as the epiphyses remain open. Often, such children experience accelerated

(catch-up) growth for some time after appropriate treatment is instituted. Complete compensation for growth failure is unlikely to occur if the disorder was many years in duration or occurred very close to the onset of normal puberty.

Sex Steroids

Sex steroid treatments may be administered to adolescents with constitutional delay of growth and development. Males with delayed puberty may be treated with testosterone enanthate or cypionate (50-100 mg/month intramuscularly or subcutaneously for 3-6 months; smaller doses given more frequently may be more physiologic and are preferred by some practitioners) to gradually bring about secondary sexual characteristics and accelerated linear growth. This is often gratifying for males and is usually followed by spontaneous pubertal development. The low dose of testosterone is designed to avoid undue advancement of bone age and loss of growth potential. Oxandrolone is a testosterone derivative with fewer androgenic effects than testosterone, and does not aromatize to estrogen, so theoretically it may be preferable to depo-testosterone injections. Several small studies report beneficial effects of oxandrolone in males with constitutional delay of growth and puberty. The usual dose is 2.5 mg daily for anywhere from 3-12 months. Giving oxandrolone (in addition to GH therapy) to females with Turner syndrome leads to better height outcomes than GH alone, so this is frequently done at around age 8-10 in females who are still well short of a normal height. Females with Turner syndrome who started GH relatively early in life are less likely to require the addition of oxandrolone. The usual dose is 0.03-0.05 mg/kg/day. Side effects at this dose are rare, but signs of virilization should prompt a reduction in dose.

Estrogen—Just as males with constitutional delay are treated with androgens, females with pubertal delay and mild short stature may be treated with a short course of estrogen therapy. However, benign constitutional delay is less likely in females (who are more likely to have an underlying pathologic cause such as Turner syndrome) and such treatment is relatively rare. If it is contemplated, care should be taken to exclude other causes of pubertal delay and to use low doses of estrogens because estrogens promote epiphyseal closure.

Counseling

Reassurance and counseling should be available for all patients. For many children with familial short stature or constitutional delay in growth and development, it is reassuring to be told that they are normal and are likely to reach a normal adult height or 1 in keeping with the family heights. This is particularly true for children with delayed puberty, in whom the discrepancy in height in comparison with peers (who have gone through their pubertal growth spurts) is disconcerting. It is helpful if parents do not dwell on the child's height but focus on the child's strengths. Gymnastics, wrestling, soccer, and swimming are often activities at which short children are not at a disadvantage and in which they may excel.

Growth Hormone Therapy

There is a broad consensus for the use of GH therapy in children with short stature caused by classic GH deficiency, Turner syndrome, Noonan syndrome, *SHOX* haploinsufficiency, PWS, and chronic renal failure. Children who were born SGA and fail to catch up to the normal range of height by age 2 years (by 4 years of age in Europe) are also candidates for GH therapy. The U.S. FDA has approved GH for children with ISS, but this treatment remains controversial and the cost-benefit ratio remains uncertain.

Side effects of GH therapy include fluid retention that is usually mild and tends to resolve with continued treatment. Mild headaches are also common and are usually benign. Increased intracranial pressure (**pseudotumor cerebri**) is a rare but serious dose-related side effect. It usually resolves if treatment is stopped, and after resolution, treatment can frequently be restarted at a lower dose. The incidence of **slipped capital femoral epiphyses** is increased and scoliosis may be worsened during GH therapy, likely secondary to accelerated growth. GH-neutralizing antibodies may appear but are rarely of clinical significance. GH can accelerate the growth of existing nevi and can induce insulin resistance but this does not appear to be clinically significant.

Because of its growth-promoting effects, there has long been concern about a possible increase in the incidence of cancer. No significant increase in common childhood cancers has been noted yet in surveillance studies, but (somewhat unexpectedly) in 1 French study (the Safety and Appropriateness of Growth hormone treatments in Europe [SAGhE] study), the group treated with GH had a standardized mortality ratio (SMR) of 1.33 (95% CI, 1.08-1.64) compared to controls. Cardiovascular disease was responsible for most of the excess mortality. Although all-type cancer-related mortality was not increased in the French cohort, bone tumor–related mortality was increased. There were weaknesses in the design of this study and a smaller study from Belgium, the Netherlands, and Sweden did not show the same results, but the study did raise concerns about long-term safety. More long-term follow-up data are being collected to determine the true long-term safety profile of GH. Until more information becomes available, most authorities do not recommend any changes in current practice, but this may change if ongoing studies reveal new hazards. It should be kept in mind that GH therapy on a large scale did not begin until 1985, so even the earliest treated subjects are not very old at this time; impact on the risk of cancer or heart disease in the elderly (if any) may not be detectable in various study cohorts at this time.

◆ Other Treatments

Recombinant human IGF-1 is indicated for the treatment of extremely short children with primary IGF-1 deficiency (both height *and* IGF-1 >3 SD below the mean for age) caused by severe GH insensitivity (e.g., Laron syndrome and IGF-1 gene defects). Availability may be an issue. Possible side effects include hypoglycemia, increased intracranial pressure, and adenotonsillar hypertrophy.

SUMMARY AND RED FLAGS

Short stature may be a variant of normal development or may indicate a serious underlying problem (Tables 43.8 and 43.9). When short stature is associated with a slow growth velocity, progressive deviation from the child's previous growth channel, obesity, headache, vomiting, dysmorphic features, or a goiter, or if short height is inconsistent with

TABLE 43.8 **Red Flags in the Evaluation of Short Stature**
Height >2-2.5 standard deviations below the mean for age
Subnormal growth velocity
Abnormal body proportions
Abnormal height:weight ratio
Dysmorphic features
Goiter
Abnormal central nervous system and ophthalmologic examinations

TABLE 43.9	Conditions Not to Miss
Hypoglycemia in a child with no risk factors for hypoglycemia	Consider hypopituitarism in the differential
Hypoglycemia, jaundice, and microphallus in a newborn boy	Rule out growth hormone deficiency
Obesity in a child who is short	Rule out hypothyroidism, growth hormone deficiency, Cushing syndrome, Prader–Willi syndrome, Laurence- Moon–Biedl syndrome
Shortness in a child with a goiter	Rule out hypothyroidism
Shortness in a child with headache, vomiting, or visual disturbance	Rule out hypopituitarism secondary to a central nervous system lesion, including craniopharyngioma or hydrocephalus

the family history, a search for an underlying medical disorder should be undertaken. Understanding how to measure a child accurately, performing simple proportion measurements, and calculating growth velocity are skills that all pediatricians must have in order to diagnose short stature and identify associated disease states and syndromes.

Hypoglycemia

Alvina R. Kansra

Hypoglycemia, although rare in children beyond the newborn period, is an acute, life-threatening medical emergency that may result in seizures, permanent brain damage, or even sudden death. In addition, hypoglycemia may be due to a serious underlying disorder. Various pathologic mechanisms, such as abnormal hormone secretion, metabolic defects, and drugs or toxins, have been attributed as causes of hypoglycemia. Therefore, to evaluate hypoglycemia either in a child or newborn, a comprehensive strategy for diagnosis and treatment is crucial. An important underlying cause of hypoglycemic disorders is a disruption in the normal response of the metabolic and endocrine systems during the transition from fed to fasted state. Hypoglycemia results from an imbalance in glucose homeostasis, either excessive glucose removal from the circulation or deficient glucose delivery into the circulation, or both. Obtaining plasma and urine specimens to evaluate the critical levels of various hormones and metabolic products at the time of hypoglycemia are essential for diagnosis and should be drawn immediately before treatment begins. However, treatment should never be delayed if there is uncertainty as to what critical labs are required. Obtaining a "red top" and "green top" blood collection tube will allow for most all studies to be run.

DEFINITION OF HYPOGLYCEMIA

The precise definition of hypoglycemia, one applicable to all age groups, is controversial. Historically, a working definition for significant hypoglycemia was initially developed based on the clinical manifestations of low blood sugars in neonates.

Attempts have been made to define hypoglycemia by using operational thresholds or a clinical approach. An operational threshold is based on the glucose in plasma or whole blood that prompts the intervention and is defined as blood glucose <40 mg/dL (plasma glucose levels <45 mg/dL); the clinical approach defines the blood glucose concentration threshold at which clinical signs and symptoms appear (and disappear by correcting the low glucose concentration). The wide range of blood glucose concentrations at which clinically overt signs may appear has led to uncertainty in definition.

Regardless of the wide fluctuations in glucose levels (between fed and fasting states), plasma blood glucose is normally maintained within a very narrow range of 70-100 mg/dL. A plasma glucose value below 40 mg/dL is commonly taken as the clinical definition of hypoglycemia. However, subtle signs and symptoms of neuroglycopenia can be documented at plasma glucose levels below 70 mg/dL and are more apparent at glucose levels below 60 or 50 mg/dL. For provocative tests, such as fasting studies, a glucose level of 50 mg/dL can be taken as sufficiently low for judging fuel and hormonal responsiveness. The response to a given level of plasma glucose can vary, depending on the underlying disorder. Patients with glucose-6-phosphatase deficiency (type 1 glycogen storage disease) may appear asymptomatic at glucose

levels below 40 mg/dL because they have concomitant elevations of plasma lactate (and ketones), which can partially spare the glucose utilization by the brain. On the other hand, children with defects in fatty acid oxidation can become very ill at plasma glucose levels as high as 60 mg/dL because they have no alternative fuels (ketones) to glucose as a substrate for the brain, heart, and skeletal muscle.

When comparing reported glucose values, the clinician must recognize some technical factors. Unless a free-flow blood sample is obtained from the infant with minimal pain, the glucose values are likely to be unreliable. Second, whole blood glucose values are slightly lower than those of plasma because of the dilution by the fluid in the red blood cells. Finally, hematocrit also influences the blood glucose concentration. This is particularly important in newborns, whose hematocrit values are higher than older infants and children. A high hematocrit level results in lower blood glucose concentration; the opposite is true for low hematocrit values.

It was once common practice to accept lower standards for glucose levels in newborns because of the high frequency of low plasma glucose levels on the day of birth. It should be stressed that these lower values represent a purely "statistical" definition of normal; there is no evidence that the neonatal brain has less need for glucose than do the brains of older children or adults. Specific maturational delays in several of the fasting systems (metabolic, endocrine) adequately explain why neonates have such a high risk of hypoglycemia during the first 12-24 hours after delivery. The use of different glucose standards for newborns should be discouraged, and the same treatment goals for hypoglycemia should be applied to newborns and older children: that is, to maintain plasma glucose levels above 60 mg/dL.

REGULATION OF BLOOD GLUCOSE CONCENTRATION

The brain is solely dependent upon glucose as a primary source of energy. However, during the period of starvation it can also use ketones an alternative (but not sole) source for energy production. Glucose is derived either from the intestinal absorption of dietary carbohydrates (exogenous source) or endogenous production (glycogenolysis or gluconeogenesis). Within 2-3 hours after a meal, glucose absorption from the intestine ceases, and the liver becomes the major source of glucose for the brain and other tissues. The liver produces glucose through a combination of glycogenolysis and gluconeogenesis (Fig. 44.1). Gluconeogenesis provides approximately 25% of hepatic glucose production in the early phases of fasting; the rate of gluconeogenesis is determined largely by rates of proteolysis and remains constant throughout fasting. Hepatic glycogenolysis provides the majority of glucose production early in a fast, but by 12 hours, liver glycogen stores become depleted. The body must then begin to depend on release of fatty acids by lipolysis

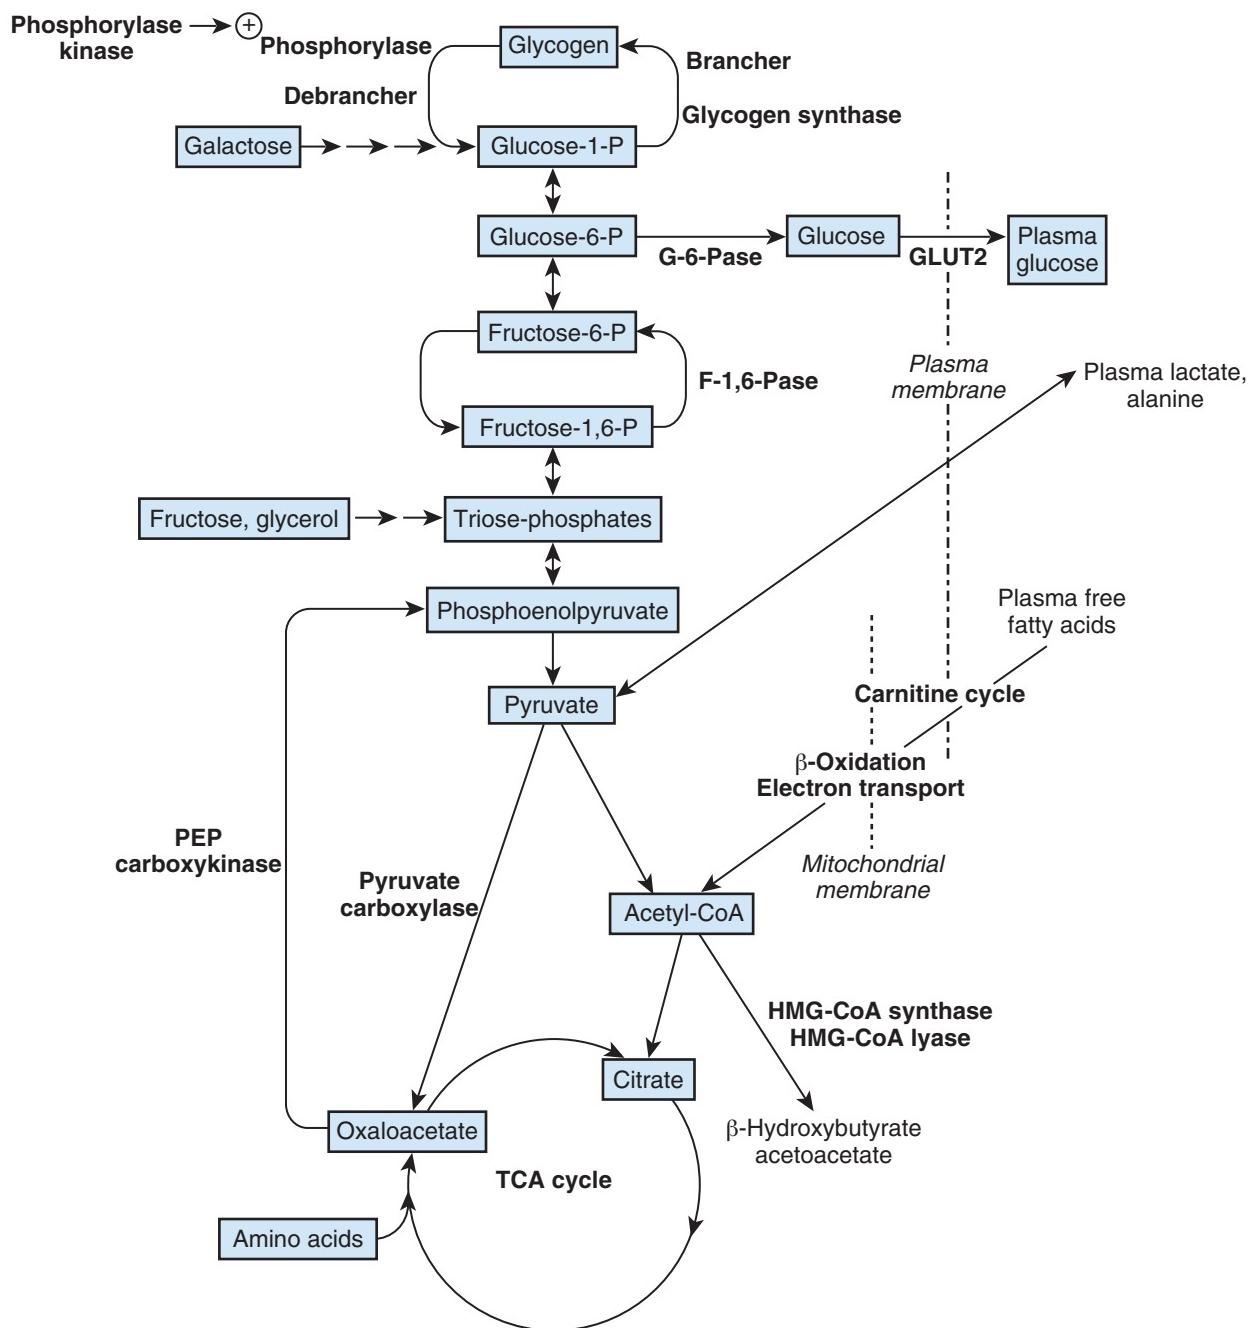
(See *Nelson Textbook of Pediatrics,* p. 773.)


FIGURE 44.1 Metabolic systems of fasting adaptation. Shown are the pathways of hepatic gluconeogenesis, glycogenolysis, and ketogenesis. Key enzyme steps are in boldface. Enzyme steps in gluconeogenesis: pyruvate carboxylase, phosphoenolpyruvate (PEP) carboxykinase, fructose-1,6-bisphosphatase (F-1,6-Pase), glucose-6-phosphatase (G-6-Pase), and the plasma membrane glucose transporter 2 (GLUT2). Enzyme steps in glycogenolysis: glycogen synthase, glycogen brancher enzyme, glycogen phosphorylase kinase, glycogen phosphorylase, and glycogen debrancher enzyme. Steps in ketogenesis include a series of enzyme steps in the carnitine cycle for transporting fatty acids across the mitochondrial membrane, enzymes of the β-oxidation cycle, enzymes of electron transport, and enzymes of ketone synthesis (3-hydroxy-3-methylglutaryl-coenzyme A [HMG-CoA] synthase and HMG-CoA lyase). P, phosphate; TCA, tricarboxylic acid.

from stores of fat in adipose tissue. Most tissues can oxidize free fatty acids directly and thus minimize their use of glucose. The major exception is the brain, which is unable to directly oxidize free fatty acids, because they cannot cross the blood-brain barrier. Partial oxidation of free fatty acids in the liver produces ketones (β-hydroxybutyrate and acetoacetate), which are readily oxidized by the brain, thus sparing cerebral glucose consumption.

Metabolic systems and hormones normally prevent hypoglycemia during fasting (Tables 44.1 and 44.2). The integration of these systems is demonstrated by the changes in plasma concentrations of the major fuels and hormones during the course of fasting (Fig. 44.2). Plasma glucose concentrations gradually decline over the course of the fast as liver glycogen reserves are depleted. In infants and young children, with their larger ratio of brain to body mass, glucose levels fall faster than

in older children and adults and may reach 50 mg/dL by 24-30 hours of fasting. Plasma levels of lactate, a representative gluconeogenic precursor, decline during the course of fasting as hepatic gluconeogenesis is stimulated and protein turnover slows. Plasma free fatty acid levels begin to rise quickly after 12-20 hours of fasting in response to the fall in insulin concentrations as glucose levels decline. The increased availability of fatty acids is accompanied by a 10- to 20-fold rise in plasma ketone levels as hepatic oxidation of fatty acids is activated. Determining the circulating levels of these fuels and hormones at the point of hypoglycemia provides the most important information for diagnosing the cause of hypoglycemia.

CLINICAL MANIFESTATIONS

A variety of signs and symptoms may occur in patients with hypoglycemia (Table 44.3). They can be divided into 2 categories. Those in the 1st category result from activation of the autonomic nervous system and release of the counter-regulatory hormone epinephrine. Those in the 2nd category are secondary to inadequate delivery of glucose to the brain (neuroglycopenia).

CAUSES OF TRANSIENT NEONATAL HYPOGLYCEMIA

Hypoglycemia is a common problem in newborns. The majority of cases are transient, although the neonatal period is also the time when inherited disorders are most likely to manifest. The differential diagnosis of hypoglycemia is extensive (Table 44.4).

Normal Newborns

As many as 30% of normal, full-term newborns and those of size appropriate for gestational age may be unable to maintain plasma

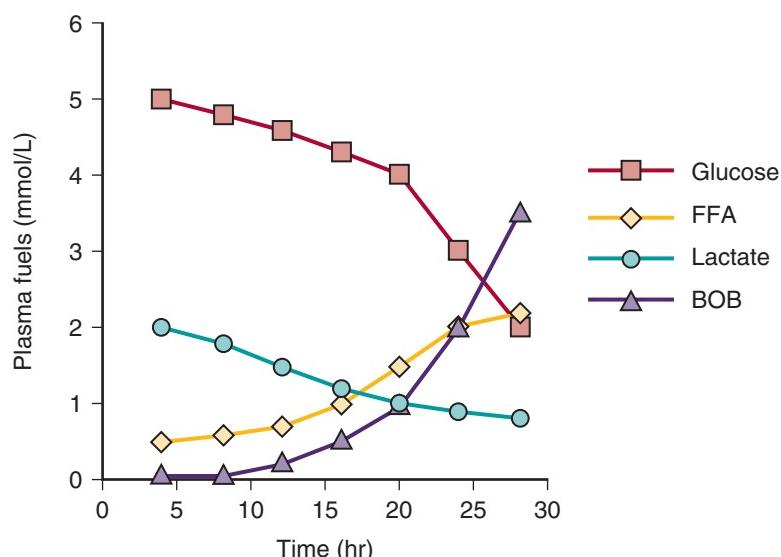

FIGURE 44.2 Changes in plasma levels of key fuels during fasting in a normal child. Note that plasma glucose declines toward hypoglycemic values by 24 hours as hepatic glycogen reserves become depleted. Plasma levels of lactate, a representative gluconeogenic substrate, decline gradually during the fast as hepatic gluconeogenesis is activated. Late in fasting, levels of plasma free fatty acids (FFA) increase as lipolysis is stimulated, followed by a dramatic rise in β-hydroxybutyrate that reflects the increase in the rates of hepatic fatty acid oxidation and ketone synthesis. BOB, β-hydroxybutyrate.

glucose levels above 50 mg/dL if they fast during the 1st 6 hours after delivery. By the 2nd day of life, the frequency of plasma glucose concentrations below 50 mg/dL decreases to less than 1%, which indicates a rapid maturation of fasting metabolic adaptation. The extremely poor fasting tolerance on the day of birth can be explained by lack of development of key enzymes in the pathways of both hepatic gluconeogenesis and ketogenesis. Transcription of these genes is delayed until after delivery but becomes well activated by the end of the first 24 hours. Glucagon and cortisol may be important for activation of enzymes involved in gluconeogenesis. Ingestion of long-chain fats (e.g., in colostrum) may be important for triggering transcription of the two enzymes of ketogenesis. Thus, on the day of birth, all newborns can be viewed as having impaired fasting adaptation. In the absence of other risk factors, hypoglycemia in the first day may necessitate only feeding and follow-up blood glucose determination to ensure that further workup is not necessary. Breast-fed babies are at special risk for hypoglycemia when there are problems initiating milk production.

Newborns Small for Gestational Age and Premature Infants

Hypoglycemia is significantly more common in premature infants and those small for gestational age because of decreased stores of glycogen, fat, and protein. In addition, the enzymes necessary for gluconeogenesis may be less developed than in normal full-term infants.

Infants of Diabetic Mothers

Infants born to mothers with any type of diabetes, including gestational diabetes, are at risk for hypoglycemia because of oversecretion of insulin during the first few days after delivery. This transient neonatal hyperinsulinemia occurs because maternal hyperglycemia stimulates fetal insulin secretion and, after delivery, affected infants have difficulty in downregulating insulin secretion to adapt to the withdrawal of the hyperglycemia. Because of the growth-stimulating effects of insulin on the fetus, infants of diabetic mothers are often large for gestational age. Blood glucose levels should be monitored after birth until they stabilize in the normal range. Enteral feedings should be initiated as soon as possible to prevent fasting hypoglycemia. Hypoglycemia should be treated with intravenous glucose; the problem should resolve promptly, within 1-2 days. Prolonged hyperinsulinism (HI) in infants of diabetic mothers should raise the suspicion of either a genetic form of HI or perinatal stress-induced HI.

Perinatal Stress-Induced Hyperinsulinism

Some infants with birth asphyxia or intrauterine growth restriction may have severe problems with hypoglycemia for prolonged periods, ranging from a few days to a few months after birth. This form of transient HI has not been well characterized, but it is probably not rare. The mechanism appears to be HI; oral diazoxide, which decreases insulin secretion, provides good control of hypoglycemia in these infants.

Erythroblastosis Fetalis

An association between hypoglycemia and erythroblastosis fetalis caused by Rh incompatibility occurs in infants who are anemic at birth (cord hemoglobin <10 g/dL). The low blood glucose levels in these infants have been attributed to high plasma insulin concentration. The cause of these high insulin levels remains undefined. The current prevention and management of Rh sensitization have markedly reduced the incidence of erythroblastosis and of fetal and neonatal anemia. Nonetheless, such infants require careful monitoring of plasma glucose concentration soon after birth.

Intrapartum Maternal Glucose Administration

Administration of excessive glucose quantities to the mother during labor results in maternal as well as fetal hyperglycemia. Increased fetal glucose concentration causes increased fetal insulin secretion and fetal HI. If the glucose has been administered to the mother immediately before the infant's birth, the infant is born with high insulin levels. In addition, high fetal blood glucose and insulin levels may also cause an increase in fetal blood lactate concentration and metabolic acidosis. These effects are more pronounced if the mother has received infusions of glucose for a prolonged time. An acute administration of large amounts of glucose-containing fluids to prevent hypotension in women receiving conduction anesthesia could result in acute fetal hyperglycemia, HI, and metabolic acidosis. This is a transient HI that leads to hypoglycemia in a fetus.

(See *Nelson Textbook of Pediatrics,* p. 897.)

TABLE 44.4 Classification of Hypoglycemia in Infants and Children

Neonatal Transitional (Adaptive) Hypoglycemia

Associated with Inadequate Substrate or Immature Enzyme Function in Otherwise Normal Neonates

Prematurity
Small for gestational age
Normal newborn

Transient Neonatal Hyperinsulinism

Infant of diabetic mother
Small for gestational age
Discordant twin
Birth asphyxia
Infant of toxemic mother

Neonatal, Infantile, or Childhood Hyperinsulinemic Hypoglycemias

Recessive K_{ATP} channel HI
Recessive HADH (hydroxyl acyl-CoA dehydrogenase) mutation HI
Recessive UCP2 (mitochondrial uncoupling protein 2) mutation HI
Focal K_{ATP} channel HI
Dominant K_{ATP} channel HI
Atypical congenital hyperinsulinemia (no mutations in *ABCC8* or *KCNJ11* genes)
Dominant glucokinase HI
Dominant glutamate dehydrogenase HI (hyperinsulinism/hyperammonemia syndrome)
Dominant mutations in *HNF-4A* and *HNF-1A* (hepatic nuclear factors 4α and 1α) HI with monogenic diabetes of youth later in life
Dominant mutation in SLC16A1 (the pyruvate transporter)—exercise-induced hypoglycemia
Acquired islet adenoma
Beckwith-Wiedemann syndrome
Factitious disorder: insulin administration (Munchausen syndrome by proxy)
Oral sulfonylurea drugs
Congenital disorders of glycosylation

Counter-Regulatory Hormone Deficiency

Panhypopituitarism
Isolated growth hormone deficiency
Adrenocorticotropic hormone deficiency
Addison disease
Epinephrine deficiency

Glycogenolysis and Gluconeogenesis Disorders

Glucose-6-phosphatase deficiency (GSD 1a)
Glucose-6-phosphate translocase deficiency (GSD 1b)
Amylo-1,6-glucosidase (debranching enzyme) deficiency (GSD 3)
Liver phosphorylase deficiency (GSD 6)
Phosphorylase kinase deficiency (GSD 9)
Glycogen synthetase deficiency (GSD 0)
Fructose-1,6-diphosphatase deficiency
Pyruvate carboxylase deficiency
Galactosemia
Hereditary fructose intolerance

Lipolysis Disorders

Fatty Acid Oxidation Disorders

Carnitine transporter deficiency (primary carnitine deficiency)
Carnitine palmitoyltransferase-1 deficiency
Carnitine translocase deficiency
Carnitine palmitoyltransferase-2 deficiency
Secondary carnitine deficiencies
Very-long-, long-, medium-chain acyl-CoA dehydrogenase deficiency

Other Etiologies

Substrate-Limited

Ketotic hypoglycemia
Poisoning—drugs
Salicylates
Alcohol
Oral hypoglycemic agents
Insulin
Propranolol
Pentamidine
Quinine
Disopyramide
Ackee fruit (unripe)—hypoglycin
Vacor (rat poison)
Trimethoprim-sulfamethoxazole (with renal failure)

Liver Disease

Reye syndrome
Hepatitis
Cirrhosis
Hepatoma

Amino Acid and Organic Acid Disorders

Maple syrup urine disease
Propionic acidemia
Methylmalonic acidemia
Tyrosinosis
Glutaric aciduria
3-Hydroxy-3-methylglutaric aciduria

Systemic Disorders

Sepsis
Carcinoma/sarcoma (secreting insulin-like growth factor II)
Heart failure
Malnutrition
Malabsorption
Anti-insulin receptor antibodies
Anti-insulin antibodies
Neonatal hyperviscosity
Renal failure
Diarrhea
Burns
Shock
Postsurgical
Pseudohypoglycemia (leukocytosis, polycythemia)
Excessive insulin therapy of insulin-dependent diabetes mellitus
Factitious
Nissen fundoplication (dumping syndrome)
Falciparum malaria

GSD, glycogen storage disease; HI, hyperinsulinemia; K_{ATP}, regulated potassium channel.

Maternal Drug Therapy

The various pharmacologic agents administered to the mother for the treatment of medical problems that can influence blood glucose levels in the newborn can be divided into 2 broad categories:

1. Some drugs, including oral hypoglycemic agents, can directly affect blood glucose. Oral hypoglycemic agents, such as chlorpropamide and sulfonylureas, are administered by some physicians for the treatment of gestational diabetes. Because these drugs are easily transported across the placenta, the infant is born with a certain amount of drug present in the circulation. These drugs, particularly those with prolonged effects, may result in profound hypoglycemia that tends to persist until the drug is removed, either by its own clearance or by exchange transfusion.

2. Some drugs are administered to the mother with indirect effects (the more common contributor to neonatal hypoglycemia). β-Sympathomimetic agents commonly used for the prevention and treatment of premature labor can result in maternal hyperglycemia by increasing hepatic glucose production and decreasing glucose utilization. Maternal hyperglycemia, in turn, can initiate fetal hyperglycemia and HI, which can cause hypoglycemia in the newborn.

Beckwith-Wiedemann Syndrome

The clinical features of infants born with Beckwith-Wiedemann syndrome (BWS) consist of macroglossia, abdominal wall defects (omphalocele, umbilical hernia), somatic gigantism, visceromegaly (liver, kidney, spleen), and hypoglycemia. Other possible features include ear anomalies, such as creases on the lobe; cardiac defects; renal abnormalities; hemihypertrophy; and neonatal polycythemia. These infants are prone to intraabdominal malignancies, including Wilms tumor, hepatoblastoma, rhabdomyosarcoma, and neuroblastoma. Most cases of BWS are sporadic, although approximately 15% have autosomal dominant inheritance. BWS appears to be caused by abnormal genomic imprinting involving multiple genes at chromosome 11p15.

Early recognition of hypoglycemia is extremely important for appropriate clinical management because there is an association in BWS between hypoglycemia and intellectual impairment. Any infant born with an omphalocele should be monitored for potential hypoglycemia. Approximately 50% of newborns with BWS have hypoglycemia; 80% of cases are mild and transient. The remaining 20% of cases are more prolonged and difficult to control. HI is the principal mechanism of the hypoglycemia. Hypertrophy and hyperplasia of the islet of Langerhans have been observed. Treatment depends on the severity of the hypoglycemia; it may include frequent feedings, intravenous dextrose, medications such as diazoxide or octreotide, and, rarely in severe cases, partial pancreatectomy. If managed medically, the hypoglycemia eventually resolves over weeks to months of care.

CAUSES OF PERSISTENT HYPOGLYCEMIA IN INFANTS AND CHILDREN

Hyperinsulinism

Congenital HI is the most common cause of persistent hypoglycemia in infants and children. Previously, this disorder was referred to as nesidioblastosis, leucine-sensitive hypoglycemia, or idiopathic hypoglycemia of infancy. Most affected patients present during infancy; macrosomia may be present at birth as a result of high fetal insulin levels, which act as a growth factor in utero. Excessive insulin secretion during fasting suppresses all of the fasting systems, including hepatic glucose production, lipolysis, and ketogenesis. Hypoglycemia results from both increased glucose utilization and underproduction of glucose. Because lipolysis and ketosis are inhibited, levels of alternative

fuels remain low, which increases the risk of seizures and permanent brain injury. There are several genetic defects of pancreatic β-cell insulin secretion in children with HI (Fig. 44.3 and Table 44.5; see also Table 44.4).

Recessive KATP Channel Hyperinsulinism

This is the most severe form of congenital HI. Affected infants are usually large for gestational age and present with symptoms of hypoglycemia in the 1st days after birth. The hypoglycemia is often extremely severe, and treatment may require intravenous glucose infusions at 20-30 mg/kg/min (4-6 times normal) to maintain plasma glucose in the normal range of 70-100 mg/dL. This disorder is caused by genetic defects of the β-cell plasma membrane adenosine triphosphate-dependent potassium (KATP) channel (Fig. 44.4). The channel is encoded by 2 adjacent genes located on chromosome 11p: *ABCC8*, which encodes the sulfonylurea receptor type 1 (SUR1) protein subunit and *KCNJ11A*, which encodes the potassium channel, inwardly rectifying, Kir6.2 subunit. Common founder mutations of *ABCC8* have been identified in Ashkenazi Jews and in Finland, but most affected patients have 1 of a large number of "private" (rare and unique) mutations. Medical management with diazoxide or octreotide (which acts like somatostatin) may be tried (see Figs. 44.3 and 44.4) but is rarely effective. Most infants require surgical near-total (98%) pancreatectomy to achieve control of hypoglycemia. Approximately 50% of infants with severe HI who require surgery have diffuse disease caused by these recessive KATP channel mutations; the remainder has focal lesions that are potentially curable by partial surgical resection.

Focal KATP Channel Hyperinsulinism

Approximately half the infants with severe neonatal-onset HI have focal lesions of the pancreas that are potentially curable by surgical resection. The molecular defect in these infants involves the same KATP channel genes as in recessive KATP channel HI through a 2-hit mechanism: loss of heterozygosity for the maternal chromosome 11p and expression of a paternally derived *ABCC8* or *KCNJ11A* mutation. Histologically, the focal lesions usually appear as adenomatosis. The clinical features are identical to those of infants with recessive KATP channel HI, including diazoxide unresponsiveness and hypoglycemia that is extremely difficult to control. Methods to diagnose and localize focal pancreatic adenomatosis preoperatively include acute insulin response tests to secretagogues such as calcium and tolbutamide, selective pancreatic arterial calcium stimulation of insulin release with pancreatic venous sampling, and positron emission tomography.

Dominant KATP Channel Hyperinsulinism

One family has been reported with HI caused by a dominantly expressed mutation of the *ABCC8* gene, rather than the usual recessive disease described previously.

Dominant Glutamate Dehydrogenase Hyperinsulinism

Dominantly expressed gain-of-function mutations of glutamate dehydrogenase have been identified in children with the unusual combination of HI plus asymptomatic hyperammonemia (HI/HA). The majority of cases arise from de novo mutations, and only 20% are familial. Hypoglycemic symptoms often do not manifest in the neonatal period, and the disorder may not be recognized until the affected patient is an adult. Birthweights of affected infants are normal.

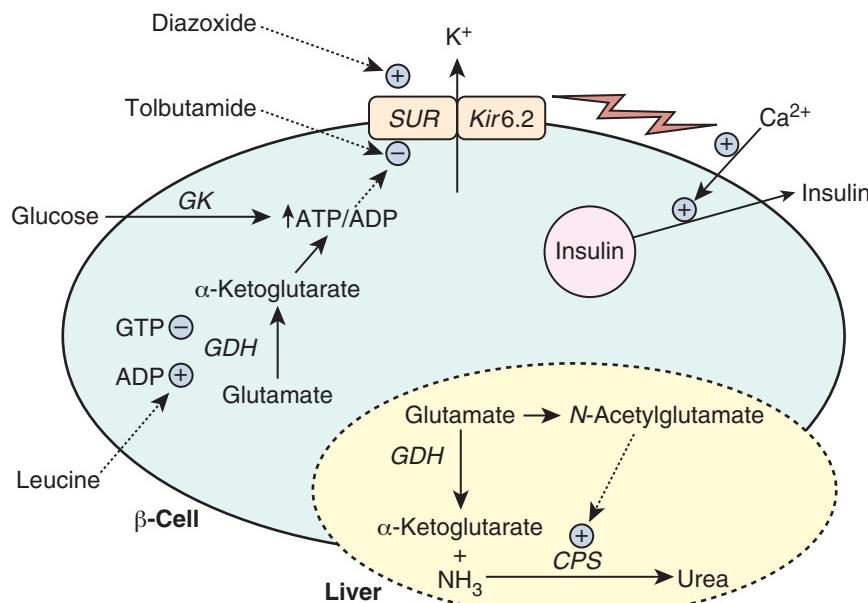
In addition to hypoglycemia, affected individuals have persistent but asymptomatic hyperammonemia in the range of 70-150 μmol/L (see Fig. 44.3). The mutations affect the pathway of leucine-stimulated insulin secretion, and patients can have protein-sensitive hypoglycemia, as well as fasting hypoglycemia. Diazoxide is effective in controlling hypoglycemia.


FIGURE 44.3 Pathways of pancreatic β-cell insulin secretion. Increases in plasma concentrations of glucose lead to increased pancreatic β-cell glucose oxidation rates and elevations of intracellular adenosine triphosphate (ATP). The increase in the ratio of ATP to adenosine diphosphate subsequently acts via the sulfonylurea receptor type 1 (SUR1) component of the ATP-sensitive potassium (KATP) channel to inhibit potassium efflux, resulting in membrane depolarization and activation of a voltage-gated calcium ion channel. The rise in intracellular calcium triggers the release of insulin from secretory granules into the plasma. Genes involved in congenital hyperinsulinism include glucokinase; glutamate dehydrogenase (GDH); SUR1; and the ion pore component of the KATP channel, Kir6.2. Note that leucine triggers β-cell insulin secretion by allosterically activating GDH to increase oxidation of glutamate, which subsequently leads to inhibition of the KATP channel. As shown in the *inset* of liver pathways of glutamate metabolism, in the hyperinsulinism/hyperammonemia syndrome, overactivity of GDH leads to excessive ammonia production from glutamate and also decreases the availability of glutamate for synthesis of *N*-acetylglutamate, a required allosteric activator of the 1st step in ureagenesis. Note that SUR1 mediates both tolbutamide activation of insulin release and diazoxide inhibition of insulin release. Somatostatin inhibits insulin release at a more distal site in the pathway. ADP, adenosine diphosphate; CPS, carbamyl phosphate synthetase; GK, glucokinase; GTP, guanosine triphosphate; SUR, sulfonylurea receptor.

Dominant Glucokinase Hyperinsulinism

This extremely rare disorder causes mild fasting hypoglycemia as a result of a dominant gain-of-function mutation of islet glucokinase (see Fig. 44.3). Birthweights of affected infants are normal, and the age at onset of hypoglycemic symptoms ranges from infancy to adulthood. Diazoxide therapy has been effective in controlling plasma glucose levels.

Insulinoma

Acquired **insulinomas** are the most common form of HI in adults but are rare in childhood, especially in early infancy. These are usually isolated, benign tumors, but multiple adenomas may occur in association with the familial multiple endocrine neoplasia syndromes. In contrast to focal congenital HI, insulinomas may be detectable by imaging procedures such as computed tomography, magnetic resonance imaging, radioactive octreotide scans, or transduodenal ultrasonography. Surgical resection is the treatment of choice.

Insulin Reaction, Oral Hypoglycemic Agents, and Surreptitious Insulin Administration

Insulin-induced hypoglycemia is a common occurrence in insulin-treated diabetic patients and may also occur in patients with type 2 diabetes who are taking oral hypoglycemic agents, such as glyburide, that stimulate insulin secretion. Surreptitious insulin administration should always be included in the differential diagnosis of unexplained hypoglycemia and, in young children, may occur as part of factitious disorder by proxy (Munchausen syndrome by proxy). Exogenous human or animal insulin use can be demonstrated by assays showing elevated plasma insulin values with simultaneous suppression of plasma C peptide (use of insulin lispro may not be detectable with some insulin immunoassays).

Counter-Regulatory Hormone Deficiencies
Hypopituitarism

Hypopituitarism with isolated deficiency of growth hormone, and particularly with deficiencies of both growth hormone and adrenocorticotropin hormone, predisposes to fasting hypoglycemia. In affected older infants, hypoglycemia may occur after 10-14 hours of fasting. Newborns with hypopituitarism sometimes present with much more severe hypoglycemia, which can closely mimic the KATP channel form of congenital HI, including increased glucose requirements of 10-20 mg/kg/min and an inappropriate glycemic response to glucagon when patients are hypoglycemic. Liver disease resembling progressive cholestatic jaundice may occur in these newborns and does not resolve until replacement therapy is begun for the deficient hormones. Hypotonia and, in affected boys, a small phallus may also be present.

A number of syndromes, such as midline craniofacial defects, septo-optic dysplasia, and Russell-Silver dwarfism, may be associated with hypopituitarism. Infant boys characteristically have microphallus, which is a useful diagnostic sign.

TABLE 44.5   Correlation of Clinical Features with Molecular Defects in Persistent Hyperinsulinemic Hypoglycemia in Infancy

Type	Macrosomia	Hypoglycemia/ Hyperinsulinemia	Family History	Molecular Defects	Associated Clinical, Biochemical, or Molecular Features	Response to Medical Management	Recommended Surgical Approach	Prognosis
Sporadic	Present at birth	Moderate/severe in 1st days to weeks of life	Negative	*ABCC8/KCNJ11A* mutations not always identified in diffuse hyperplasia	Loss of heterozygosity in microadenomatous tissue	Generally poor; may respond better to somatostatin than to diazoxide	Partial pancreatectomy if frozen section shows β-cell crowding with small nuclei—suggests microadenoma. Subtotal >95% pancreatectomy if frozen section shows giant nuclei in β cells—suggests diffuse hyperplasia	Excellent if focal adenoma is removed, thereby curing hypoglycemia and retaining sufficient pancreas to avoid diabetes. Guarded if subtotal pancreatectomy (>95%) is performed; diabetes mellitus develops in 50% of patients; hypoglycemia persists in 33%
Autosomal recessive	Present at birth	Severe in 1st days to weeks of life	Positive	*ABCC8/KCNJ11A*	Consanguinity a feature in some populations	Poor	Subtotal pancreatectomy	Guarded
Autosomal dominant	Unusual	Moderate onset usually post 6 mo of age	Positive	Glucokinase (activating) Some cases gene unknown	None	Very good to excellent	Surgery usually not required Partial pancreatectomy only if medical management fails	Excellent
Autosomal dominant	Unusual	Moderate onset usually post 6 mo of age	Positive	Glutamate dehydrogenase (activating)	Modest hyperammonemia	Very good to excellent	Surgery usually not required	Excellent
Beckwith–Wiedemann syndrome	Present at birth	Moderate, spontaneously resolves post 6 mo of age	Negative	Duplicating/ imprinting in chromosome 11p15.1	Macroglossia, omphalocele, hemihypertrophy	Good	Not recommended	Excellent for hypoglycemia; guarded for possible development of embryonal tumors (Wilms hepatoblastoma)
Congenital disorders of glycosylation	Not usual	Moderate/onset post 3 mo of age	Negative	Phosphomannose isomerase deficiency	Hepatomegaly, vomiting, intractable diarrhea	Good with mannose supplement	Not recommended	Fair

Isolated Cortisol Deficiency

Fasting hypoglycemia may occur in infants and children with adrenal insufficiency of various causes, including adrenocorticotropin hormone deficiency and primary adrenal insufficiency (Addison disease), or as a consequence of adrenal suppression resulting from exogenous glucocorticoid administration. Hypoglycemia is uncommon in the presentation of newborns with congenital adrenal hyperplasia, but once glucocorticoid replacement treatment is begun, these children are also at risk for adrenal crises and hypoglycemia if not given supplemental doses during intercurrent illness.

Epinephrine Deficiency

Catecholamine deficiency is extremely rare and has been described as secondary to adrenal hemorrhage in infants small for gestational age. These patients may present for the 1st time during childhood with hypoglycemia during fasting. The diagnosis is confirmed by measurement of plasma or urinary catecholamine levels. Some affected children may show evidence, on abdominal films, of previous adrenal hemorrhage in the form of adrenal calcification.

Fasting hypoglycemia has been observed occasionally in children treated with β-blocking agents, such as propranolol. The mechanism appears to be suppression of lipolysis as a result of the interference with epinephrine stimulation of adipose tissue; this suppression impairs the 3rd stage of fasting adaptation. Hypoglycemia may occur after 12 or more hours of fasting. Hypoglycemic attacks may be associated with acute hypertension as a result of the unopposed α-adrenergic effects of epinephrine.

Metabolic Enzyme Defects
Hepatic Gluconeogenesis

The genetic metabolic defects in hepatic gluconeogenesis lead to fasting hypoglycemia associated with increased plasma concentrations of gluconeogenic precursors, such as lactate and alanine.

Glucose-6-phosphatase deficiency (Glycogen storage disease type 1a and type 1b). This is the most common form of the glycogen storage disorders, although (see Fig. 44.1) deficiency of glucose-6-phosphatase is actually a gluconeogenic defect as it blocks the release of glucose from both gluconeogenesis and glycogenolysis. Hypoglycemia occurs within 2-3 hours after a meal, as soon as intestinal carbohydrate absorption is complete. Affected infants usually do not present with symptomatic hypoglycemia, because the associated elevations of lactate provide an alternative fuel for the brain when the glucose level is low. Instead, the manifestation is usually growth failure late in the 1st year. The liver is massively enlarged as a result of fat and glycogen deposition and extends into the left upper quadrant and down into the pelvis. Associated abnormalities include elevations of plasma triglyceride (up to 2000-4000 mg/dL) and hyperuricemia. Treatment is aimed at correcting the frequent cycling into fasting that leads to growth failure by a combination of high-carbohydrate meals together with either uncooked cornstarch or continuous intragastric dextrose infusions. Carbohydrates that cannot be converted to glucose, such as galactose in milk, fructose in fruits, and sucrose, should be limited. The type 1b variant is caused by deficiency of the microsomal glucose-6-phosphate translocase and is associated with the additional problem of neutropenia, leading to mouth ulcers and skin infections.

Treatment with granulocyte colony-stimulating factor has been beneficial in these patients.

Glucose transporter 2 deficiency (Fanconi-Bickel syndrome). A small number of infants have been described with a combination of hepatomegaly, increased liver glycogen store, renal Fanconi syndrome, and galactose intolerance. This recessively inherited disorder is caused by pathogenic variants in the gene *SLC2A2*, which encodes glucose transporter 2 (GLUT2), a plasma membrane glucose transporter, which is expressed in liver, kidney, and pancreatic β cells. GLUT2 is necessary to export free glucose from the cytosol into the plasma (see Fig. 44.1). Deficiency of GLUT2 interferes with glucose release from the liver not only from glycogenolysis but also from gluconeogenesis and from other sugars, such as galactose and fructose.

Fructose-1,6-diphosphatase deficiency. This defect blocks gluconeogenesis immediately above the triose-phosphates (see Fig. 44.1). Affected children present in the 1st year or the neonatal period with life-threatening attacks of hypoglycemia and lactic acidemia provoked by fasting stress. Moderate fatty hepatomegaly is commonly seen together with hyperuricemia. Fructose ingestion can precipitate hypoglycemia and lactic acidemia. During controlled fasting, plasma glucose can be maintained in the normal range until 8-12 hours, because glycogenolysis remains normal. Treatment with avoidance of prolonged fasting and restriction of fructose-containing foods and glycerol is effective in avoiding hypoglycemia.

Pyruvate carboxylase deficiency. Pyruvate carboxylase is 1 of the 4 key gluconeogenic enzymes (see Fig. 44.1). It also plays an important role in pyruvate oxidation because it generates oxaloacetate needed to maintain tricarboxylic acid (TCA) cycle activity. The clinical features are often dominated by the defect in pyruvate oxidation and include those of Leigh syndrome and congenital lactic acidemia. However, affected infants are also susceptible to the development of symptomatic hypoglycemia after 8-10 hours of fasting.

Hepatic Glycogenolysis

Defects in hepatic glycogenolysis are associated with abbreviated fasting tolerance, leading to hypoglycemia and hyperketonemia. Defects can occur in either the synthesis or breakdown of hepatic glycogen (see Fig. 44.1). Debrancher enzyme deficiency is the most severe of these defects.

Debrancher enzyme deficiency (type 3 glycogen storage disease). Children with this disorder usually present in the 1st year of life with growth delay and massive hepatomegaly. Symptomatic hypoglycemia is not common, because plasma ketone levels are usually elevated and provide the brain with alternative substrate when the glucose level is low. Hypoglycemia develops quickly, often within 3-6 hours after a meal. Treatment with uncooked cornstarch to prolong glucose absorption is useful in preventing hypoglycemia and improving growth. Problems caused by hypoglycemia are ameliorated later in childhood as body mass increases. However, half or more of patients with debrancher enzyme deficiency are at risk for developing progressive muscle weakness and/or cardiomyopathy by the 2nd and 3rd decades of life.

Phosphorylase/phosphorylase kinase deficiency. The manifestations of either of these 2 enzyme defects clinically resemble a very mild form of debrancher enzyme deficiency. Affected infants present with enlarged livers, often in association with impaired growth. Symptomatic hypoglycemia is unusual. Fasting tests show a pattern of accelerated starvation with early onset of hyperketonemia. Treatment to reduce fasting intervals to less than 4-6 hours (e.g., with uncooked cornstarch) is helpful in correcting the failure to thrive. As in debrancher enzyme deficiency, the fasting disturbance becomes less apparent as body mass increases, and the hepatomegaly and growth delay may totally resolve by the end of the 1st decade. Liver phosphorylase deficiency is recessively inherited; both recessive inheritance and X-linked inheritance have been reported for phosphorylase kinase deficiency.

Glycogen synthase deficiency. A small number of patients with deficiency of glycogen synthase have been reported. They have presented with episodes of symptomatic, hyperketotic hypoglycemia after fasts of 10-12 hours. Mild hepatomegaly may be present as a result of the increased deposition of triglycerides that is common in all of the glycogenoses. Treatment with uncooked cornstarch at bedtime may be helpful in avoiding symptomatic episodes of early morning hypoglycemia.

Fatty Acid Oxidation Disorders

Genetic defects in fatty acid oxidation interfere with the ketotic phase of fasting adaptation. The most common of the disorders is medium-chain acyl-coenzyme A (CoA) dehydrogenase (MCAD) deficiency. Children with MCAD deficiency present with acute attacks of life-threatening coma and **hypoketotic hypoglycemia** that are usually precipitated by fasting stresses of 12 hours or longer. Attacks are triggered by intercurrent illnesses that impair feeding, especially gastroenteritis. The clinical features mimic Reye syndrome, with coma, elevated liver transaminase levels, and mild hepatomegaly with steatosis. More severe forms of fatty acid oxidation disorders also involve skeletal and cardiac muscle and may manifest with cardiomyopathy and chronic muscle weakness or acute episodes of rhabdomyolysis. More than 12 different defects in the pathway of fatty acid oxidation have been identified; all are recessively inherited. Many states have neonatal screening programs in which dual tandem mass spectrometry of blood spot acylcarnitine profiles are used to detect MCAD deficiency and several of the other fatty acid oxidation disorders. This is important for presymptomatic detection and treatment, because the mortality rate at the 1st presentation may be higher than 25%.

Other Metabolic Causes of Hypoglycemia

Glucose transporter 1 deficiency. Isolated hypoglycorrhachia (low cerebrospinal fluid glucose level) in association with normal concentrations of plasma glucose has been demonstrated in a number of infants with intractable seizures in early infancy caused by a deficiency of glucose transporter 1 (GLUT1). GLUT1 is the plasma membrane carrier protein responsible for glucose transport across the blood-brain barrier, as well as into red blood cells. Affected patients are heterozygous for a GLUT1 mutation and have persistently low levels of spinal fluid glucose, ranging from 20-30 mg/dL. Seizures may begin in the neonatal period and respond poorly to treatment with antiseizure drugs. Progressive brain damage, microcephaly, and developmental delay occur in untreated patients. Several patients have been reported to respond very well to treatment with a ketogenic diet, which restricts carbohydrates and keeps plasma levels of ketones elevated to 3-6 mEq/L.

Hereditary fructose intolerance. Hereditary fructose intolerance is caused by a recessively inherited deficiency of hepatic fructose-aldolase, which transforms fructose-1-phosphate to the triose-phosphates. Affected patients cannot metabolize dietary fructose or sucrose (table sugar) in the liver or intestinal mucosa for conversion to glucose. Chronic fructose intake in young infants may cause liver dysfunction, acidemia, failure to thrive, hyperuricemia, and, ultimately, liver failure. In affected older children, ingestion of fructose causes severe abdominal pain, and these children may learn by experience to avoid fructose and thus escape identification. Fasting tolerance is normal, but ingestion of large amounts of fructose may provoke postprandial hypoglycemia by tying up intracellular phosphate and thus blocking glycogenolysis. Treatment is avoidance of dietary sources of fructose.

Galactosemia (galactose-1-phosphate uridyl transferase deficiency). This is a serious inborn error of metabolism wherein many of the long-term consequences of the metabolic defect can potentially be prevented by early intervention. For this reason, all infants born in the United States are screened for galactosemia in the neonatal period. Absence of galactose-1-phosphate uridyl transferase prevents the conversion of galactose to glucose and results in accumulation of galactose-1-phosphate in the liver and other tissues. It has been suggested that accumulation of this metabolite inhibits the enzyme involved in the conversion of glucose-1-phosphate to glucose-6-phosphate and thus decreases the production of glucose from glycogen, thereby producing hypoglycemia. Depending on the magnitude of the defect, affected infants may present in the immediate neonatal period or later in infancy. The patients do not tolerate galactose or lactose. Intolerance to lactose in milk, the major nutrient containing galactose, is evident soon after birth when feedings are initiated. The infant may present with vomiting, failure to thrive, hepatomegaly, and indirect or direct hyperbilirubinemia. In severe or untreated cases, lenticular opacities, aminoaciduria, and intellectual disability may occur. In untreated patients, progressive hepatomegaly, cirrhosis, and hepatic failure may develop. Affected infants are at increased risk for *Escherichia coli* sepsis.

Any infant with persistent jaundice, hepatomegaly, and failure to thrive should be tested for galactosemia. A presumptive diagnosis can be made by the presence of reducing sugar (Clinitest positive) that is not glucose (i.e., the glucose enzyme test result is negative) in the urine. This test should be performed while the infant is being fed a galactose-containing formula. The diagnosis should be confirmed by measuring the enzyme activity in the red blood cells.

Treatment consists of elimination of galactose from the diet. In spite of treatment, which results in prevention of hepatic disease and of intellectual disability, many affected older children demonstrate learning and behavior problems.

Reactive Hypoglycemia

Reactive or postprandial hypoglycemia is extremely rare in the pediatric age range and, even in adults, may be overdiagnosed. Only 2 situations in infants and children present with reactive hypoglycemia:

Glutamate dehydrogenase-hyperinsulinism, hyperinsulinism/hyperammonemia syndrome. Affected children have fasting hypoglycemia, but because of their leucine sensitivity, may also develop symptomatic hypoglycemia within 30-90 minutes of eating a high-protein meal.

Post–Nissen fundoplication hypoglycemia (late dumping syndrome). Similar to patients who have had gastric surgery, infants who have undergone Nissen fundoplication procedures for gastroesophageal reflux can develop recurrent attacks of postprandial hypoglycemia. The hypoglycemia may be severe enough to produce seizures and permanent brain damage. The mechanism is thought to involve rapid gastric emptying that leads to a rapid rise in plasma glucose accompanied by a delayed but excessive insulin response, which is followed by a precipitous fall in plasma glucose to hypoglycemic levels 30-90 minutes after a meal.

Hereditary fructose intolerance. Patients with this disorder develop acute abdominal discomfort and hypoglycemia within a short period of time after an oral load of fructose (e.g., fruit, fruit juice, or sucrose).

DIAGNOSIS OF HYPOGLYCEMIA

Critical Samples

Tests on the specimens of blood and urine obtained at the time of hypoglycemia provide the key information for diagnosis (Table 44.6 and Fig. 44.5). Ideally, these specimens are collected during hypoglycemia, immediately before treatment is begun. It is best to collect some extra tubes of plasma and urine just before giving intravenous dextrose, to set aside for later decisions about which other tests to order. Tests should include plasma glucose measurement, various metabolic precursors and hormones involved in glucose counter-regulation, including glucose, bicarbonate, insulin, growth hormone, cortisol, lactate, pyruvate, ammonia, β-hydroxybutyrate, free fatty acid, carnitine, acylcarnitine profile, and a urine sample for organic acid analysis and ketones. Additional tests to consider include transaminases, uric acid, triglycerides, and creatinine kinase levels. Fig. 44.5 shows a paradigm for diagnosis of different hypoglycemic disorders that is based on analysis of the critical samples.

Fasting Study

In some cases, a formal fasting test is advised to establish the etiology of hypoglycemia. This should only be done in a well controlled setting with adequate monitoring by experienced medical and nursing staff.

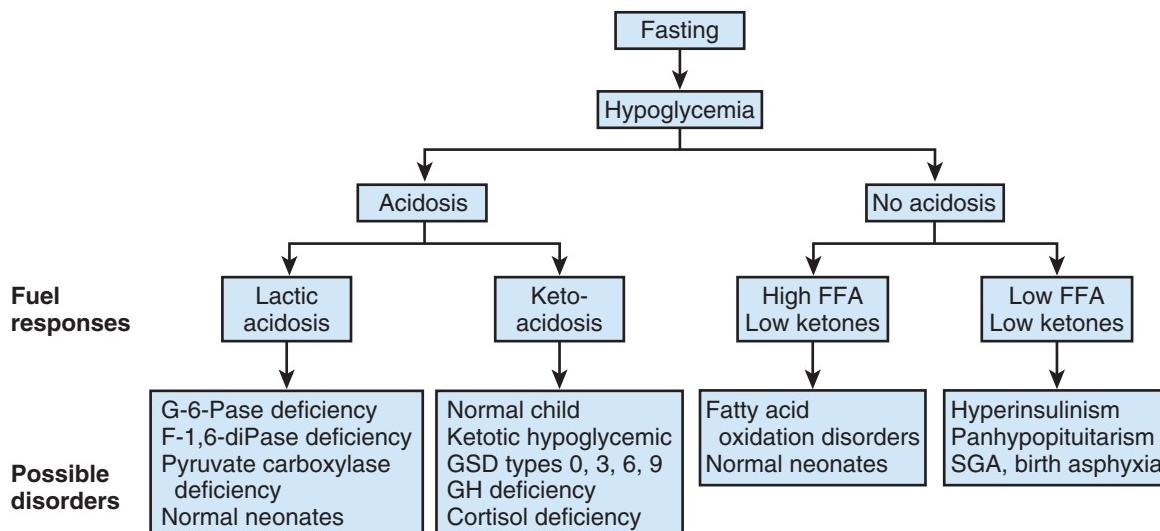

FIGURE 44.5 Algorithm for diagnosis of hypoglycemia, based on fasting fuel responses. F-1,6-diPase, fructose-1,6-diphosphatase; FFA, free fatty acid; G-6-Pase, glucose-6-phosphatase; GH, growth hormone; GSD, glycogen storage disease; SGA, small for gestational age.

TABLE 44.6 Clinical Manifestations and Differential Diagnosis in Childhood Hypoglycemia

Condition	Hypoglycemia	Urinary Ketones or Reducing Sugars	Hepatomegaly	SERUM Lipids	SERUM Uric Acid	EFFECT OF 24–36 hr FAST ON PLASMA Glucose	Insulin	Ketones	Alanine	Lactate	GLYCEMIC RESPONSE TO GLUCAGON Fed	Fasted	GLYCEMIC RESPONSE TO INFUSION OF Alanine	Glycerol
Normal	0	0	0	Normal	Normal	↓	↓	↑	↓	Normal	↑	↓		Not indicated
Hyperinsulinemia	Recurrent severe	0	0	Normal or ↑	Normal	↓↓	↑↑	↓↓	Normal	Normal	↑	↑		Not indicated
Ketotic hypoglycemia	Severe with missed meals	Ketonuria +++	0	Normal	Normal	↓↓	↓	↑↑	↓↓	Normal	↑	↓↓		Not indicated
Fatty acid oxidation disorder	Severe with missed meals	Absent	0 to + Abnormal liver function test results	Abnormal	↑	Contraindicated					↑	↓		Not indicated
Hypopituitarism	Moderate with missed meals	Ketonuria ++	0	Normal	Normal	↓↓	↓	↑↑	↓↓	Normal	↑	↓↓	↑	↑
Adrenal insufficiency	Severe with missed meals	Ketonuria ++	0	Normal	Normal	↓↓	↓	↑↑	↓↓	Normal	↑	↓↓	↑	↑
Enzyme deficiencies	Severe-constant	Ketonuria +++	+++	↑↑	↑↑	↓↓	↓	↑↑	↑↑	↑↑	0	0-↓↓	0	0
Glucose-6-phosphatase debrancher	Moderate with fasting	++	++	Normal	Normal	↓↓	↓	↑↑	↓↓	Normal	↑	0-↓↓	↑	↑
Phosphorylase	Mild-moderate	Ketonuria ++	+	Normal	Normal	↓	↓	↑↑	↓↓	Normal	0-↑	0-↓↓	↑	↑
Fructose-1, 6-diphosphatase	Severe with fasting	Ketonuria +++	+++	↑↑	↑↑	↓↓	↓	↑↑	↑↑	↑↑	↑	0-↓↓	→	→
Galactosemia	After milk or milk products	0 Ketones; (s) +	+++	Normal	Normal	↓	↓	↑	→	Normal	↑	0-↓↓	↑	↑
Fructose intolerance	After fructose	0 Ketones; (s) +	+++	Normal	Normal	↓	↓	↑	→	Normal	↑	0-↓↓	↑	↑

Details of each condition are discussed in the text.

0, absence; ↑ or ↓, small increase or decrease, respectively; ↑↑ or ↓↓, large increase or decrease, respectively; +, less likely; ++, likely; +++, definitively.

From Sperling MA. Hypoglycemia. In: Kliegman RM, Stanton BF, St. Geme JW III, et al., eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2016:780.

Fasting is usually begun at 8 P.M. after bedtime snack or sometimes in the morning, especially in younger patients, to make sure that there is enough supervision and staff available during the time hypoglycemia occurs.

Useful "Casual Specimen" Tests

Only a few tests are informative except at times of hypoglycemia. These include plasma acyl-carnitine profiles and plasma total and free carnitine levels (for suspected fatty acid oxidation defects) and plasma ammonia (for the HI/HA syndrome).

Glucagon Stimulation

If HI is suspected, a glucagon stimulation test at the onset of hypoglycemia (50 mg/dL) may be confirmatory. A glycemic response exceeding 30 mg/dL is consistent with HI, because the normal response would be to have depleted liver glycogen reserves well before reaching hypoglycemia.

Acute Insulin Response Tests for Hyperinsulinism

β-Cell responsiveness to different secretagogues (calcium, leucine, glucose, tolbutamide) can be used to define specific genetic forms of HI and to distinguish focal from diffuse pancreatic disease preoperatively.

Plasma Acyl-Carnitine Profile

Dual tandem mass spectrometry methods have been developed for analyzing plasma acyl-carnitine profiles and other metabolites in small samples, such as filter paper blood spots. These assays are useful for screening for most of the genetic fatty acid oxidation disorders (e.g., MCAD deficiency) and should be performed before patients suspected to have such a defect begin a formal fasting test. Many states incorporate these methods for neonatal screening of up to 30 different inborn errors of metabolism. Some fatty acid oxidation defects do not cause abnormal acyl-carnitine profiles; examples include carnitine palmityl-transferase 1 deficiency, carnitine transporter deficiency, and β-hydroxy-β-methylglutaryl-CoA dehydrogenase deficiency. These disorders must be investigated with additional in vivo and in vitro tests.

Urinary Organic Acid Quantitation

Assays of urinary metabolites by gas chromatography–mass spectrometry are also useful in identifying specific defects in fatty acid oxidation. Abnormalities are most pronounced during activation of lipolysis, such as at the end of a diagnostic fasting test or in the "critical sample" urine collected at the time of an acute illness.

Cultured Cells

For in vitro diagnosis of fatty acid oxidation defects, cultured cells from patients, such as skin fibroblasts or lymphoblasts, may be useful for testing overall pathway activity, for assaying activities of candidate enzymes, or as a source of DNA for mutation analysis. Most enzymes in the pathway are expressed in cultured cells, with the exception of 3-hydroxy-3-methylglutaryl–CoA synthase, which is restricted to liver, intestine, and kidney.

Mutation Analysis

Mutation identification is useful for confirmation of diagnosis and genetic counseling. In a limited number of disorders, common mutations that can be easily screened for as a primary diagnostic test have been identified. These include MCAD deficiency, glucose-6-phosphatase deficiency, and hyperinsulinemia due to ATP-binding cassette transporter 8 *(ABCC8)*, ATP sensitive inward rectifier potassium channel 11 *(KCNJ11A)*, mitochondrial glutamate dehydrogenase 1 *(GLUD1)*, hepatic nuclear factor 4-alpha *(HNF4A)*, glucokinase *(GCK)*, mitochondrial hydroxylacyl-coenzyme A *(HADH)*, and mitochondrial uncoupling protein 2 *(UCP2)*. Easy access to information about disease-associated mutations is available through the Online Mendelian Inheritance in Man (OMIM) web site (http://www.ncbi.nlm.nih.gov/Omim/).

TREATMENT OF HYPOGLYCEMIA

The initial treatment of hypoglycemia is to promptly raise the plasma glucose level to normal and maintain it in the range of 80-100 mg/dL. For long-term management, the minimum goal of therapy is to keep the plasma glucose level above 60 mg/dL at all times.

Whenever treatment begins in a patient with new-onset hypoglycemia, every effort should be made to collect the critical samples for diagnosis. One extra tube of 5 mL of plasma or serum (green-top or red-top tube) is sufficient to measure key chemistry levels, fuels, and hormones. An extra tube of 10 mL or more of urine should also be collected for urinary organic acid quantitation.

For emergency treatment of hypoglycemia, a bolus of dextrose, 200 mg/kg, is given rapidly, and then a continuous infusion is begun to run at a rate equal to at least normal hepatic glucose output (about 4-6 mg/kg/min). With 10% dextrose solutions, this means a bolus of 2 mL/kg followed by continuous infusion at maintenance rates. Infants with HI may require considerably higher rates of dextrose infusion, up to 20-30 mg/kg/min. Infants with fatty acid oxidation disorders should receive sufficient dextrose to ensure that insulin secretion is stimulated enough to suppress lipolysis—that is, 10% dextrose at 8-10 mg/kg/min—and to maintain all plasma glucose levels slightly above 100 mg/dL. Glucagon may be used to treat hypoglycemia on an emergency basis, but only if the hypoglycemia is known to be caused by HI; a dose of 1 mg should be used at all ages to avoid undertreatment.

■ SUMMARY AND RED FLAGS

Hypoglycemia has many manifestations and must be thought of as a cause of nonspecific signs in newborns. It is a readily treatable cause of lethargy, coma, and seizures. Other affected children have signs of catecholamine excess. Untreated symptomatic hypoglycemia is life-threatening and can produce significant, irreversible central nervous system injury.

Red flags include metabolic acidosis (inborn errors of metabolism, sepsis); a positive family history (inborn errors of metabolism, hyperinsulinism, hypoglycemic agents); hypoketonuria (hyperinsulinemia, fatty acid oxidation defects) and high glucose infusion rates (hyperinsulinism); onset during adolescence (drugs or alcohol); hepatomegaly (glycogen storage disease, other inborn errors of metabolism); feeding intolerance (galactosemia); or recurrent or a family history of emesis, lethargy, coma, or sudden infant death syndrome (medium-chain acyl dehydrogenase deficiency).

Urinary Incontinence and Polyuria

Cynthia G. Pan

Urinary incontinence is a normal developmental stage. When present beyond a certain age defined by parental and societal expectations, it can cause concern and anxiety in the patient and family. Urinary incontinence can also be a symptom of significant pathologic processes. The challenge to the clinician is identifying the child with an organic disorder among the many who are proceeding along a normal developmental track.

VOIDING PHYSIOLOGY

Urinary continence is dependent on normal bladder function and normal urine production. Normal development of bladder function results in the storage and release of urine in a socially and physically acceptable way. During storage, the detrusor muscle is relaxed, and the capacity of the bladder allows urine to be held for several hours. Micturition is then voluntary, with coordinated detrusor contraction and sphincter relaxation, resulting in complete bladder emptying. The bladder capacity in children learning to be toilet trained is variable, being dependent on their own sensation of bladder fullness. The maximum functional bladder capacity may differ greatly among children when measured by home diaries. Cystometry, a method of measuring bladder volume, can be estimated by the following 2 formulas:

In children <2 years of age:

$$\text{Cystometric bladder capacity (ounces)} = (2 \times \text{age [years]}) + 2$$

In children ≥2 years of age:

$$\text{Cystometric bladder capacity (ounces)} = \frac{\text{age (years)}}{2} + 6$$

Although the innervation of the bladder is predominantly autonomic, bladder function is under control of cortical function. Thus, a complex integration of visceral and somatic innervation is necessary for normal voiding, which perhaps explains the wide spectrum in the ages for urinary continence. Parasympathetic neural activity provides the primary input during micturition, leading to relaxation of the urethral smooth muscle and initiating detrusor contractions. Pelvic nerves conducting parasympathetic activity form a reflex arc with the centrally located pontine micturition center. The thoracolumbar sympathetic branch, via hypogastric and pelvic sympathetic nerves, innervates the detrusor to relax and the urinary sphincter to contract during urine storage.

Urinary continence thus relies on the abilities to (1) store urine without leakage, (2) release urine voluntarily and completely, and (3) interrupt micturition voluntarily. The third ability is indicative of fully coordinated cortical-autonomic function.

TOILET TRAINING

The age at which toilet training is achieved is influenced by cultural factors as well as the individual temperament of the child. The achievement of daytime urinary continence follows the attainment of bowel control. There is evidence that the age of daytime and nighttime continence has increased worldwide in the past century. Data suggest a change in parental attitudes toward the toilet training process and their expectations. Temperament of the child and cognitive ability may play a less significant role. Among social factors, children of single parents are successfully toilet trained at an earlier age, whereas enrollment in daycare does not have a significant influence. Consistent findings are the predictive factors of gender and race: Girls are toilet trained earlier than boys, and African-American children are trained earlier than white children. Techniques for toilet training are varied and range from the child-oriented approach to single-day training intensive methods to the use of daytime wet alarms.

URINE VOLUME AND SOLUTE DIURESIS

Polyuria is the overproduction of urine. Polyuria is a symptom that is fixed and therefore occurs during both the daytime and the nighttime. "Nocturnal polyuria," a symptom proposed in a subset of patients with primary nocturnal enuresis, is discussed separately. Overproduction of urine indicates a defect in 1 of several mechanisms regulating water and solute homeostasis. Identification of children with incontinence caused by polyuria is essential for diagnosing a variety of disorders (Table 45.1).

Urine production varies depending on the intake of fluids and solute, activity, caloric expenditure, and the environment. The volume reflects the maintenance of normal fluid and electrolyte balance (1) through the regulation of plasma osmolality by vasopressin and through the thirst mechanism and (2) by the regulation of extracellular volume and solute (mainly sodium) homeostasis by the kidney. The sensation of thirst occurs when plasma osmolality rises above a threshold of 280-290 mOsm/L. Release of vasopressin, a peptide produced by the hypothalamus, parallels the sensation of thirst and then acts on receptors in the collecting ducts of the kidney to diminish water excretion and to concentrate the urine. Hypovolemia is also a stimulant for vasopressin. Once serum osmolality is restored to normal, vasopressin release is inhibited, and renal water excretion increases. Maintenance of extracellular fluid volume depends on sodium homeostasis and directly affects urine volume. It involves the interaction of several systems, including (1) the renin-angiotensin system, (2) atrial natriuretic peptide, and (3) the sympathetic nervous system.

Among patients with primary nocturnal enuresis, there is a subset of patients with "nocturnal polyuria," in which larger volumes of more

Cystinosis
Sickle cell nephropathy
Juvenile nephronophthisis
Renal dysplasia
Cystic kidney disease
Bartter syndrome
Storage diseases (tyrosinemia, Fabry disease)

dilute urine are produced than in patients who remain dry. Responsiveness to the administration of vasopressin analogs, such as desmopressin acetate (1-deamino[8-D-arginine] vasopressin [DDAVP]), differentiates such patients into responders and nonresponders.

◆ History

The history should begin with careful questioning to determine whether the patient has polyuria. The presence of polyuria suggests a variety of metabolic, systemic, and kidney diseases, whereas the absence of polyuria places the focus on the lower urinary tract (Table 45.2; see also Table 45.1).

Polyuria

Polyuria, the excessive production of urine, can result from the absence of release of antidiuretic hormone (ADH), the failure of the kidney to respond to ADH, or an osmotic diuresis. This can lead to urinary incontinence, especially in young children. Polyuria always results in polydipsia. It is often easier to query parents as to whether the volume of fluid intake by the child is excessive rather than to obtain an estimate of the volume of urine output. The 1st clue to polydipsia in infants is irritability and "hunger" after a successful feeding of formula or breast milk. In young children, favoring water over solids or milk, as well as seeking water in unusual places (e.g., toilets), can be a sign of polydipsia. Waking to seek fluids at night in a consistent pattern is also a sign of polydipsia. Parental stories of bed linens being soaked despite a "double diaper" or training pull-on diaper, are remarkable, especially when recounted by experienced parents who are able to compare the child to other healthy siblings.

An osmotic diuresis leading to polyuria may be an early sign of diabetes mellitus. The previously dry child may develop secondary nocturnal or even daytime enuresis. Associated symptoms include polydipsia and polyphagia with poor weight gain, and fatigue. Children with central diabetes insipidus (CDI) and the genetic forms of nephrogenic diabetes insipidus (NDI) produce very large amounts of hypotonic urine. Along with polyuria and enuresis, these children may have a history of frequent hospitalizations for dehydration, often provoked by relatively minor illnesses. The dehydration is often associated with moderate or severe hypernatremia. Failure to thrive may develop as a result of a preference of low calorie-containing fluids over solid foods. The secondary causes of NDI may include a partial defect in the mechanism for renal concentrating, and urinary incontinence may be the only symptom (see Table 45.2). Conversely, other children may also have growth retardation as a result of associated chronic renal failure or the associated metabolic abnormalities (e.g., metabolic acidosis in renal tubular acidosis [RTA] or rickets in Fanconi syndrome, metabolic alkalosis in Bartter syndrome).

Voiding History

In the presence of enuresis but the absence of polyuria, a voiding history helps to determine whether additional evaluation is warranted. Is the urinary incontinence nocturnal only, or is daytime incontinence also present? Does the patient have stool incontinence? Voiding frequency is sometimes difficult to ascertain in a school-age child, and an assignment to keep a diary of voiding can be given on the 1st visit. This should include information on both bladder and bowel habits, specifically urine volumes and when urinary incontinence occurs. Urine holding patterns with overflow incontinence are most easily identifiable with a diary. Incontinence can be a symptom of a urinary tract infection (UTI) (see Chapter 18). Associated symptoms may include dysuria, frequency, and urgency. Other urinary symptoms such as dysuria, urgency, dampness in the underwear, or other signs of UTI, can all be signs of dysfunctional elimination. Asking parents for specific observations—such as (1) the sudden urge to void followed by incontinence or (2) maneuvers to prevent urine leakage, such as squatting and pressing the heel of the foot into the perineum—elicits clues to a hyperactive detrusor muscle. Incontinence may occur with giggling, with physical stress while jumping, or with activities that require Valsalva maneuvers.

(See *Nelson Textbook of Pediatrics,* p. 2645.)

Secondary enuresis is defined as enuresis occurring after a dry period of at least 6 consecutive months and can be the 1st sign of an acquired renal or metabolic disease. Fecal soiling or constipation may be an accompanying sign of dysfunctional elimination, but it should first raise suspicion for an occult spinal lesion such as spina bifida or a tethered cord. In addition, continuous dribbling, a poor urinary stream, or recurrent infections may be a sign of anatomic or neuropathic lesions (see Table 45.2).

Primary Nocturnal Enuresis

The patient with nocturnal enuresis (bedwetting) is typically without any major daytime symptoms. Enuresis is considered primary when the patient has not had any dry periods for greater than 6 months. Toilet training for daytime control is often achieved easily. The frequency of wet nights should be ascertained to gauge the magnitude of the problem. A family history of nocturnal enuresis increases a patient's risk for nocturnal enuresis. If both parents have a history of enuresis, the rate of recurrence in offspring may be as high as 70-80%. If the father had primary nocturnal enuresis, the child has a fivefold to sevenfold increase in risk.

Behavioral Issues

Social stressors should be ascertained because psychologic factors are important in the occurrence of secondary enuresis. Other psychiatric issues, such as attention-deficit/hyperactivity disorder, have been associated with a higher incidence of daytime and nighttime incontinence. It has been widely accepted, however, that primary nocturnal enuresis is not a psychiatric disorder and that affected children are often emotionally well adjusted. Nonetheless, care should be taken not to underestimate the sequelae of enuresis in the older school-age child, who may feel "abnormal" among peers. Evaluation of the patient should always include inquiring how the patient and other family members are reacting to the problem and how it may be interfering with social or school issues.

Finally, primary nocturnal enuresis may be a sleep disorder or a disorder of arousal. Patients with severe nocturnal enuresis may have defects in arousal to auditory stimuli. Inquiry into symptoms of sleep apnea should also be made, such as snoring or restless sleep, as it may lead to altered arousal states leading to nocturnal enuresis in patients with sleep apnea (see Chapter 5).

◆ Physical Examination

In all affected patients, their growth should be evaluated, because failure to thrive can be seen in many of the metabolic disorders that produce polyuria. The presence of hypertension suggests underlying renal or urologic abnormalities. Careful evaluation of the lower back may reveal cutaneous abnormalities such as hair tufts, pits, dimpling, or vascular malformations, which are possible signs of spina bifida occulta or tethered cord. A significant deviation of the gluteal cleft may also suggest the possibility of spinal dysraphism. The abdominal examination is important for detecting a distended bladder, suprapubic tenderness, or significant stool retention. A neurologic examination should include assessment of lower extremity deep tendon reflexes, observation of the gait, and evaluation of perineal sensation and anal sphincter tone, again screening for the possibility of a neuropathic bladder. Anatomic abnormalities leading to incontinence should be sought by inspection of the genitalia. In girls, the examination includes a search for fused labial folds and dribbling urine from an ectopic ureter. In boys, the phallus should be inspected for the presence of epispadias or undescended testicles.

◆ Diagnosis

The presence or absence of polyuria helps guide the necessary laboratory and radiologic testing (Figs. 45.1 and 45.2). An immediate

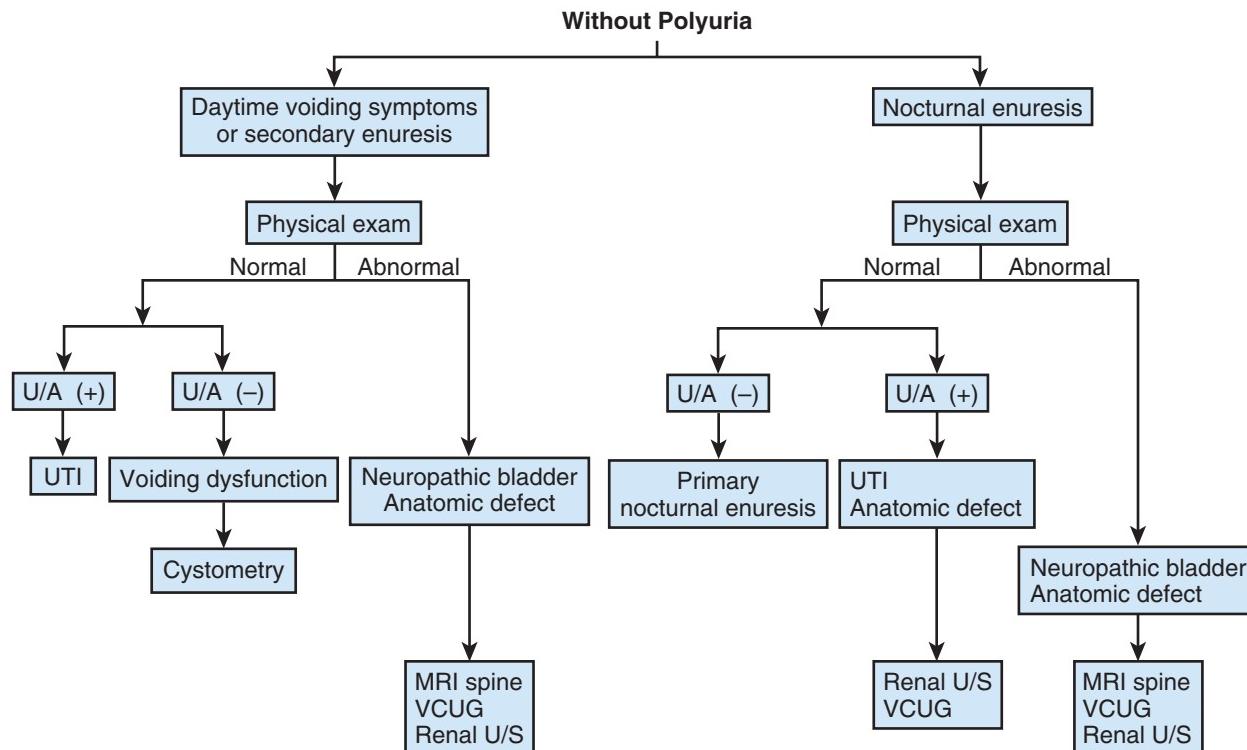

FIGURE 45.1 Diagnosis of enuresis without polyuria. MRI, magnetic resonance imaging; U/A, urinalysis; U/S, ultrasonography; UTI, urinary tract infection; VCUG, voiding cystourethrogram; +, positive; −, negative.

With Polyuria

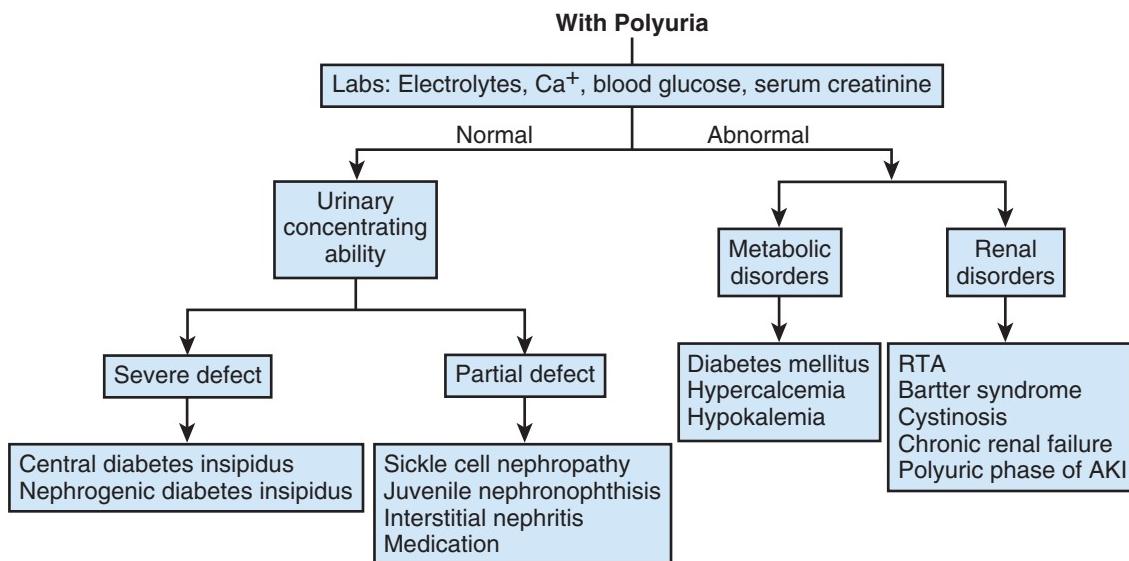
```
Labs: Electrolytes, Ca⁺, blood glucose, serum creatinine
```


FIGURE 45.2 Diagnosis of enuresis with polyuria. RTA, renal tubular acidosis; AKI, acute kidney injury.

urinalysis is critical for differentiating the glycosuria of diabetes mellitus from the low specific gravity (osmolality) of diabetes insipidus or the proteinuria and/or hematuria of chronic renal disease.

A water deprivation test to examine urine concentrating capacity of patients when diabetes insipidus is suspected should be done in a hospital setting, with close observation of and attention to urine and serum osmolarity, urine output, and weight loss. In patients with significant polyuria, dehydration and hyperosmolarity are easily precipitated with several hours of water deprivation. For patients with a less suspect history of polyuria, a 1st morning void after an overnight fast should be sufficient for checking urine osmolarity or specific gravity.

In some patients, the problem can be better defined with a home voiding diary, which outlines how often and how much they are voiding, and when urinary incontinence, constipation, or encopresis occurs.

◆ Laboratory Assessment

Routine laboratory examination in patients with monosymptomatic nocturnal enuresis includes a urinalysis and then is diagnosed by taking a good history and performing a complete physical examination. In patients with diurnal enuresis or secondary enuresis or when polyuria or polydipsia is present, a screening urinalysis, followed by appropriate blood chemistry studies are important for confirming diabetes mellitus or electrolyte disorders such as metabolic acidosis (RTA), metabolic alkalosis (Bartter syndrome), hypercalcemia, and hypokalemia. Hypernatremia can be seen in the severe forms of diabetes insipidus. UTI should be sought in most patients with incontinence by obtaining a urinalysis and urine culture. A urinalysis also helps screen for occult, chronic glomerular or tubular renal disease. Hematuria or proteinuria can be a sign of renal disease, although its absence does not exclude this possibility. Glycosuria, when associated with normal serum glucose, can indicate tubulointerstitial disease, where proximal tubular injury results in a lowered threshold for glucose reabsorption (see Table 45.2).

◆ Imaging and Cystometry

Radiologic imaging is not necessary in most patients with primary nocturnal enuresis. In select patients with secondary enuresis, daytime symptoms, or a suspect history or urinalysis, renal ultrasonography may provide information regarding acquired or congenital renal diseases. Images of the bladder can reveal urologic abnormalities, including poor bladder emptying or thickened bladder wall. A voiding cystourethrogram is indicated only in patients with a questionable urinary stream, continuous dribbling (aberrant ectopic ureter), or suspected spinal cord lesions with lower extremity neurologic signs. Magnetic resonance imaging of the lower spine should be reserved for patients with cutaneous signs, neurologic or orthopedic symptoms of the lumbar-sacral spine, or complex spinal bone deformities seen on plain radiographs. All patients with central diabetes insipidus must undergo cerebral magnetic resonance imaging with specific focus on the hypothalamic-pituitary region.

Cystometry examination is useful for a select group of patients with a history of dysfunctional voiding symptoms whose response to therapy is poor. Bladder instability is characterized by involuntary contractions at more than 15 cm of water pressure during filling. Small bladder capacity is almost always a functional problem, not anatomic.

◆ Differential Diagnosis
Primary Nocturnal Enuresis

Primary nocturnal enuresis (bedwetting) is considered abnormal in most social contexts after the age of 5 years. The majority of affected patients have no daytime symptoms. It is a common problem, but only a small proportion of patients actually seek medical advice. The prevalence, when the condition is defined as a wet night more than once a month, is estimated at 10% among 6-year-olds, 5% among 10-year-olds, and 0.5-1.0% among teens and young adults. The spontaneous cure rate is approximately 15% per year. The incidence of pure primary nocturnal enuresis without other symptoms is twice as common among boys as among girls. The pathophysiologic mechanism is multifactorial; explanations include defects in osmoregulation, small bladder capacity, and disorders of sleep or arousal states.

Dysfunctional Voiding

This occurs when there is an imbalance or lack of coordination of activity between the detrusor muscle activity (bladder contracture) and the bladder neck or external sphincter activity (bladder outlet control). This poor coordination can, over time, cause a wide spectrum of disorders, including incontinence. The severity depends on the balance of forces among the detrusor activity, bladder neck, and

external sphincter. In the extreme case, high bladder pressures produce acquired urologic abnormalities, including hydronephrosis, vesicoureteral reflux (VUR), and renal damage. Dysfunctional voiding is often classified as mild, moderate, or severe. Early recognition can lead to proper management and avoidance of long-term sequelae.

Mild voiding dysfunction. Daytime urinary frequency is characterized by frequency and urgency every 15-20 minutes. This is usually associated with incontinence or mild pain and occurs in children aged 3-8 years. The condition is also usually self-limiting. A thorough history should be documented, a careful physical examination conducted, and urinalysis performed to rule out other pathologic processes.

Giggle incontinence is most often seen in girls and is characterized by incontinence after laughter. It too is usually self-limiting. Stress incontinence follows athletic activities such as running or jumping and landing; it is common with activities such as gymnastics and cheerleading. Timely bladder emptying before exercise is effective in preventing this problem. Postvoid dribbling can occur in young girls who develop habits of incomplete voiding or can result from urine that is collected in the vagina during voiding. Sitting with the knees slightly apart or sitting on the toilet facing backwards eliminates this problem.

Moderate voiding dysfunction. There are 2 extremes in the spectrum of moderate dysfunctional voiding. Over time, urine holding, as infrequent as once every 8-12 hours, results in incontinence as well as recurrent UTIs. This can be a consequence of behaviors developed when the young child is learning voluntary contraction of the external sphincter muscle while toilet training. It may also develop when a child goes to school or camp and does not want to use an unfamiliar or embarrassing toilet. The child learns additional maneuvers to void infrequently, such as squatting and pressing the heel of the foot in the perineum. Dysfunctional voiding may worsen over time when the child is unable to relax the external sphincter in coordination with detrusor activity during voiding. This results in incomplete and inefficient bladder emptying.

The overactive bladder, or unstable bladder, is the most common abnormality. Low quantity, frequent voiding leading to incontinence is secondary to delayed resolution of uninhibited bladder contractions that normally resolve as the child matures. This asynchronous activity between detrusor muscle and sphincter contraction leads to higher intravesical pressures. Urgency and urge incontinence are the most common symptoms, but recurrent UTIs and VUR may result as well. Complications may include thickening, trabeculations, or diverticula of the bladder. *High bladder pressure can also cause hydroureter and hydronephrosis.*

Severe dysfunctional voiding. This is often referred to as the "non-neurogenic neurogenic bladder," a syndrome representing the extreme end of the spectrum of dysfunctional voiding. Inappropriate voluntary contraction of the external sphincter during voiding produces high intravesical pressure and a functional outlet obstruction, leading to abnormal bladder function, hydronephrosis, and possibly renal failure. With time, the voiding pattern becomes habitual, and the anatomic changes in the bladder impede the ability to void normally. Biofeedback and clean intermittent straight catheterization may restore bladder emptying and function and prevent renal failure.

Neuropathic Bladder

The neuropathic bladder most often occurs in patients with spina bifida, an open or closed congenital spinal cord fusion defect. This results in distortion of normal neural tissues in the spinal cord or nerve roots. The range of anomalies includes meningocele, lipomeningocele, primary tethered cord, dermoid cyst, syrinx, and sacral agenesis. Closed defects can be initially asymptomatic and manifest during toilet training years with incontinence, recurrent UTIs, or orthopedic problems in later childhood. Many children who present with symptoms have a cutaneous finding over the lumbosacral spine noted since birth. The severity of the symptoms does not seem to predict the severity of the bladder dysfunction or renal damage. Despite lesser neurologic deficits in closed spina bifida, affected patients have demonstrated bladder dysfunction as severe as that observed in open spina bifida. Acute spinal injury (trauma), compression (tumor), or infection (transverse myelitis) may produce similar bladder conditions such as acute urinary retention.

Anatomic Defects

Posterior urethral valves and urethral obstruction. This is the most common form of urinary obstruction leading to kidney failure in male infants and children. It is a result of persistence of fetal folds in the posterior urethra, which act as a valve to create urinary obstruction. Poor urinary stream and bladder distention are the most common urinary complaints, but dribbling and incontinence are also observed. UTI can be the presenting problem, and, when it is diagnosed in young boys, especially infants, posterior urethral valves should always be sought.

Prune-belly syndrome is another important cause of urethral obstruction. Early obstruction during embryogenesis leads to hydronephrosis, hydroureter, abdominal distention, abdominal musculature deficiency, and excessive skin folds, thus giving the wrinkly "prune" appearance of the abdomen in severe cases. A spectrum of renal dysplasia can result.

Renal duplication. This is a result of duplication of the ureteric bud during embryogenesis, causing a double collecting system, or 2 ureters. Duplicated ureters can open separately inside the bladder, but in rare cases, an ectopic ureter can end in the vagina, urethra, or vestibule, leading to dribbling and incontinence.

Vesicoureteral reflux. VUR is the retrograde flow of urine from the bladder into the ureters and kidney. Normal insertion of the ureter into the bladder submucosal wall forms a flap-valve mechanism that prevents urine backup during filling and contraction. Congenital VUR is secondary to shorter ureteric segments in the bladder wall. Urine flow mechanics are disrupted by the constant filling of the bladder with urine that has flowed backward and then returns to the emptied bladder. The inability to completely empty the bladder eliminates an important defense against UTIs. Secondary VUR can be associated with dysfunctional voiding. Dyssynergia between detrusor contraction and sphincter relaxation can result in VUR and recurrent UTIs. Urethral obstruction leading to high intravesical pressure also leads to VUR, poor bladder emptying, and thus UTIs and incontinence.

Metabolic Disorders

Hypercalcemia. This is an uncommon electrolyte disorder in children but can be observed in primary hyperparathyroidism, vitamin D intoxication, immobilization, Williams syndrome, malignancy, and idiopathic hypercalcemia of infancy. Polyuria is a symptom of hypercalcemia and is a result of its inhibitory effect on Na^+, K^+-ATPase function in renal tubules. This leads to renal sodium and water losses and thus to polyuria and volume contraction. In chronic hypercalcemia, increased calcium excretion over time can lead to nephrocalcinosis, tubular damage, and poor urinary concentrating ability, thus enhancing polyuria.

Hypokalemia. This is another electrolyte disorder that induces polyuria. In children, it occurs clinically as a result of diuretic use, aldosterone excess states, Cushing syndrome, and intrinsic renal disorders that affect potassium handling. The latter includes disorders such as RTA, Bartter syndrome, or renal injury from nephrotoxic

(See *Nelson Textbook of Pediatrics,* p. 2584.)

medications. Hypokalemia interferes with water reabsorption in the collecting duct of the kidneys.

Diabetes mellitus. Polyuria and urinary incontinence can be the 1st symptoms of diabetes mellitus and are secondary to hyperglycemia and the osmotic diuresis resulting from chronic glycosuria. The renal threshold for reabsorption of glucose is exceeded when the blood glucose level is higher than approximately 180 mg/dL. If oral intake of fluid decreases, as occurs when diabetic ketoacidosis causes anorexia and emesis, significant dehydration and shock frequently develop.

Central Diabetes Insipidus

In CDI, the lack of circulating ADH prevents concentration of the urine, leading to high quantities of dilute urine. The defect can be complete or partial, and thus the degree of polyuria is variable. In complete CDI, the massive polyuria can lead to severe dehydration and hypernatremia. CDI can be secondary to intracranial surgery, head trauma, or tumor involving the nuclei of the hypothalamus (where ADH is produced) or the neurohypophysial axis itself. There is also an idiopathic form and familial forms of CDI. In the idiopathic form, infiltrative diseases such as Langerhans cell histiocytosis (Letterer-Siwe syndrome) should be sought. A significant proportion of young children initially diagnosed with idiopathic CDI have been found to have histiocytosis in subsequent years. Treatment is with ADH or its analogs.

Renal Concentrating Defects

Renal tubular acidosis. In distal (type 1) RTA, the most common form of RTA, there is a defect in the tubular secretion of hydrogen ions and decreased formation of NH_4^+ cations in the urine. In children, the presentation includes failure to thrive, polyuria, and polydipsia. Hypokalemia is a common finding and can be profound, leading to weakness. Hypercalciuria and low urine citrate excretion combine to produce nephrocalcinosis. The autosomal recessive form of the disease is frequently associated with hearing loss. There are also autosomal dominant forms of the disease. Distal RTA may be secondary to medications (e.g., amphotericin) or a variety of conditions, including interstitial nephritis, obstructive uropathy, nephrocalcinosis, renal transplantation, sickle cell disease, and systemic lupus erythematosus.

Proximal RTA is less common and is a primary defect in bicarbonate reabsorption in the proximal tubule. When associated with other proximal tubular defects, such as salt wasting, phosphate wasting, glycosuria, and aminoaciduria, it is referred to as Fanconi syndrome. Manifesting in infancy to early adulthood, cystinosis is the most common cause of proximal RTA in children. This autosomal recessive disorder results from a defect in cystine transport and results in the lysosomal accumulation of cystine throughout the body. The infantile form usually manifests in the 1st year of life. Without intervention, this form results in end-stage renal failure. Acidosis, rickets, polyuria, and severe failure to thrive are hallmarks of the disease. Early intervention with oral cysteamine to bind cysteine has dramatically improved the outcome in affected patients. Proximal RTA is a feature of several other genetic disorders manifesting in childhood (such as galactosemia, tyrosinemia, hereditary fructose intolerance, glycogen storage disease type I, Lowe syndrome, Wilson disease, osteopetrosis) or ingestion of toxins (heavy metals, outdated tetracyclines, carbonic anhydrase inhibitors).

Sickle cell disease. Hemoglobin S is a genetic defect in hemoglobin A that results in red blood cells that deform under low oxygen tension (see Chapter 37). The renal medulla is a site with high osmolality, low oxygen tension, and relative acidosis, all conditions that promote sickling. This results in occlusion of blood vessels and damage

to the renal medulla, the primary site where the urine is concentrated. The resultant decreased ability to concentrate leads to a higher incidence of nocturnal enuresis in affected patients.

Nephronophthisis. Juvenile nephronophthisis is an autosomal recessive disorder that leads to end-stage renal failure between preadolescence and early adulthood. Patients have high urine output because of poor renal concentrating ability and renal salt wasting. Patients may have primary or secondary nocturnal enuresis. The salt wasting causes salt craving, and patients have a preference for salty foods or even eat salt directly from the saltshaker. A small percentage of these patients have retinitis pigmentosa, which may cause blindness at birth or later in life. Patients may present with symptoms of chronic renal failure.

Nephrogenic diabetes insipidus. The congenital form of NDI is often diagnosed before toilet training, but it can lead to urinary incontinence in later childhood. Infants may present with poor growth, severe dehydration, seizures, and central nervous system injury or death. In families in which the diagnosis has already been made, early intervention in infants can prevent these symptoms and lead to an excellent outcome. Most patients have the X-linked form of the disease, which is caused by a mutated ADH receptor. Female carriers may be mildly affected. The autosomal recessive and autosomal dominant forms of NDI are caused by mutations in aquaporin, the water channel that allows uptake of water in the collecting duct.

◆ Treatment
Primary Nocturnal Enuresis

Establishing whether the primary nocturnal enuresis is the only symptom or whether there are associated symptoms such as diurnal incontinence, constipation, sleep disorders, or behavioral issues, such as attention-deficit/hyperactivity disorder, is necessary before a treatment strategy is developed.

Many families simply want reassurance that there is not an organic explanation. It is also helpful to let the family and child know that almost all patients "outgrow" primary nocturnal enuresis. Positive reinforcement for dry nights, dispelling any negative attitudes, and avoiding blame enhance the child's self-esteem. If treatment is sought, the enuresis alarm has a high success rate, but patient selection is important. These devices are designed to awaken patients when micturition begins and result in the development of increased bladder capacity. Its effect may not be seen for up to 12 weeks, and therefore the family and patient must be highly motivated. Older patients who are ready to take charge of the problem and who do not have difficulty waking are the best candidates.

Pharmacologic therapy for primary nocturnal enuresis includes the use of DDAVP, an ADH analog. There is probably a subpopulation of patients with enuresis who have "nocturnal polyuria," which led to the drug's popularity, but there is evidence that this is independent of vasopressin secretion. DDAVP is most effective in children with a positive family history of primary nocturnal enuresis, with normal bladder capacity, and who are older than 7 years. Its safety profile has been excellent, but patients should be given careful instruction on restricting fluid intake after the bedtime dose. There are occasional reports of hyponatremic seizures in children who drink excessively while taking DDAVP.

Patients with small bladder capacity and diurnal symptoms tend not to respond to DDAVP; these patients may benefit from anticholinergic therapy, such as oxybutynin. Combination therapy involving a bed alarm plus DDAVP or DDAVP plus anticholinergic therapy may be helpful in select patients.

Imipramine, a tricyclic antidepressant, has been shown to be effective, but its side effects and toxicity have limited its use for this benign condition. Patients with enuresis and other behavioral problems who

(See *Nelson Textbook of Pediatrics,* p. 2646.)

take selective serotonin reuptake inhibitors have reported improvement in the enuresis. This may be an appropriate option in this population.

Dysfunctional Voiding

Treatment of mild voiding dysfunction should begin with nonpharmacologic management. Children should be instructed to void on a regular schedule, typically every 1-2 hours, even if they do not feel the urge to void. This encourages voiding when the patient is relaxed and will lead to fewer contractions of the external sphincter during micturition. Keeping a diary of the voiding schedule involves the child in management and makes him or her more aware of bladder habits. Aggressive management of constipation (see Chapter 16) improves good bladder emptying and decreases bladder instability.

When incontinence continues despite nonpharmacologic methods, anticholinergic therapy should be added in the treatment of a child with an overactive or unstable bladder. Oxybutynin should be started at a low dosage and titrated to its maximum dosage if necessary. The minimum effective dosage should be used to minimize side effects.

Patients with recurrent UTIs who develop urine-holding patterns that lead to overflow incontinence may benefit from a trial of antibiotic prophylaxis. This may keep the child free of infection and may prevent the painful urination that reinforces exaggerated external sphincter contraction and urine holding.

Biofeedback is reserved for patients with moderate to severe dysfunctional voiding. Patients can learn to increase bladder capacity and inhibit detrusor contractions through this method.

Polyuria

The treatment of polyuria depends on the cause. In certain disorders, such as diabetes mellitus, hypokalemia, or hypercalcemia, the underlying disorder can be corrected. The high urine output in central diabetes insipidus decreases markedly with the use of DDAVP. In contrast, there is no effective therapy for reducing urine output in patients with disorders such as juvenile nephronophthisis or obstructive uropathy.

The hereditary forms of NDI cause massive polyuria. A combination of sodium restriction and a thiazide diuretic can decrease this high urine output by producing a subtle volume depletion that results in less water being delivered to the collecting duct. The addition of a nonsteroidal antiinflammatory drug can, by reducing renal blood flow, further decrease urine output in patients with NDI. The use of indomethacin also reduces the high urine output in Bartter syndrome. Despite therapy, patients with Bartter syndrome and NDI continue to have high urine output, and the family should be counseled that a delay in achieving nighttime continence is expected.

TABLE 45.3	Red Flags
Polyuria	
Polydipsia	
Failure to thrive	
Poor urinary stream	
Encopresis	
Secondary enuresis	
Abnormal gait, including toe walking	
Recurrent urinary tract infections	
Cutaneous lesions over lumbosacral spine	
Diminished lower extremity reflexes	
Abnormal genitalia	
Palpable bladder	
Hypertension	
Headache	
Visual disturbances	
Obstructive sleep apneas	

Neuropathic Bladder and Anatomic Disorders

The treatment of these disorders depends on the specific defect. In patients with neuropathic bladders resulting from spina bifida, chronic intermittent catheterization of the bladder may be the only way to achieve continence. Uninhibited bladder contractions may necessitate anticholinergic therapy as an adjunct.

Anatomic disorders such as posterior urethral valves or VUR may still necessitate medical therapy or biofeedback after corrective surgery. Urodynamic testing can be very helpful in this population to define the problem leading to incontinence.

SUMMARY AND RED FLAGS

The majority of children with voiding problems do not have an organic problem. The work-up consists of a thorough history and physical examination. Red flags that indicate the need for diagnostic tests are shown in Table 45.3.

# Acid–Base and Electrolyte Disturbances

Sarah Vepraskas, Heather Toth, and Michael Weisgerber

The presence of an acid–base or an electrolyte disorder may explain a patient's symptoms or may lead to a specific diagnosis.

ACID–BASE BALANCE

Normal acid–base balance is maintained by the lungs and kidneys. Carbon dioxide, a by-product of normal metabolism, is a weak acid. The lungs are able to prevent an increase in the partial pressure of carbon dioxide (P_{CO_2}) in the blood by excreting the carbon dioxide (CO_2) produced by the body. The pulmonary response to changes in the CO_2 concentration is fast, as it occurs via central sensing of the P_{CO_2}, and there is a subsequent increase or decrease in ventilation to maintain a normal P_{CO_2} (35-45 mm Hg). There is an inverse relationship between P_{CO_2} and ventilation because an increase in ventilation decreases the P_{CO_2}, and a decrease in ventilation increases the P_{CO_2}.

The kidneys are responsible for excreting acid produced by the body. Sources of hydrogen ions include protein metabolism and incomplete metabolism of carbohydrates and fat; urine or stool losses of bicarbonate may contribute to acidemia. The hydrogen ions formed from endogenous acid production are neutralized by bicarbonate from the bicarbonate buffer system. The bicarbonate buffer system, based on the relationship between carbon dioxide and bicarbonate (HCO_3^-), is displayed by the following equation:

$$CO_2 + H_2O \leftrightarrow H^+ + HCO_3^-$$

This equation can help us understand how changes in CO_2 or HCO_3^- affect the acid–base balance.

ACID–BASE DISORDERS

A pH <7.35 is defined as acidosis, and a pH >7.45 is defined as alkalosis. An acid–base disorder is **respiratory** in etiology when it is caused by a primary abnormality in respiratory function (a change in Pa_{CO_2}) and is **metabolic** when the primary change is due to a variation in bicarbonate concentration. Acid–base disorders may also be mixed, which occurs when 2 or even 3 primary events act to alter the acid–base state at the same time.

In metabolic disorders, extracellular buffers (bicarbonate) rapidly titrate the presence of strong acids or bases. Intracellular buffers chiefly accomplish the buffering of respiratory disorders. Secondary respiratory compensation for metabolic acid–base disorders begins within minutes by changes in ventilation and is usually complete in 12-24 hours. In contrast, secondary metabolic compensation for respiratory disorders occurs more slowly, beginning within hours but requiring 2-5 days for completion. The kidneys increase net acid excretion in response to a primary respiratory acidosis; renal net acid excretion also increases during a metabolic acidosis if the kidneys themselves are not the cause of the metabolic acidosis. The expected compensation for primary acid–base disorders is shown in Table 46.1. *These compensatory mechanisms never return the pH back to normal until the underlying disease process has subsided or has been effectively treated.*

When only 1 primary acid–base abnormality occurs and its compensatory mechanisms are activated, the disorder is classified as a simple acid–base disorder. When a combination of acid–base disturbances occurs, the disorder is classified as a mixed acid–base disorder. The latter should be suspected if the compensation in a given patient differs from the predicted values (see Table 46.1). Interpretation of data in infants and young children requires caution. Crying results in hyperventilation and can quickly change P_{CO_2} and consequently the pH.

SYMPTOMS OF ACID–BASE DISORDERS

History and clinical evaluation are the 1st steps in assessing a patient with an acid–base disorder. Although the signs and symptoms associated with an acid–base abnormality can be nonspecific, there are certain clues that one can obtain from the signs and symptoms that can assist in the diagnosis of the acid–base disorder. Metabolic acidosis results in increased minute ventilation (manifesting as increased respiratory rate and/or effort) because of respiratory compensation. A patient may have tachypnea present with a metabolic acidosis from a diarrheal illness, metabolic disorder, ingestion, or infection. In more severe acidosis (pH <7.20), the respiratory pattern is characterized by deep and rapid breaths (Kussmaul respiration). Severe acidosis may also lead to hypotension, pulmonary edema, and asystole; its harmful effects are accentuated in the presence of hypoxia. Chronic metabolic acidosis leads to growth retardation and hypercalciuria with subsequent bone disease because bone buffering of acid produces marked mineral losses.

A child with metabolic alkalosis may be asymptomatic. In some cases, careful examination of the child may detect hypoventilation. One should consider metabolic alkalosis in a child who has been vomiting or in a child who has had chronic diuretic use. Severe alkalosis (pH >7.55) can lead to tissue hypoxia, mental confusion, obtundation, muscular irritability, tetany, and an increased risk of seizures and cardiac arrhythmias. Some of these signs and symptoms are related to decreased concentration of serum ionized calcium as a result of its increased binding to protein in the presence of alkalosis. Acid–base disturbances can be assessed through laboratory analysis by obtaining a basic chemistry panel and/or a blood gas analysis.

RENAL REGULATION OF ACID–BASE BALANCE

The kidneys are the principal regulator of bicarbonate homeostasis. The renal regulation of HCO_3^- can be divided into 2 processes:

(See *Nelson Textbook of Pediatrics,* p. 369.)

TABLE 46.1   Changes in P_{CO_2}, HCO_3^-, and pH in Primary Acid–Base Disorders*

Disorder	Primary Event	Degree of Initial Disturbance	Compensation	Degree of Compensation
Metabolic acidosis	↓ [HCO_3^-]	For every 10 mEq/L ↓ in HCO_3^-, pH ↓ by 0.15	↓ P_{CO_2}	For 1 mEq/L ↓ [HCO_3^-], P_{CO_2} ↓ 1-1.5 mm Hg
Metabolic alkalosis	↑ [HCO_3^-]	For every 10 mEq/L ↑ in HCO_3^-, pH ↑ by 0.15	↑ P_{CO_2}	For 1 mEq/L ↑ [HCO_3^-], P_{CO_2} ↑ 0.5-1 mm Hg
Respiratory acidosis		For every 10 mm Hg ↑ in P_{CO_2}, pH ↓ by 0.08		
Acute (<12-24 hr)	↑ P_{CO_2}		↑ [HCO_3^-]	For 10 mm Hg ↑ P_{CO_2}, [HCO_3^-] ↑ 1 mEq/L
Chronic (3-5 days)	↑ P_{CO_2}		↑↑ [HCO_3^-]	For 10 mm Hg ↑ P_{CO_2}, [HCO_3^-] ↑ 4 mEq/L
Respiratory alkalosis		For every 10 mm Hg ↓ in P_{CO_2}, pH ↑ by 0.08		
Acute (<12 hr)	↓ P_{CO_2}		↓ [HCO_3^-]	For 10 mm Hg ↓ P_{CO_2}, [HCO_3^-] ↓ 1-3 mEq/L
Chronic (1-2 days)	↓ P_{CO_2}		↓↓ [HCO_3^-]	For 10 mm Hg ↓ P_{CO_2}, [HCO_3^-] ↓ 1-3 mEq/L

*Normal serum [HCO_3^-] is 24 mEq/L, and normal arterial partial pressure of carbon dioxide (P_{CO_2}) is 40 mm Hg.
↓, decrease; ↓↓, greater decrease; ↑, increase; ↑↑, greater increase.

Disorders of water metabolism. In: Schrier RW, ed. *Renal and Electrolyte Disorders*. Philadelphia: Lippincott-Raven; 1997.)

reabsorption of HCO_3^- and excretion of H^+. The 1st role of the kidneys is to reabsorb the filtered HCO_3^- so that this important extracellular buffer is not excreted in the urine. The 2nd role of the kidneys is to excrete H^+ that is produced from protein and phospholipid catabolism.

Most (80-90%) of the filtered HCO_3^- is reabsorbed in the proximal tubule (Fig. 46.1). Bicarbonate reabsorption at this site is increased by the contraction of the extracellular fluid (ECF) volume, activation of the renin-angiotensin system (mainly through the effect of angiotensin II), elevated P_{CO_2}, and hypokalemia. Conversely, HCO_3^- reabsorption is decreased when there is expansion of the ECF volume, inhibition of

angiotensin II, a fall in P_{CO_2}, and an elevation of the parathyroid hormone level.

The distal tubule and collecting duct regenerate bicarbonate via H^+ ion secretion into the tubular lumen by an H^+-adenosine triphosphatase (H^+-ATPase) pump in the luminal membrane. This active secretion can generate an H^+ ion gradient of 1000:1 between tubular fluid and cells, permitting the urine pH to fall to as low as 4.5. The active H^+ secretion is significantly influenced by the luminal electronegativity caused by active Na^+ reabsorption in the cortical collecting duct. Thus, in the cortical collecting duct, H^+ excretion is influenced by distal Na^+ delivery and reabsorption. In contrast, in the outer medullary portion

of the collecting duct, aldosterone stimulates the H^+ excretion independently of Na^+ delivery or reabsorption. Some of the H^+ secreted is consumed in reclaiming the small amount of HCO_3^- that escaped reabsorption at proximal sites; the rest of the H^+ is excreted in the urine. The ability to excrete large amount of H^+ ions is dependent on the presence of buffers. The H^+ ions are buffered by phosphates and, to a lesser extent, by other nonreabsorbable anions. The other very important urinary buffer is ammonia (NH_3), which combines with a secreted H^+ to generate an ammonium ion (NH_4^+). The proximal tubular cells generate ammonia through the metabolism of the amino acid glutamine. For every H^+ that is finally excreted, an HCO_3^- is added to the ECF compartment. Metabolic acidosis by itself enhances NH_4^+ production and excretion. Ammonia genesis by proximal tubular cells is also stimulated by hypokalemia, whereas hyperkalemia inhibits ammonia genesis. The ability of the kidney to produce ammonia is markedly decreased in conditions such as chronic renal failure as a result of reduced renal mass and in some types of renal tubular acidosis (RTA). The ability to lower urine pH and increase net acid excretion may not be achieved until 4-6 weeks of age.

METABOLIC ACIDOSIS

A metabolic acidosis can result from addition of H^+ to the body, failure to excrete H^+, or loss of HCO_3^-. The differential diagnosis of metabolic acidosis is simplified by classifying the causes into those associated with a normal anion gap (also known as a hyperchloremic metabolic acidosis) and those associated with an increased anion gap (Table 46.2).

The anion gap is easily calculated: $Na^+ - (Cl^- + HCO_3^-)$. The anion gap is normally 8-16 mEq/L. When a strong acid (e.g., lactic acid) is added to or produced in the body, hydrogen ions are neutralized by bicarbonate, HCO_3^- is consumed by the H^+, and the bicarbonate concentration falls. The accompanying anion, such as lactate, is a new unmeasured anion, which increases the anion gap. The increase in the anion gap is usually proportional to the fall in serum (HCO_3^-). In contrast, when HCO_3^- is lost from the body, no new anion is generated. In this situation, there is a reciprocal increase in the serum Cl^- to maintain electroneutrality. The anion gap does not change; the rise in (Cl^-) is proportional to the fall in (HCO_3^-).

Normal Anion Gap (Hyperchloremic) Metabolic Acidosis

Renal Tubular Acidosis
RTA is a group of disorders characterized by impairment of renal HCO_3^- reabsorption and/or H^+ excretion in the presence of a relatively normal glomerular filtration rate (GFR). On the basis of the distinctive pathophysiologic features, 3 types of RTA—type I (distal or classic), type II (proximal or bicarbonate wasting), and type IV (hyperkalemic) are recognized (Table 46.3).

Type I RTA is caused by the inability to secrete H^+ in the distal tubule, resulting in hypokalemic hyperchloremic metabolic acidosis. These patients have a tendency to develop nephrocalcinosis and nephrolithiasis, which results from the excretion of large quantities of calcium, combined with an alkaline urine pH and hypocitraturia. In addition to the deficient H^+ secretion, these patients are unable to increase ammonia genesis. The patient's urine pH remains alkaline (>5.5) despite extreme systemic metabolic acidosis. Type I RTA may occur as an isolated condition or may develop secondary to several diseases, medications, or toxins (Table 46.4).

Type II RTA is caused by an impairment of HCO_3^- reabsorption in the proximal tubule, resulting in hypokalemic hyperchloremic metabolic acidosis. Because the distal acidification mechanisms are

*Along with these genetic disorders, distal RTA may be secondary to renal disease or medications.
[†]Most cases of proximal RTA are not caused by this primary genetic disorder. Proximal RTA is usually part of Fanconi syndrome, which has multiple etiologies.
[‡]Hyperkalemic RTA can be secondary to a genetic disorder (some of the more common are listed) or other etiologies.
OMIM, database number from the Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim).

intact, these patients can lower the urine pH to less than 5.5 and can excrete adequate amounts of NH_4^+ when the serum HCO_3^- is below the filtration threshold. As a result, their acidosis is usually less profound than that which occurs in distal RTA. In some patients, there may be an increase in urinary calcium excretion, but because citrate excretion is normal, nephrocalcinosis is uncommon. Type II RTA may rarely occur as an isolated defect, but it usually coexists with other defects in proximal tubule function. **Fanconi syndrome** is the combination of multiple defects in proximal tubule reabsorption and, in addition to type II RTA, includes excessive urinary losses of glucose, amino acids, phosphate, and uric acid. The excessive losses of

TABLE 46.3	**Differentiation of RTA Types**

From Palmer BF. Metabolic acidosis. In: Johnson RJ, Feehally J, Floege J, eds. *Comprehensive Clinical Nephrology*. 5th ed. Philadelphia: Saunders; 2015:153.

phosphate often cause hypophosphatemic rickets. There are many causes of type II RTA (see Table 46.4).

Type IV RTA results from low circulating aldosterone concentrations, partial or complete end-organ resistance to aldosterone, or aldosterone antagonism. Because of the lack of aldosterone effect, there is decreased distal acidification and decreased distal sodium reabsorption with hyperkalemic hyperchloremic acidosis. The hyperkalemia seen in type IV RTA is the most characteristic feature and differentiates it from the other 2 types.

The examination of a child with RTA may be normal. Poor skin turgor may be present from dehydration. Muscle weakness and muscle aches from hypokalemia may occur. Low back pain and bone pain may be present in patients with abnormalities of calcium metabolism (type II). All forms of RTA are associated with growth failure. Patients with Fanconi syndrome have severe rickets/osteomalacia and malnutrition.

Laboratory work-up in all patients with RTA shows metabolic acidosis with hyperchloremia and a normal anion gap. The urine pH always exceeds 5.5 in type I RTA but can be less than 5.5 in type II and type IV RTA.

Type I and II RTA are treated with oral sodium bicarbonate titrated to correct the acidosis. Potassium supplementation is needed in hypokalemic patients. Type IV RTA can be treated with furosemide to lower elevated potassium levels, along with sodium bicarbonate to correct significant acidosis. Fludrocortisone can be used to correct mineralocorticoid deficiency. In patients with secondary proximal RTA, treatment should be aimed at the primary disorder.

There needs to be frequent monitoring of potassium levels in type IV RTA. Because of the common occurrence of nephrocalcinosis and nephrolithiasis in type I RTA, renal ultrasound can be used to monitor these patients. A skeletal survey to look for bone disease should also be done, especially in cases of type II RTA. Patients with Fanconi syndrome should be evaluated for cystinosis, the most common cause of Fanconi syndrome in children. Some patients with inherited distal RTA have sensorineural deafness; therefore, infants and children with established distal RTA need routine audiograms.

Additional Causes of Renal Loss of Bicarbonate

Carbonic anhydrase inhibitors such as acetazolamide inhibit the carbonic anhydrase present in the proximal tubule, thus preventing the reabsorption of HCO_3^-. The net effect is similar to that of proximal RTA.

Potassium-sparing diuretics such as spironolactone or amiloride can impair H^+ secretion by the distal nephron by blocking Na^+ absorption in this segment.

Gastrointestinal Loss of Bicarbonate

Diarrhea is the most common cause of non–anion gap hyperchloremic metabolic acidosis in children. The acidosis is secondary to loss of stool bicarbonate. The degree of dehydration should be assessed and appropriate fluid resuscitation should be given, which should help correct the acidosis. If there is persistent acidosis, one should consider additional etiologies such as worsening infection/sepsis, an inborn error of metabolism, or bacteria-associated methemoglobinemia, or production of D-lactate.

Miscellaneous Causes of Hyperchloremic Acidosis

Recovery from ketoacidosis. During recovery from diabetic ketoacidosis (DKA), many patients may eliminate the organic anions (through increased renal clearance and utilization) faster than their acidosis resolves. The clinical picture can resemble normal anion gap acidosis. Excessive fluids with isotonic chloride levels may contribute to this acidemia.

Dilutional acidosis. The rapid expansion of ECF volume with fluids that do not contain HCO_3^- leads to a dilution of HCO_3^- and mild metabolic acidosis. In addition, the expansion of ECF volume by itself promotes urinary HCO_3^- loss, possibly contributing to the dilutional acidosis.

Parenteral alimentation. Amino acid infusions without concomitant administration of alkali (or alkali-generating precursors) may produce a normal anion gap acidosis in a manner similar to that of addition of HCl.

Increased Anion Gap Acidosis
Increased Acid Production

Diabetic ketoacidosis. In DKA, the lack of insulin and excess of glucagon shunts free fatty acids into ketone body formation. The rate of formation of ketone bodies, principally β-hydroxybutyrate and acetoacetate, exceeds the capacity for their peripheral utilization and renal excretion. Accumulation of ketoacids (both of which are relatively strong acids and dissociate rapidly into H^+ and the ketoacid anions) results in metabolic acidosis. Acetone is formed by nonenzymatic conversion of acetoacetate and is responsible for the fruity odor of the patient's breath.

Patients with DKA typically present with polyuria and polydipsia in addition to altered mental status (ranging from confusion and drowsiness, which can progress to obtundation and loss of consciousness), and deep, sighing respirations (Kussmaul respirations). Additional clinical manifestations of DKA can be dehydration, nausea, vomiting, abdominal pain, and tachypnea. Laboratory analysis of a patient with DKA is significant for a severely increased anion gap metabolic acidosis with pH values that may be lower than 7.0. Initially, the increase in the anion gap is in proportion to the decrease in HCO_3^-, but once the patients start recovering with successful management, the kidneys clear the ketoacid anions, and the increase in the anion gap becomes less than the fall in HCO_3^-. The loss of ketoacid anions in urine increases the urinary losses of Na^+ and K^+ as the accompanying cations.

The diagnosis of DKA is made by the combination of increased anion gap metabolic acidosis, hyperglycemia, and demonstration of serum (or urine) ketoacid anions. The therapy for DKA includes careful volume repletion, insulin, and correction of electrolyte disturbances. Severe acidosis is reversible by fluid and insulin replacement. Insulin inhibits ketosis and allows ketoacids to be metabolized, which

TABLE 46.4 Common Causes of Renal Tubular Acidosis

Proximal Renal Tubular Acidosis

Primary

Sporadic (common)

Inherited
- Inherited renal disease (idiopathic Fanconi)
- Autosomal dominant
- Autosomal recessive
- X-linked (Dent disease)
- Inherited syndromes
- Cystinosis
- Tyrosinemia type 1
- Galactosemia
- Oculocerebral dystrophy (Lowe syndrome)
- Wilson disease
- Hereditary fructose intolerance

Secondary

Intrinsic renal disease
- Autoimmune diseases (Sjögren syndrome)
- Hypokalemic nephropathy
- Renal transplant rejection

- Prolonged heparinization

Addison disease

From Sreedharan S, Avner ED. Renal tubular acidosis. In: Kliegman RM, Stanton BF, St Geme JW, et al., eds. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2016:2530.

generates bicarbonate. Treatment of hypovolemia improves tissue perfusion and renal function thereby increasing the excretion of organic acids. Most patients with DKA present with considerable total body deficits of potassium, magnesium, and phosphorus, even though serum levels, particularly of potassium, may actually be high on presentation.

Lactic acidosis. Under normal conditions, lactate is formed in relatively small amounts and is further metabolized by the liver. Pathologic conditions associated with either local or systemic hypoxia or ischemia, hypotension (shock), impaired oxidative metabolism, or impaired hepatic clearance can cause significant lactic acidosis.

The diagnosis of lactic acidosis must be considered in all forms of increased anion gap metabolic acidosis. The diagnosis can be confirmed by measuring the serum lactate level. Treatment must be directed at the underlying pathophysiologic process.

Inborn errors of metabolism. Most patients with inborn errors of metabolism that cause a metabolic acidosis present in the neonatal period or shortly thereafter. Organic acidemias, aminoacidopathies, disorders of fatty acid oxidation, mitochondrial disorders, and defects in carbohydrate metabolism are associated with acidosis. Associated presenting signs and symptoms may include vomiting, failure to thrive, lethargy, seizures, developmental abnormalities, hepatomegaly, and elevated blood or urine levels of a particular metabolite. Some of these disorders will be detected by the state newborn screening protocols. In contrast, urea cycle disorders during the 1st few days of life manifest with respiratory alkalosis because of stimulation of the respiratory center by increased ammonia levels.

Poisonings. A variety of toxic agents may be associated with increased anion gap metabolic acidosis; these include salicylate intoxication, ethylene glycol (a component of antifreeze), and methanol. Carbon monoxide, cyanide poisoning, or methemoglobinemia induces hypoxic acidosis.

Classically, **salicylate intoxication** is described as causing respiratory alkalosis (stimulation of the respiratory center), followed by increased anion gap metabolic acidosis (accumulation of salicylic acid itself and lactic acidosis as a result of uncoupling of mitochondrial oxidative phosphorylation). However, children may present with simple increased anion gap metabolic acidosis. Nausea, tinnitus, noncardiogenic pulmonary edema, and prolonged prothrombin time are other associated features. Alkalization of the blood and urine with sodium bicarbonate is beneficial despite the potential problems associated with its use in acute metabolic acidosis. Alkalization of the plasma decreases the diffusion of salicylate into the central nervous system, and alkaline urine improves renal excretion. In severe poisoning, hemodialysis is quite effective at removing salicylate from the body. In cases of poisonings, dialysis serves the dual purposes of removing the poison (if dialyzable) and correcting the acid–base and electrolyte abnormalities.

Failure of Acid Excretion

In both acute and chronic renal failure, the kidneys fail to excrete the acid produced from normal daily metabolism. Both H^+ and anions accumulate in the body, resulting in slow consumption of bicarbonate stores. However, the acidosis is generally not severe unless a markedly catabolic state occurs or other associated conditions coexist. In acute renal failure, there is abrupt and complete inhibition of acid excretion, whereas in chronic renal failure, there initially is enhanced ammonia genesis by the remaining nephrons. As renal failure progresses, excretion of both NH_4^+ and phosphate declines. In addition, the secondary hyperparathyroidism seen with chronic renal failure decreases proximal tubular HCO_3^- reabsorption and adds a component of hyperchloremic acidosis to the increased anion gap acidosis.

◆ Treatment of Metabolic Acidosis

The morbidity and mortality caused by metabolic acidosis are determined not only by the severity of acidosis but also by the amenability of the underlying disorder to medical management. During treatment of metabolic acidosis, the primary effort should focus on the management of the underlying condition. The recommendations and goals of buffer therapy differ for acute acidotic disorders such as DKA and for chronic acidotic states such as RTA.

During the correction of acute metabolic acidosis, particular attention should be paid to ensure an appropriate potassium balance. During an episode of metabolic acidosis, potassium shifts from the intracellular space to the extracellular space in exchange for H^+, and thus the presence of a total body potassium deficit may not be appreciated. Hypokalemia may become evident only as the pH increases and potassium returns to the intracellular space. Chronic metabolic acidosis slows linear growth and interferes with bone mineralization. In chronic metabolic acidosis, there is a need for alkali therapy.

METABOLIC ALKALOSIS

Metabolic alkalosis (pH >7.45) occurs as a result of a primary increase in the serum HCO_3^-, which may occur as a result of (1) net loss of H^+, (2) net gain of HCO_3^- (or its precursors), or (3) loss of fluid with more Cl^- than HCO_3^-. Normally functioning kidneys can excrete large amounts of HCO_3^- and should offset any increase in serum HCO_3^- resulting from these causes. Therefore, factors that prevent the kidneys from excreting HCO_3^- also must be present to maintain the metabolic alkalosis.

Factors Initiating Metabolic Alkalosis

The H^+ can be lost externally, either through the gastrointestinal tract or through the kidneys. For every H^+ lost at these sites, the body gains 1 HCO_3^- ion. This is because H^+ production at both these sites (gastric parietal cell and renal tubular cells) is associated with generation of an equivalent number of HCO_3^- molecules. H^+ can also be "lost" internally, by shifting into the intracellular compartment. This occurs in states of severe potassium depletion (H^+ moves in, whereas K^+ exits the cell, to maintain electroneutrality).

The administration of HCO_3^- or its precursors (such as lactate, citrate, and acetate), at a rate greater than normal metabolic production of acid can lead to net gain of HCO_3^- by the body.

External loss of fluid (gastric fluid) containing more Cl^- than HCO_3^- raises the concentration of HCO_3^- in the body. One of the factors responsible for this type of alkalosis is the associated volume contraction, which leads to increased bicarbonate reabsorption by the proximal tubule of the kidney.

Factors Responsible for Sustaining Alkalosis

Decrease in effective blood volume and kidney perfusion causes increased Na^+ reabsorption, in both the proximal tubule (angiotensin II effect) and the distal renal tubule (mineralocorticoid effect), thereby increasing H^+ excretion.

Increased mineralocorticoid levels directly increase H^+ secretion in the outer medullary collecting duct.

Chloride depletion increases HCO_3^- reabsorption in the proximal tubule. This effect is independent of ECF volume status.

Hypokalemia sustains metabolic alkalosis by decreasing bicarbonate loss. Hypokalemia promotes hydrogen ion secretion in the distal nephron and stimulates ammonia genesis in the proximal tubular cells. When produced, ammonia enhances renal excretion of hydrogen ions.

(See *Nelson Textbook of Pediatrics,* Table 55.11.)

Hypercapnia induces a state of intracellular acidosis, which increases H^+ secretion. Although Pco_2 increases as a normal compensatory response to metabolic alkalosis, the elevated Pco_2 prevents the renal correction of alkalosis.

◆ Differential Diagnosis of Metabolic Alkalosis

The causes of metabolic alkalosis can be divided into 2 categories on the basis of the urinary chloride level. The alkalosis in patients with low urinary chloride is maintained by volume depletion; volume repletion is needed to correct the alkalosis. In the process of volume depletion, there are losses of sodium, potassium, and chloride, but the loss of chloride is usually greater than the losses of sodium and potassium combined. Since chloride losses are the main cause of the volume depletion, these patients require chloride to correct the volume deficit and metabolic alkalosis; these patients have chloride-responsive metabolic alkalosis. Conversely, patients with alkalosis and an elevated urinary chloride concentration do not respond to volume repletion and have chloride-resistant metabolic alkalosis. Blood pressure can also be useful when considering the etiology of a patient's chloride-resistant metabolic alkalosis (Table 46.5).

Urinary Chloride Level Lower Than 15 mEq/L

Chloride-deficient diet. Although uncommon in developed countries, the ingestion of milk formula with low chloride content has been shown to result in hypochloremic metabolic alkalosis and failure to

---

thrive in infants and to result in later neurodevelopmental abnormalities in childhood.

Upper gastrointestinal losses. The gastric fluid has a high H^+ concentration; loss of gastric fluid by vomiting or by nasogastric drainage leads to a net gain of HCO_3^- in the body. Although this is the initiating factor, the alkalosis is sustained by concomitant Cl^- and K^+ losses. Secondary hyperaldosteronism, resulting from volume contraction, promotes further urinary potassium and H^+ excretion, worsening the hypokalemia and alkalosis; urine is the source of most of the potassium losses caused by emesis. The degree of metabolic alkalosis associated with vomiting is generally mild except in conditions in which gastric secretions are greatly stimulated (e.g., Zollinger-Ellison syndrome) or there is protracted vomiting (e.g., pyloric stenosis).

Metabolic alkalosis can also be seen in newborns of mothers with eating disorders (bulimia). The baby reflects the electrolyte changes of the mother and sustains alkalosis because of the Cl^- deficiency.

Chloride secreting diarrhea. This is a rare congenital syndrome characterized by a defect in small- and large-bowel chloride absorption that leads to a chronic diarrhea with high chloride losses in the stool. The ongoing chloride depletion leads to a sustained metabolic alkalosis.

Diuretic therapy. Chronic use of loop and thiazide diuretics may cause a metabolic alkalosis. The alkalosis is sustained because of hypochloremia, hypokalemia, and volume contraction with resultant secondary hyperaldosteronism. The urinary Cl^- may be high if the diuretics have been ingested recently. The metabolic derangements caused by loop diuretics are identical to those seen in Bartter syndrome.

Hypercapnia. Chronic hypercapnia, as seen in bronchopulmonary dysplasia or cystic fibrosis, leads to an elevated serum bicarbonate concentration from metabolic compensation. The increase in serum bicarbonate is balanced by a decrease in serum chloride. Affected patients have chloride depletion, which may be worsened by concomitant diuretic use. With resolution of the hypercapnia, the bicarbonate concentration remains high until the chloride depletion is corrected.

Urinary Chloride Level Higher Than 20 mEq/L with Hypertension

Pediatric patients with hypertension either have increased levels of aldosterone or act as if they do. Increased aldosterone "effects" cause renal retention of sodium, which results in elevated blood pressure. The disorders of mineralocorticoid excess are characterized by volume expansion and hypertension (see Table 46.5). The mineralocorticoid excess stimulates the renal excretion of H^+ and K^+, resulting in metabolic alkalosis and hypokalemia. The various causes can be differentiated by evaluating the renin-aldosterone axis. Treatment is aimed at removing or correcting the source of the mineralocorticoid excess.

Urinary Chloride Level Higher Than 20 mEq/L with Normal Blood Pressure

Bartter syndrome and Gitelman syndrome. These uncommon autosomal recessive disorders result from defects in various ion transporters within the nephron. Bartter syndrome is a severe disorder that is characterized by urinary chloride wasting, hypokalemia, metabolic alkalosis, and increased serum levels of aldosterone and renin. Hypercalciuria is also common and leads to nephrocalcinosis in some patients. Affected patients present with a history of failure to thrive, polyuria, polydipsia, and a tendency for dehydration. In neonatal Bartter syndrome, there is usually a history of polyhydramnios and premature delivery. Gitelman syndrome, in contrast, is a milder disorder characterized by hypokalemia, metabolic alkalosis, and

hypomagnesemia caused by urinary magnesium wasting; calcium excretion is normal. The growth retardation is not as severe. Children with Gitelman syndrome, however, are more prone to febrile seizures and tetanic episodes (Table 46.6).

◆ Treatment of Metabolic Alkalosis

Treatment focuses on correcting the underlying disorder and depends on the pathophysiologic mechanisms of the alkalosis. Patients with a chloride-responsive metabolic alkalosis (urine Cl⁻ <15 mEq/L) respond to volume repletion; both sodium and potassium chloride are necessary. In rare cases, if alkalosis persists despite chloride supplementation, the carbonic anhydrase inhibitor acetazolamide can be used to increase urinary bicarbonate losses. In patients undergoing persistent gastric drainage, administration of either an H₂ blocker or H⁺ pump inhibitor can be beneficial by decreasing the gastric H⁺ secretion.

Treatment of chloride-resistant metabolic alkalosis with hypertension (urinary Cl⁻ >20 mEq/L) mandates interference with the mineralocorticoid (or mineralocorticoid-like substance) that is maintaining renal H⁺ losses. This can sometimes be accomplished pharmacologically (e.g., with spironolactone or with other distal potassium-sparing diuretics such as amiloride).

RESPIRATORY ACIDOSIS

Respiratory acidosis results when there is an inappropriate increase in blood P_{CO_2} that is secondary to impaired pulmonary ventilation. Respiratory acidosis can result from either pulmonary disease, such as in severe bronchiolitis, or nonpulmonary disease, such as a narcotic overdose. In acute compensation, plasma bicarbonate increases by 1 for each 10 mm Hg increase in the P_{CO_2}. In chronic respiratory acidosis, the kidneys increase acid secretion. Renal compensation starts in 12-24 hours and reaches maximum in 3-5 days. In chronic compensation, plasma bicarbonate increases by 3-5 for each 10 mm Hg increase in the P_{CO_2}.

Patients with a respiratory acidosis are often tachypneic as they are trying to correct the inadequate ventilation. The degree of hypercarbia drives the symptoms in a patient with respiratory acidosis. Patients with acute respiratory acidosis have more symptoms than patients with chronic respiratory acidosis. Hypoxia is usually seen in a patient with acute respiratory acidosis who is breathing room air. There may also be central nervous system manifestations of respiratory acidosis, which can include, but are not limited to, anxiety, dizziness, headache, confusion, hallucinations, myoclonic jerks, seizures, psychosis, and coma. The management of respiratory acidosis is directed toward improving alveolar ventilation and treating the underlying disorder.

RESPIRATORY ALKALOSIS

Respiratory alkalosis occurs when there is an inappropriate decrease in P_{CO_2} as a result of pulmonary hyperventilation. In a spontaneously breathing child, this can result from fever, sepsis, mild asthma, panic attack, or central nervous system disorders. In the intensive care unit, the most common cause is mechanical overventilation of an intubated child. A metabolic response to an acute respiratory alkalosis is mediated by hydrogen ion release from nonbicarbonate buffers and occurs within minutes. In this acute compensation, plasma bicarbonate falls by 2 for each 10 mm Hg decrease in P_{CO_2}. In chronic respiratory alkalosis, the kidneys decrease H⁺ secretion, which produces a decrease in the serum HCO_3^- concentration. Metabolic compensation for a respiratory alkalosis develops gradually and takes 2-3 days. In chronic compensation, plasma bicarbonate falls by 4 for each 10 mm Hg decrease in the P_{CO_2}. Chronic respiratory alkalosis is the only acid–base disorder in which the pH may be completely normalized by the compensatory mechanisms.

Symptoms of acute respiratory alkalosis may be chest tightness, palpitations, lightheadedness, circumoral numbness, or extremity paresthesias. Less commonly, tetany, seizures, muscle cramps, or syncope can be seen. The lightheadedness and syncope are felt to be a result of

the decrease in cerebral blood flow that is caused by hypocapnia. The parethesias, tetany, and seizures are thought to be related to the decrease in ionized calcium that occurs because alkalemia causes more calcium to bind to albumin. The treatment is management of the underlying process.

MIXED ACID–BASE DISORDERS

Mixed acid–base disorders occur when 2 or 3 primary events act to alter the acid–base state at the same time. The deviations in pH are more marked when 2 primary events block the compensation of each other, such as the combination of a metabolic acidosis and a respiratory acidosis seen in a patient with shock and respiratory failure. In contrast, in the presence of 2 opposing primary events, the pH may be normal or only minimally abnormal, as can be seen with combined vomiting and diarrhea. A mixed acid–base disorder is commonly seen when neonates with respiratory acidosis caused by chronic lung disease also receive diuretics, which can cause a metabolic alkalosis.

The diagnosis of mixed acid–base disorder should be suspected in the following situations:

If the compensation for the primary event is absent or is out of the expected range.

If the deviation in anion gap and/or serum Cl^- is out of proportion to the change in HCO_3^-.

If the anion gap is significantly increased in the presence of a near-normal pH.

POTASSIUM DISORDERS

Potassium is the major intracellular cation with a normal serum concentration of 3.5-5.5 mEq/L. The differential distribution of potassium between the intracellular (150 mEq/L) and extracellular compartments, sustained by the action of the Na^+,K^+-ATPase pump, is the chief determinant of the resting membrane potential. Not surprisingly, both hyperkalemia (serum K^+ >5.5 mEq/L) and hypokalemia (serum K^+ <3.5 mEq/L) have a profound effect on the excitability of the neuromuscular tissue, especially the cardiac tissue. As a result, fatal cardiac arrhythmias are possible sequelae of hypokalemia or hyperkalemia.

Almost all dietary potassium is absorbed. The kidney is the major organ responsible for K^+ excretion, eliminating more than 90% of the daily K^+ intake. However, after an acute ingestion of K^+, the kidneys excrete only half of it over the 1st 4-6 hours; the remainder is transiently redistributed intracellularly before the kidneys eventually excrete it. This intracellular redistribution has a very important role in offsetting acute changes in serum K^+, but it has a limited capacity to do so. Redistribution of a very small fraction (1-2%) of intracellular K^+ into the ECF can easily increase serum K^+ to a dangerous level. A number of factors affect the distribution of K^+ between the intracellular space and the ECF (Table 46.7). The colonic excretion of K^+ is of no significance under normal conditions, but in patients with chronic renal failure, it becomes an important route of K^+ elimination, when colonic excretion increases substantially.

Because the kidney is the major route of potassium elimination from the body, a disturbance in renal potassium handling can be the cause of excessive loss or retention.

In clinical practice, spironolactone, amiloride, and triamterene decrease urinary K^+ excretion. Whereas spironolactone is an aldosterone antagonist, amiloride and triamterene block the Na^+ conductance channels present in the principal cell luminal membrane. The antimicrobial trimethoprim prevents K^+ secretion by the same mechanism as amiloride.

HYPOKALEMIA

Hypokalemia (Table 46.8) may result from (1) increased renal losses, (2) increased extrarenal losses, (3) redistribution, or (4) prolonged decreased intake of potassium. When interpreting cases of hypokalemia, the clinician should pay careful attention to blood pressure and obtain laboratory data concerning acid–base status, electrolytes, osmolality of blood and urine, and the renin-aldosterone axis.

Increased Renal Losses with Hypertension
Mineralocorticoid Excess
The presence of excess mineralocorticoid hormone, regardless of its source, results in stimulation of potassium secretion by the distal tubular cells of the nephron. Mineralocorticoid excess can result from primary hyperaldosteronism, rare forms of congenital adrenal hyperplasia (17α-hydroxylase or 11β-hydroxylase deficiency), syndrome of apparent mineralcorticoid excess, glucocorticoid remediable aldosteronism, and Cushing syndrome. The hypokalemia in these conditions is associated with increased sodium chloride retention, causing hypertension. The expansion of the extracellular volume eventually leads to the suppression of Na^+-retaining mechanisms, but the K^+ losses continue unabated. Metabolic alkalosis develops as a result of enhanced proximal ammonium production secondary to potassium depletion.

Liddle Syndrome

Liddle syndrome is characterized by a primary increase in sodium reabsorption in the collecting tubule and associated with increased potassium secretion. The sodium reabsorption is increased through activation of the amiloride-sensitive renal sodium channel. Because serum aldosterone levels are low, spironolactone is ineffective, but amiloride or triamterene, which block the sodium channel, decrease potassium losses and help ameliorate the hypokalemia and the hypertension.

Increased Renal Losses with Normal Blood Pressure
The hypokalemia associated with Bartter syndrome, Gitelman syndrome, RTA, DKA, and vomiting are discussed in the section on acid–base disorders.

Hypomagnesemia of any cause can lead to K^+ depletion, and correction of hypokalemia is not possible until magnesium balance is restored. These effects are believed to be secondary to magnesium's effect on aldosterone secretion and K^+ channels. Magnesium

replacement in this situation should be done with magnesium oxide, because the sulfate ion of magnesium sulfate can increase the urinary K+ losses.

The polyuric recovery phase of acute tubular necrosis and the postobstructive diuresis after relief of urinary tract obstruction are commonly encountered clinical conditions that may be associated with excess urine potassium losses. Penicillins can increase urinary K+ losses by increased delivery of sodium and nonabsorbable anions to the distal nephron. Amphotericin B enhances urinary K+ loss by increasing the tubular K+ permeability and also by causing type I RTA.

Increased Extrarenal Losses

Diarrhea is a very common cause of hypokalemia in pediatric practice. Profuse sweating is a much less frequent cause of hypokalemia.

Redistribution

Alkalosis causes potassium to enter cells in exchange for H+. β-Adrenergic agonists increase intracellular movement of potassium.

Familial hypokalemic periodic paralysis is a rare disorder characterized by recurring transient episodes of net K+ transfer from ECF to intracellular fluid (ICF). The autosomal dominant form manifests between the ages of 10 and 19 years. The dominant finding is muscle weakness, which may advance to paralysis. Episodes typically occur after large carbohydrate-rich meals, strenuous exercise, or insulin administration. Hyperthyroid states may also produce hypokalemic paralysis. Therapy is largely symptomatic; empirical treatment with acetazolamide has yielded some results.

Consequences of Hypokalemia

Hypokalemia produces functional alterations in skeletal muscle, smooth muscle, and the heart. The cardiac conduction effects are the most serious consequence of hypokalemia. The characteristic electrocardiographic (ECG) changes include flattening of the T wave with appearance of the U wave. Skeletal muscle weakness usually starts in the limbs before involving the trunk and respiratory muscles. Paralytic ileus and gastric dilatation reflect smooth muscle dysfunction. Rhabdomyolysis is a dramatic and serious complication of hypokalemia. Hypokalemia is particularly dangerous in patients taking digoxin.

In the kidney, potassium deficiency may result in vacuolar changes in the tubular epithelium. The renal concentrating capacity is decreased, causing polyuria. Prolonged and sustained hypokalemia leads to systemic alkalosis.

◆ Treatment of Hypokalemia

The immediate objective of potassium replacement is to prevent life-threatening cardiac conduction and muscle complications. The ultimate goal is to replenish total body potassium stores. There is no method of determining the potassium deficit, because there is no definite correlation between the plasma potassium concentration and body potassium stores. A decrease of 1 mEq/L in serum potassium concentration secondary to potassium loss generally corresponds to a loss of approximately 10-30% of body potassium. In conditions with associated acidosis and/or hyperosmolality (e.g., RTA, DKA), the plasma potassium concentration may underestimate potassium stores, and correction of acidosis with bicarbonate in these conditions may rapidly lower the serum potassium concentration.

The safest route to administer potassium is by mouth, but in states of severe symptomatic hypokalemia or when there are gastrointestinal problems, potassium must be given intravenously. The usual concentration of potassium in intravenous fluid solutions is up to 40 mEq/L. Higher concentrations of up to 60-80 mEq/L can be given in a central vein under continuous ECG monitoring. Dextrose should be avoided in the initial fluids because its administration with secondary increased insulin secretion may result in further lowering of the plasma potassium concentration. The choice of potassium salt depends on the clinical situation. Under most circumstances, when hypovolemia coexists, potassium chloride is appropriate. Potassium bicarbonate (or, more often, other salts such as citrate or acetate, which generate bicarbonate) can be given in the presence of coexistent metabolic acidosis. If there is an associated phosphate deficiency (as in DKA), potassium phosphate can be used. It is important to remember that correction of total body potassium deficits can take days to weeks.

HYPERKALEMIA

Moderate (6.1-7.0 mEq/L) to severe (>7.0 mEq/L) hyperkalemia, especially if it develops acutely, can lead to grave consequences and requires prompt treatment. **Pseudohyperkalemia** can occur as result of release of intracellular potassium (e.g., hemolysis caused by mechanical trauma during venipuncture), and it can also be seen in conditions with marked leukocytosis and thrombocytosis. It can be avoided by minimizing trauma and hand clenching during venipuncture, by rapidly separating red blood cells, and by using plasma rather than serum for potassium measurements. *An unexpected elevated potassium level should be immediately repeated.*

Hyperkalemia can be caused by (1) reduced urinary potassium excretion, (2) increased potassium intake, (3) release of intracellular potassium, and/or (4) impaired cellular potassium uptake (Table 46.9).

Reduced Urinary Potassium Excretion

Renal potassium excretion decreases when the GFR is decreased or when there is a defect in tubular potassium excretion resulting from lack of aldosterone, medications, or a primary defect in tubular potassium excretion.

Renal Failure

Potassium excretion is decreased in both acute and chronic renal failure. Severe hyperkalemia occurs more commonly in acute renal failure. In contrast, in patients with chronic renal failure, hyperkalemia does not occur unless the GFR is lower than 10 mL/min or some other factor predisposing to hyperkalemia is present. In patients with chronic renal failure, potassium balance is maintained by increased K^+ secretion per functioning nephron and also by enhanced excretion of K^+ through the gastrointestinal tract.

Hypoaldosteronism

Low levels or absence of aldosterone (or aldosterone receptor defects) may result from a variety of conditions (Addison disease, congenital adrenal hyperplasia [deficiency of 21-hydroxylase], and hyporeninemic hypoaldosteronism). In addition to hyperkalemia, hyponatremia and hyperchloremic metabolic acidosis are the associated features in these disorders. The diagnosis can be confirmed by measurement of renin activity and aldosterone levels.

Drugs

Several drugs are known to be associated with hyperkalemia; they can either impair renin-aldosterone secretion or action (angiotensin-converting enzyme inhibitors, spironolactone, cyclosporine, or heparin) or impair renal tubular potassium secretion (amiloride, triamterene, trimethoprim, or cyclosporine).

Primary Tubular Defects

In some patients, hyperkalemia occurs as a result of low urinary K^+ excretion despite normal renin and aldosterone levels. The presence of a selective defect in K^+ secretion has been described in subjects with renal transplant rejection and lupus nephritis.

Increased Potassium Intake/Tissue Release

Acute increases in potassium intake, usually through parenteral administration, may result in hyperkalemia. The hyperkalemia is typically transient because normal kidneys have a large capacity for excreting potassium. Sustained hyperkalemia is seen only when renal excretory mechanisms are impaired.

In **tumor lysis syndrome** and rhabdomyolysis, massive amounts of K^+ are released from the intracellular compartment, but hyperkalemia does not usually occur unless acute renal failure supervenes. Similarly,

trauma, intravascular hemolysis, transfusion of stored blood, and catabolic states such as infection or high fever are associated with release of K^+ from the cells; however, hyperkalemia is uncommon as long as renal function is normal and normal to high urine output is maintained with fluid therapy.

Redistribution

Acidosis and insulin deficiency result in egress of intracellular potassium. β_2-Receptor blockers, digitalis (by inhibiting the Na^+,K^+-ATPase pump), and succinylcholine (by inhibiting cellular repolarization) cause hyperkalemia by impairing cellular potassium uptake.

Consequences of Hyperkalemia

Overt clinical manifestations are uncommon with hyperkalemia, but cardiac arrhythmias are potentially life-threatening. Generalized muscular weakness and paralysis can occur. The characteristic ECG findings seen with increasing $[K^+]$ are tall, peaked T waves; widening of the QRS complex; decreased amplitude of the P wave; and fusion of the QRS complex with the T wave, forming a sine wave. This can be rapidly followed by atrioventricular dissociation and ventricular tachycardia or fibrillation. Cardiac arrest is more common with hyperkalemia than with hypokalemia.

◆ Treatment of Hyperkalemia

The treatment of hyperkalemia depends on the magnitude of the hyperkalemia, the severity of ECG changes, and the anticipated future rise in $[K^+]$. The specific therapy should always focus on the underlying cause. However, a plasma potassium concentration higher than 7.0 mEq/L or marked ECG changes are potentially life-threatening and necessitate immediate treatment. A normal ECG result should not lead to a more casual approach, because significant ECG changes can appear over a short period of time. All potassium intake (parenteral nutrition, medications with potassium salt) and medications that cause hyperkalemia, such as potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, and trimethoprim, should be discontinued. The treatment modalities usually belong to the following 3 categories: (1) antagonism of membrane excitability, (2) shifting of potassium into the intracellular compartment, and (3) elimination of excess potassium (Table 46.10).

TABLE 46.10 Treatment of Hyperkalemia

Antagonism of Membrane Excitability
Calcium gluconate 10% (elemental calcium, 0.45 mEq/mL), 0.5-1.0 mL/kg body weight (maximum = 10 mL), injected intravenously and slowly over 5-10 min, with continuous monitoring of heart rate)

Shift of Potassium into the Intracellular Compartment
- Sodium bicarbonate, 1-2 mEq/kg body weight intravenously over 10-20 min; usefulness is limited in patients with volume expansion
- Glucose, 1 g/kg body weight, and insulin, 1 unit per every 4 g of glucose, intravenously over 20-30 min
- β_2-Adrenergic agonists, such as albuterol, intravenously or by nebulizer or aerosol

Elimination of Excess Potassium
- Loop/thiazide diuretics
- Fludrocortisone (0.05-0.1 mg/day); should be avoided or given with great caution to hypertensive patients
- Cation exchange resin, sodium polystyrene sulfonate, 1 g/kg body weight (maximum, 15 g/dose), administered orally or rectally in 20-30% sorbitol or 10% glucose, 1 g resin/4 mL (additional 70% sorbitol syrup may be given if constipation occurs)
- Peritoneal dialysis, hemodialysis, or hemodiafiltration

Modified from Hellerstein S, Alon US, Warady BA. Renal impairment. In: Ashcraft KW, Murphy JP, Sharp RJ, et al., eds. *Pediatric Surgery*, 3rd ed. Philadelphia: Saunders; 2000:47-57.

Calcium protects the heart from fatal arrhythmias caused by hyperkalemia by normalizing the difference between the resting and threshold potentials. This protective effect is quite rapid but relatively short-lived; therefore, other measures to reduce the concentration of serum potassium are necessary.

Potassium can be shifted from the extracellular to the intracellular compartment by administration of glucose and insulin, or β_2-adrenergic agonists, as detailed in Table 46.10. Although the intracellular shift of potassium can be accomplished rather quickly, this is only a temporary measure, and further steps should be taken to establish a negative potassium balance.

Loop or thiazide diuretics increase renal potassium excretion. In patients with aldosterone deficiency, fludrocortisone increases renal potassium excretion. Alkalinizing the urine through systemic base administration can further enhance urinary potassium losses.

Cation exchange resins actually remove potassium from the body and are effective in acute situations, particularly when poor renal function is present. Dialysis is needed in patients with severe hyperkalemia, especially in the presence of advanced renal failure or when accompanied by a hypercatabolic state or severe tissue necrosis. For urgent potassium removal, hemodialysis is more effective than continuous hemodiafiltration or peritoneal dialysis.

SODIUM DISORDERS

Sodium is the principal cation of the ECF compartment, and total body sodium content is the major determinant of ECF volume. A normal ECF volume is essential for maintaining an adequate circulating blood volume. The sodium concentration determines cell volume by directing water movement between the ECF compartment and the intracellular compartment. An increase in ECF osmolality causes water to move out of cells, and a decrease in ECF osmolality causes water to move into cells. Sodium homeostasis is coupled with water homeostasis; therefore, disorders of sodium homeostasis usually occur as a result of imbalances of both sodium and water rather than an isolated imbalance of either sodium or water.

The kidneys are pivotal regulators of sodium and water balance. Sodium excretion, which is regulated by the renin-angiotensin-aldosterone system and atrial natruretic peptide, increases in response to an expanded intravascular volume, as may occur with a high sodium intake. In response to a decreased intravascular volume, the urine can be made virtually sodium free.

A detailed history of the underlying disease, food and fluid intake, fluid losses in the form of stool, emesis, and urine should be obtained. The physical examination focuses on an evaluation of the patient's volume status, including the nature and rate of peripheral pulses, blood pressure, fullness of the fontanel, level of consciousness, dryness of mucous membranes, coolness of extremities, and capillary refill time. Urinary sodium concentration can provide valuable information regarding the child's effective blood volume, but it can be misleading if the patient is receiving diuretics or has abnormal renal sodium handling. The clinical features associated with alterations in plasma osmolality are nonspecific. Osmolality is regulated by thirst and vasopressin production, which determines renal water excretion. A low serum osmolality may produce lethargy and confusion, whereas a high serum osmolality may lead to irritability, a high-pitched cry, and a doughy skin texture. The determination of plasma osmolality requires a direct laboratory measurement or can be estimated from the following formula:

$$\text{Serum osmolality}_{(mOsm)} = 2 \times [Na^+]_{mEq/L} + [glucose]_{mg/dL}/18 + [urea]_{mg/dL}/2.8$$

HYPONATREMIA

Hyponatremia is defined as a plasma sodium less than 135 mEq/L and is generally characterized as a disproportionate concentration of water to sodium. This may arise from either water retention or sodium losses. Hyponatremia should be differentiated from pseudohyponatremia and factitious hyponatremia. **Pseudohyponatremia** occurs in the presence of excessive amounts of plasma proteins and lipids, which decrease the percentage of plasma water and thus artificially lower the plasma sodium concentration. The measured plasma osmolality of these patients is normal, inasmuch as lipids and proteins do not contribute significantly to osmolality because of their large size. Therefore, a gap between measured and calculated osmolalities can indicate pseudohyponatremia.

Factitious hyponatremia results from high plasma concentrations of impermeable solutes such as glucose or mannitol that cause movement of water from the intracellular to the extracellular space. In contrast to pseudohyponatremia, the low plasma sodium concentration in these situations is a true value, and plasma osmolality is increased as a result of the presence of the extra solutes. The decrease in plasma sodium is approximately 1.6 mEq/L for every 100 mg/dL increase in the plasma glucose concentration.

In true hyponatremia, the plasma osmolality is low (<280 mOsm/kg), and the pathophysiologic processes are caused by (1) loss of both plasma sodium and water (sodium losses exceeding water losses), (2) increase in plasma water (without edema), or (3) increase in both total body water and sodium (increase in water exceeding that of sodium; usually with edema). Estimating the status of the ECF volume (hypovolemia, euvolemia, or hypervolemia) is therefore useful in narrowing the differential diagnosis (see Fig. 46.1).

Hypovolemic Hyponatremia

Hypovolemia hyponatremia occurs when urinary and/or gastrointestinal sodium losses exceed those of water, fluids are sequestered into third spaces such as the peritoneal cavity, subcutaneous tissue, or bowel lumen, or uncommonly, sodium losses in sweat for patients with cystic fibrosis or excessively hot climatic zones. The most common cause of hypovolemic hyponatremia in children is gastroenteritis. Fistulas and various types of gastrointestinal drainage tubes can also lead to a similar clinical picture. The normally functioning kidneys respond by conserving sodium, and the urine sodium concentration is usually less than 20 mEq/L.

The kidneys can be the source of excessive sodium loss in premature infants (tubular immaturity), in patients receiving diuretics, and in those having an osmotic diuresis (DKA). The presence of increased urinary bicarbonate, as seen in certain patients with metabolic alkalosis and RTA, leads to obligatory losses of sodium in the urine. The urinary sodium losses are increased during the recovery phase of acute tubular necrosis, after relief of urinary tract obstruction, and in certain renal diseases (salt-wasting nephropathies) such as medullary cystic disease, polycystic kidney disease, and tubulointerstitial diseases. All of these disorders are usually accompanied by hypokalemia. The presence of hyperkalemia and normal renal function in patients with hypovolemic hyponatremia suggests mineralocorticoid deficiency or type IV RTA.

Some children with acute or chronic central nervous system injury (closed-head trauma, surgery, tumors, or meningitis) present with excessive renal sodium losses and develop hypovolemic hyponatremia. The condition, known as **cerebral (renal) salt-wasting** syndrome, may occur because of secretion of atrial natriuretic hormone or other undetermined factors. Cerebral salt wasting is usually associated with hypovolemia but may be confused with the syndrome of inappropriate antidiuretic hormone secretion (SIADH), which does not demonstrate volume depletion. The 2 syndromes can be differentiated by measuring plasma uric acid concentration, which is increased in cerebral salt-wasting syndrome and decreased in SIADH. Apart from managing the underlying condition, patients with cerebral salt-wasting syndrome require complete replacement of urinary sodium and water losses.

In all patients with renal losses of sodium as a cause of hypovolemic hyponatremia the urinary sodium concentration is usually greater than 20 mEq/L, despite the presence of hypovolemia.

Euvolemic Hyponatremia

The ECF volume status of patients in this group is usually normal; some persons have a slightly increased ECF volume, but they are not edematous. Owing to slight ECF volume expansion, urinary sodium concentration is usually greater than 20 mEq/L.

The **syndrome of inappropriate antidiuretic hormone secretion (SIADH)** is a common cause of euvolemic hyponatremia. Exogenous administration of DDAVP (synthetic analog of vasopressin) can produce a similar clinical picture. SIADH, which has multiple causes (e.g., central nervous system infections, trauma, hypoxia, and various malignancies), results from antidiuretic hormone (ADH) secretion despite the absence of increased plasma osmolality or volume depletion, the normal stimuli for ADH secretion. The diagnostic criteria are as follows:

1. Hypoosmolar hyponatremia
2. Urine osmolality higher than serum osmolality
3. Normal renal function
4. Normal adrenal and thyroid function
5. High urinary sodium concentration (this is not an absolute criterion, inasmuch as urinary sodium concentrations may be low in patients who are severely sodium depleted)
6. Absence of hypovolemia or edema
7. Hypouricemia

In the absence of any obvious clinical signs, the incidental laboratory finding of hyponatremia is usually the 1st clue to the presence of SIADH.

Because SIADH is a problem of water retention and not of sodium depletion, the most appropriate treatment is water restriction. Attempts to correct the hyponatremia with sodium administration cause an increase in urinary sodium excretion and little change in the plasma sodium concentration. Nonetheless, sodium administration is needed if severe hyponatremia leads to neurologic symptoms.

Glucocorticoid and thyroid hormone deficiency can cause hyponatremia similar to that of SIADH. Adrenal insufficiency may also produce volume depletion and an addisonian crisis. The hyponatremia resolves with appropriate hormonal replacement therapy.

Acute water intoxication is an uncommon cause of euvolemic hyponatremia in children receiving hypotonic intravenous fluids; it is likely to happen only if there is an associated impairment of free water excretion capability. Postoperative patients are at particularly increased risk because of high ADH secretion secondary to pain and emotional stress. As the free water excretion ability of infants is limited in comparison with that in older children, they are at increased risk of developing hyponatremia from excessive oral water intake. Infants younger than 1 year fed water without electrolytes may develop hyponatremia and associated symptoms such as lethargy, seizures, and hypothermia. Symptoms correct rapidly with water restriction.

Hypervolemic Hyponatremia

In the absence of renal disease, patients with hypervolemic hyponatremia have decreased effective circulating blood volume with resulting sodium and water retention. Urine sodium concentration is low. The

(See *Nelson Textbook of Pediatrics,* p. 2647.)

edema-forming states such as heart failure, cirrhosis, and nephrosis are characterized by decreased effective blood volume (despite an increased ECF) that leads to stimulation of the renin-angiotensin-aldosterone axis as well as ADH secretion. Although both sodium and water are retained, hyponatremia develops because of proportionately greater water retention. The urinary sodium is usually less than 10 mEq/L because of avid sodium reabsorption as a consequence of decreased effective blood volume and decreased renal perfusion.

◆ Clinical Signs and Symptoms of Hyponatremia

Most patients with mild degrees of hyponatremia (plasma sodium levels, 125-135 mEq/L) are asymptomatic. Once the serum sodium concentration falls below 120 mEq/L, serious sequelae, especially involving the central nervous system, may follow. Cerebral edema develops because the decrease in plasma osmolality causes water to move into the cells. Cerebral overhydration can manifest with varied symptoms, such as headache, vomiting, altered consciousness, seizures, and coma. The severity of symptoms is dependent on both the magnitude and rapidity of the fall in the plasma sodium concentration. Although seizures are common with acute hyponatremia, patients with chronic hyponatremia may manifest focal neurologic deficits and ataxia. The brain is protected during chronic hyponatremia by adaptive changes involving loss of intracellular osmolytes. However, the same protective changes can be responsible for the harmful effects seen when chronic hyponatremia is corrected too rapidly (see later discussion).

Patients with hypovolemic hyponatremia can develop shock at lesser degrees of body water depletion in comparison with patients with normal or increased serum sodium concentration, because of the associated fluid shift from the ECF to the ICF compartment. The decrease in the intravascular volume is a stimulus for ADH secretion, which serves to perpetuate the hyponatremia by limiting renal water excretion.

◆ Treatment of Hyponatremia

The treatment of hyponatremia depends on its severity, its duration, and the ECF volume status. The primary goal should be to treat the underlying condition giving rise to hyponatremia (e.g., management of diarrhea, mineralocorticoid deficiency, nephrosis, or heart failure). However, management of hypovolemia often requires initiation of corrective therapy before the underlying disease is controlled.

Patients with severe hypovolemia should promptly receive parenteral fluids to restore the circulating blood volume and normalize tissue perfusion. Blood and urine specimens should ideally be obtained as soon as possible to assess serum electrolytes, blood urea nitrogen level, creatinine level, and urinary sodium excretion. *Because correction of severe hypovolemia takes precedence over normalization of osmolality, isotonic solutions can be safely administered before the blood chemistry results are available.* Crystalloids are the preferred replacement fluids except if blood transfusion is required in cases of hemorrhagic shock. Isotonic crystalloids such as 0.9% saline (sodium level, 154 mEq/L) or lactated Ringer solution (sodium level, 130 mEq/L) are administered at rate of 10-20 mL/kg over a short period of time. Fluid boluses can be repeated as needed until clinical improvement has occurred. The correction of hypovolemia helps in reversing the pathophysiologic factors causing water retention, thus ameliorating the hyponatremia. In patients with known cardiac, renal, or pulmonary diseases, fluid should be administered with caution, and concomitant measurement of central venous pressure and respiratory function is desirable.

After correction of acute hypovolemia, the remaining fluid deficit should be corrected slowly over 24-48 hours; additional fluid should be given to accommodate ongoing losses.

Patients with significant symptoms attributable to severe hyponatremia should receive hypertonic (3%) saline. Central nervous system symptoms almost always lessen when the serum sodium concentration is increased by 10 mEq/L. It is recommended that the initial serum sodium correction not exceed 125 mEq/L with this treatment.

Patients with SIADH require water restriction. In this group of patients, it is difficult to raise the plasma sodium concentration even with hypertonic saline, unless the ECF volume is simultaneously reduced. Whereas water restriction is enough for patients with mild hyponatremia, patients with symptoms should receive intravenous furosemide followed by intravenous hypertonic saline. In chronic SIADH, demeclocycline is effective because it diminishes the renal response to ADH.

Patients with hypervolemic hyponatremia require salt and water restriction. Any effort to increase the serum sodium concentration by saline administration causes further ECF volume expansion and may worsen the patient's condition. In cases of severe salt and water overload associated with renal failure, dialysis is the most effective therapy.

The management of patients with chronic hyponatremia is controversial. These patients usually have very subtle symptoms because the brain has time to adapt to the disturbance with a decrease in the intracellular osmolytes. Rapid correction of hyponatremia can lead to cellular shrinkage and can cause an osmotically induced **demyelination syndrome**, particularly in the pons. The patients with extensive lesions can have flaccid quadriplegia, dysphagia, and dysarthria.

HYPERNATREMIA

Hypernatremia is a plasma sodium level greater than 145 mEq/L and may occur as result of (1) loss of both body sodium and water (water losses exceeding those of sodium), (2) isolated loss of water, and rarely (3) increase in body sodium. The development of hypernatremia is usually prevented by thirst and renal concentrating mechanisms. Thirst is so effective that even patients with complete diabetes insipidus (DI) avoid hypernatremia by increasing fluid intake. Hypernatremia develops only when hypotonic fluid losses occur in combination with a disturbance in water intake, as a result of inadequate access (as in comatose, developmentally delayed, or very young patients), or as a result of a primary abnormality of thirst mechanism (e.g., hypothalamic adipsic syndrome). Establishing the differential diagnosis of hypernatremia is aided by determining the patient's ECF volume status (hypovolemia, euvolemia, or hypervolemia) (Fig. 46.2).

Hypovolemic Hypernatremia

Disorders associated with losses of both sodium and water but with a relatively greater loss of water lead to hypovolemic hypernatremia. Many of the common causes (e.g., diarrhea, diuretic use) are similar to those that cause hypovolemic hyponatremia. Hypernatremia in these situations develops because of failure to ingest hypotonic fluids. Hypernatremic dehydration and failure to thrive often develop in neonates who nurse poorly, especially if the mother's breast milk has not come in. If the losses are extrarenal (e.g., through diarrhea, vomiting, profuse sweating), the urinary sodium concentration is less than 10 mEq/L. The renal causes are usually associated with a urine sodium concentration higher than 20 mEq/L.

Euvolemic Hypernatremia

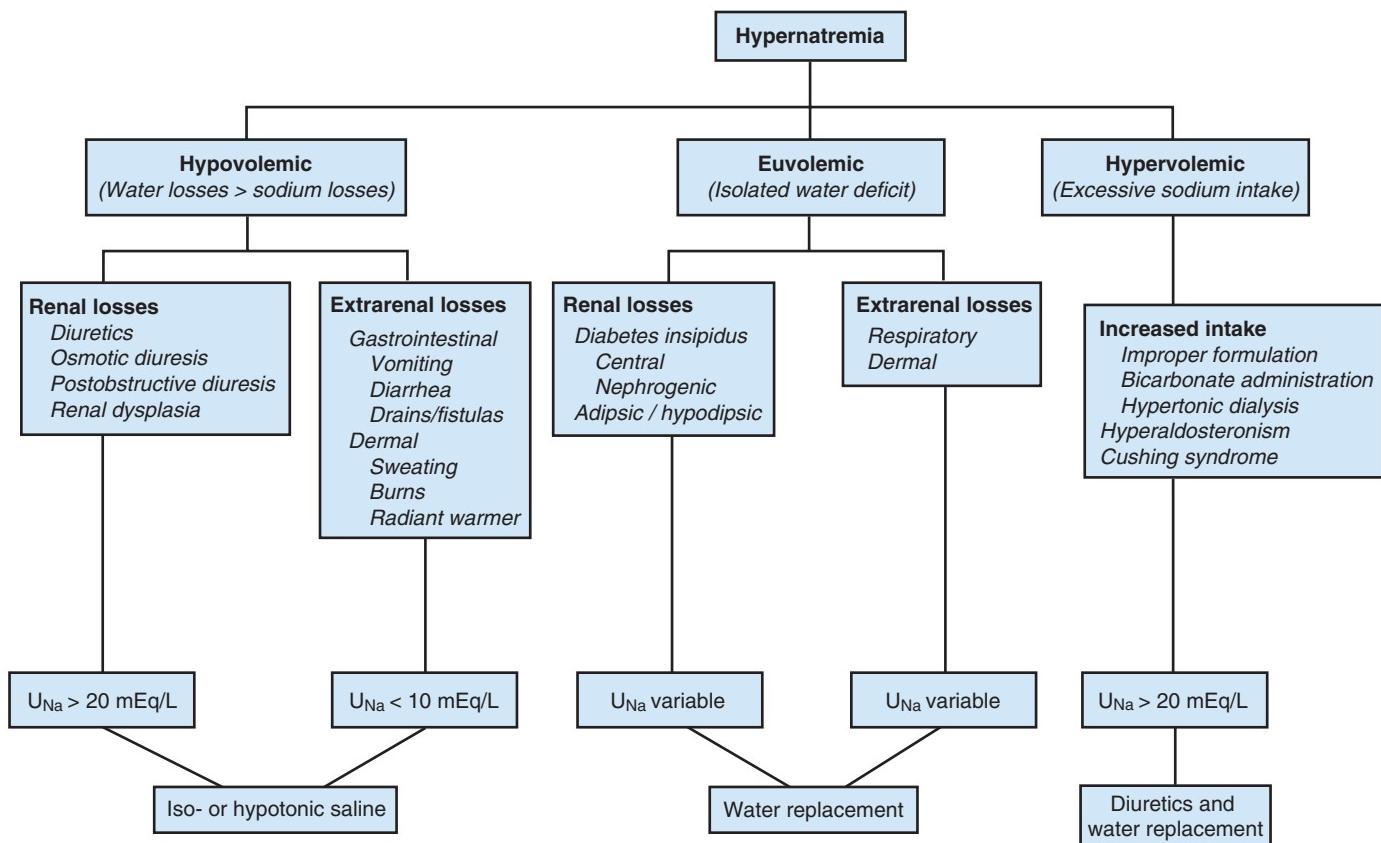
Pure water losses do not lead to volume contraction unless the water losses are large; these patients therefore appear euvolemic. In addition, hypernatremia develops only when the hypotonic losses are not accompanied by appropriate water intake. Although water loss can


FIGURE 46.2 Classification, Diagnosis, and Treatment of Hypernatremic States. (Modified from Beri T, Schrier RW. Disorders of water metabolism. In: Schrier RW, ed. *Renal and Electrolyte Disorders.* Philadelphia: Lippincott-Raven; 1997.)

occur through the skin or the respiratory tract, the most important disorder in this group is DI.

Patients with DI have a very low urine osmolality. Central DI is caused by a failure to secrete ADH; nephrogenic DI is secondary to a renal resistance to ADH. Acquired forms of central and nephrogenic DI are more common than the hereditary forms.

Hereditary central DI can be either autosomal dominant or, less commonly, autosomal recessive. The autosomal recessive form occurs in association with diabetes mellitus, optic atrophy, and deafness (**Wolfram syndrome**). The acquired causes of central DI include central nervous system trauma, infections, tumors, granulomatous infiltration, and vascular malformations.

Congenital nephrogenic DI is a rare X-linked disorder affecting mainly boys, with variable penetrance in girls. The **acquired form of nephrogenic DI** can be seen in association with chronic renal diseases (e.g., polycystic disease, medullary cystic disease, ureteral obstruction), electrolyte disorders (e.g., hypokalemia, hypercalcemia), drugs (e.g., lithium, demeclocycline, amphotericin, foscarnet), and sickle cell disease/trait.

Older children with DI have polyuria, polydipsia, and nocturia. The urine is hypo-osmolar and remains so even when these children develop dehydration and consequently increased serum osmolality. During infancy, DI can manifest with recurrent episodes of unexplained dehydration and fever. Repeated episodes of hypernatremic dehydration can lead to permanent neurologic sequelae.

Performing a fluid deprivation test and then determining the response to injectable vasopressin can help diagnose DI and differentiate between the central and nephrogenic forms. Primary treatment should focus on the underlying cause. Central DI is managed with hormonal replacement therapy with desmopressin (DDAVP). There is considerable individual variation in the required dosage, and it is important to allow patients to revert to mild polyuria before the next dose is given, to prevent excessive water accumulation. An intravenous form of antidiuretic hormone can be used in sick and comatose patients.

Therapy for nephrogenic DI should ensure a sufficient intake of water to replace the large urinary losses. Because obligatory urinary water losses increase with increasing solute load, restriction of sodium intake reduces the urine output. Administration of diuretics, such as thiazides and amiloride, keeps these patients in a mildly dehydrated state, which leads to increased water reabsorption in the more proximal segments of the nephron, thereby decreasing urine output. Nonsteroidal antiinflammatory drugs such as indomethacin also reduce polyuria and may be used in combination with diuretics. Careful attention should be paid to the fluid balance in these patients when they are sick and have poor oral fluid intake because they require large quantities of water replacement. Frequent monitoring of serum electrolytes is mandatory during these periods.

Adipsic/hypodipsic hypernatremia (essential hypernatremia; reset osmostat) characterizes a group of patients who have persistent hypernatremia, absence or attenuation of thirst, and often partial DI. Many patients are obese as a result of polyphagia. These patients require regimental intake of fluids; they may need supplementation with DDAVP.

Hypervolemic Hypernatremia

This is the least common type of hypernatremia. Most of the causes are iatrogenic (administration of improperly formulated oral rehydration solution, administration of intravenous fluids, excessive bicarbonate administration during resuscitative efforts, inadvertent dialysis against a high sodium concentration dialysate, salt poisoning, and seawater drowning). Other causes include primary hyperaldosteronism and Cushing syndrome.

◆ Clinical Signs and Symptoms of Hypernatremia

Hypernatremia causes intracellular dehydration by movement of water from the intracellular to the extracellular compartment. The consequences of intracellular dehydration are particularly marked in the brain and manifest with irritability, altered sensorium, lethargy, and hyperreflexia and eventually seizures, coma, and death. Brain hemorrhages can result from tearing of small blood vessels when the brain contracts as a result of intracellular dehydration. **Hypernatremia and dehydration may predispose to dural sinus thrombosis**. During chronic hypernatremia, the brain cells adapt to the increased ECF osmolality by accumulating idiogenic osmoles (which are mostly amino acids, particularly taurine). They increase intracellular osmolality, consequently restoring intracellular volume. This protective response has significant implications for therapy and the speed with which hypernatremia should be corrected.

◆ Treatment of Hypernatremia

The treatment of hypernatremia is guided by its severity, its chronicity, and the ECF volume status of the patient.

It is important to realize that patients with hyperosmolality maintain the ECF space at the expense of the ICF compartment, and, therefore, the degree of sodium and fluid losses may be profound before clinical signs of hypovolemia develop. Large volumes of isotonic crystalloid may be necessary to replace the fluid deficit.

Once initial fluid resuscitation has been performed, the serum sodium concentration should be restored slowly over a minimum period of 48 hours. The total water deficit can be estimated as follows (FW, free water; NA, sodium):

$$FW\ deficit\ (child) = 0.6 \times weight\ (kg) \times (current\ NA\ /140 - 1)$$

Hypernatremia is corrected especially slowly when it is more severe and chronic. The rate of fall in plasma sodium concentration should be less than 1 mEq/L/hr. During the correction of hypernatremia, the idiogenic osmoles that brain cells produce to prevent cellular dehydration dissipate slowly. If hypernatremia is corrected too rapidly, the increased intracellular osmolality from the idiogenic osmoles can lead to cerebral edema. In patients with hypervolemic hypernatremia, the 1st line of therapy is restriction of salt intake, followed by administration of diuretics.

CALCIUM DISORDERS

Serum calcium concentration in the extracellular fluid is regulated by parathyroid hormone (PTH), which acts on the kidney and bones, and by 1,25-dihydroxyvitamin D, which acts on the intestines and bones. About 50% of the calcium is in the ionized form, 40% is protein bound (mainly to albumin), and 10% is associated with anions, such as bicarbonate, citrate, sulfate, phosphate, and lactate. It is important to remember that serum albumin levels and pH affect calcium levels. There is a direct relationship between serum albumin concentration and total serum calcium. An alkaline pH will increase protein binding, leading to decreased ionized calcium levels. It is important to obtain an ionized calcium level when evaluating calcium derangements.

Hypocalcemia

There are many causes of hypocalcemia, and measurements of parathyroid hormone can help classify the etiology of hypocalcemia (Fig. 46.3). Hypocalcemia is defined as a total serum calcium level below 8.5 mg/dL and an ionized serum calcium level below 4.65 mg/dL. Patients with mild hypocalcemia are usually asymptomatic. With severe hypocalcemia, patients may present with paresthesias of the extremities, Chvostek sign, Trousseau sign, muscle cramps or spasm, laryngospasm, tetany, and seizures. Cardiac manifestations of hypocalcemia include a prolonged QT interval, which can progress to heart block.

Hypercalcemia

Similar to hypocalcemia, there are also many causes of hypercalcemia (Fig. 46.4). Hypercalcemia usually occurs through 1 of 3 mechanisms: increased bone resorption, increased gastrointestinal absorption of calcium, and decreased renal excretion. Hypercalcemia is defined as total serum calcium above 10.5 mg/dL and an ionized serum calcium of above 5.25 mg/dL. Patients with mild hypercalcemia usually do not have symptoms. Patients with severe hypercalcemia may have neurologic manifestations ranging from drowsiness to coma.

RICKETS

Rickets is a disease caused by deficient mineralization of the osteoid matrix before closure of the epiphyseal plate that results in softening and weakening of bones in infants and children. In patients with rickets, the growth plate cartilage and osteoid continues to expand but mineralization is inadequate, and as a result, the growth plate thickens. The circumference of the growth plate and the metaphysis also increases, which expands bone width at the location of the growth plates and causes some of the classic clinical manifestations, such as widening of the wrists and ankles. There is also softening of the bones that can lead to bone deformities and causes them to bend easily, especially when subject to certain forces.

Rickets is usually caused by vitamin D deficiency. Children at risk are those with limited sun exposure, ages 6-24 months, prematurity, solely breast-fed infants, use of anticonvulsants, and darker skin pigmentation. Rickets is still a significant problem in developing countries, likely due to nutritional vitamin D deficiency and inadequate calcium intake.

◆ Clinical Manifestations

Most clinical features of rickets are due to skeletal changes. Craniotabes is a softening of the cranial bones, which can be appreciated by applying pressure at the occiput or over the parietal bones. Widening of the costochondral junctions produces a rachitic rosary, which can be detected on exam by moving one's fingers along the costochondral junctions from rib to rib, named because it feels like the beads of a rosary. Increased circumference of the wrists and ankles is a result of growth plate widening. Patients with rickets may have an indentation of the lower ribs, known as a Harrison groove, which occurs from the pulling of the softened ribs by the diaphragm during inspiration. Softening of the ribs can impair air movement and predisposes patients to atelectasis and pneumonia. In addition to the skeletal manifestations, rickets can present with hypocalcemia, hypophosphatemia, and tetany (Table 46.11). It is important to note that most children are asymptomatic, and rickets is diagnosed through an incidental finding on physical or radiologic examination.

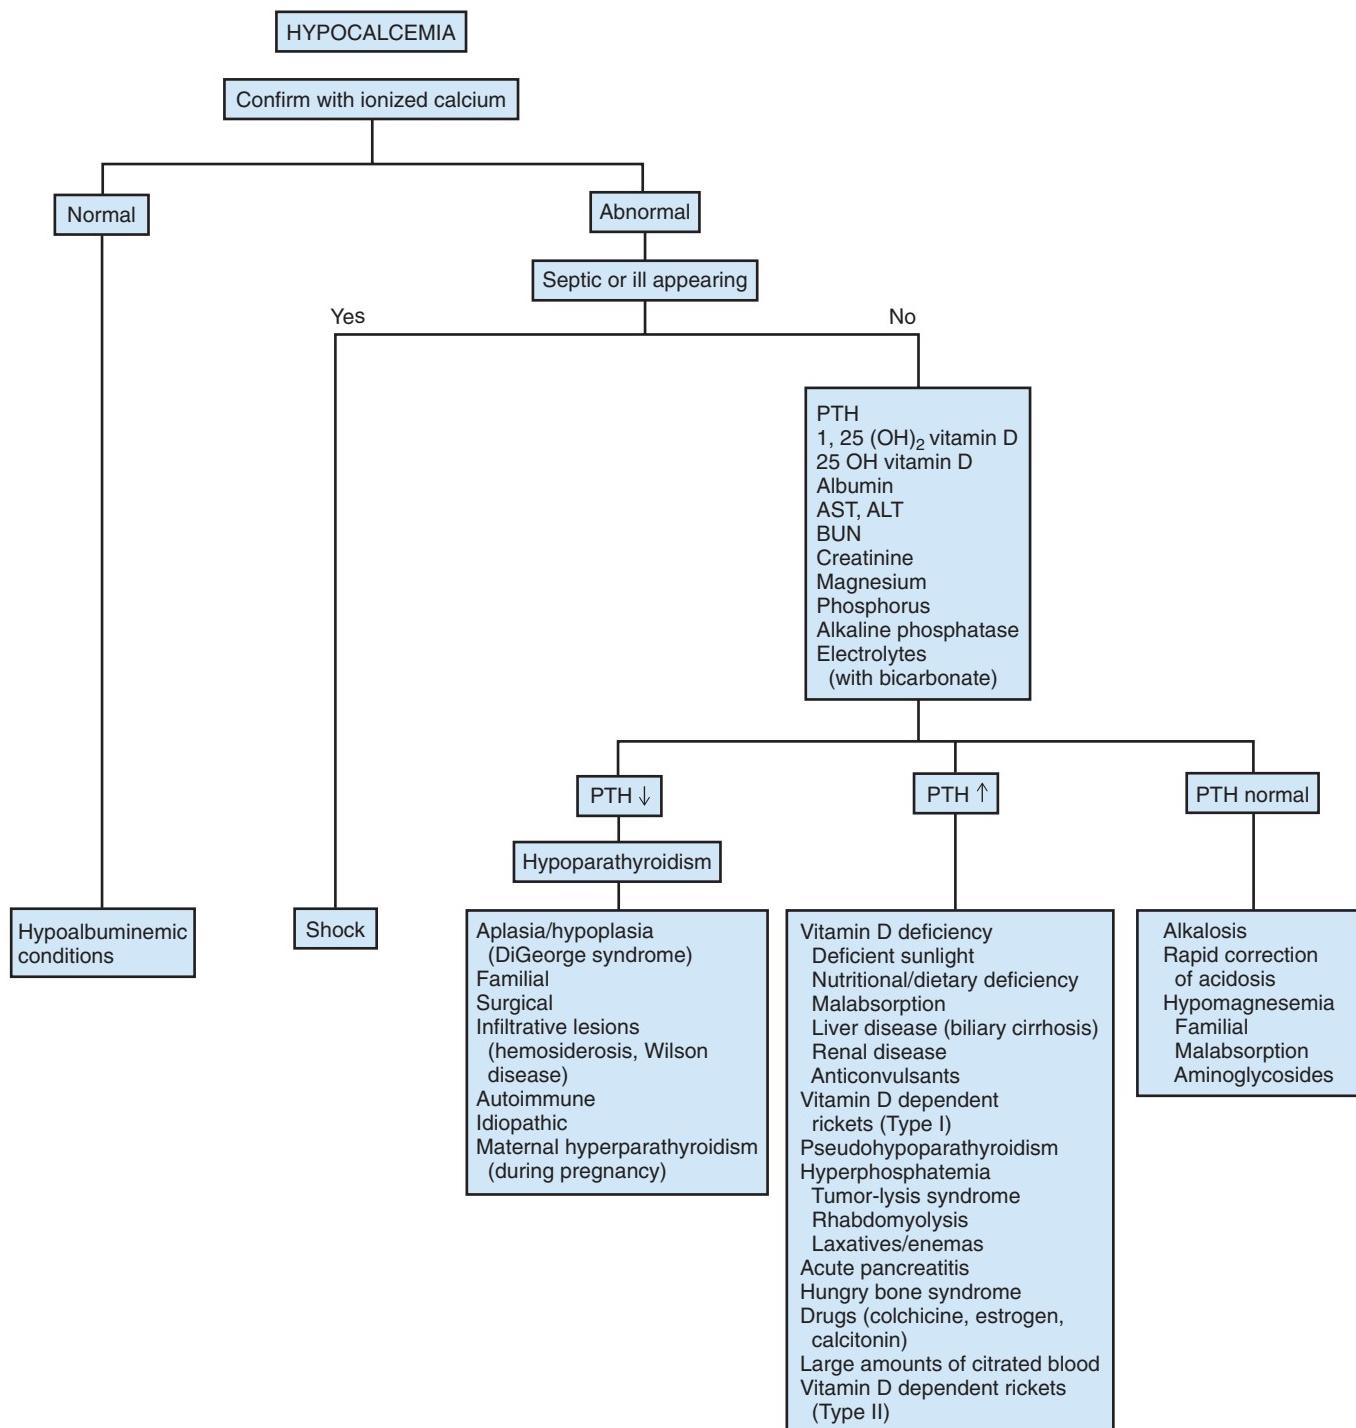
(See *Nelson Textbook of Pediatrics,* Fig. 571.1.)


FIGURE 46.3 Causes of Hypocalcemia. ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; PTH, parathyroid hormone. (From Pomeranz AJ, Sabnis S, Busey SL, et al. Hypocalcemia. In: Pomeranz AJ, Sabnis S, Busey SL, et al., eds. *Pediatric Decision-Making Strategies*. 2nd ed. Philadelphia: Elsevier; 2016:335.)
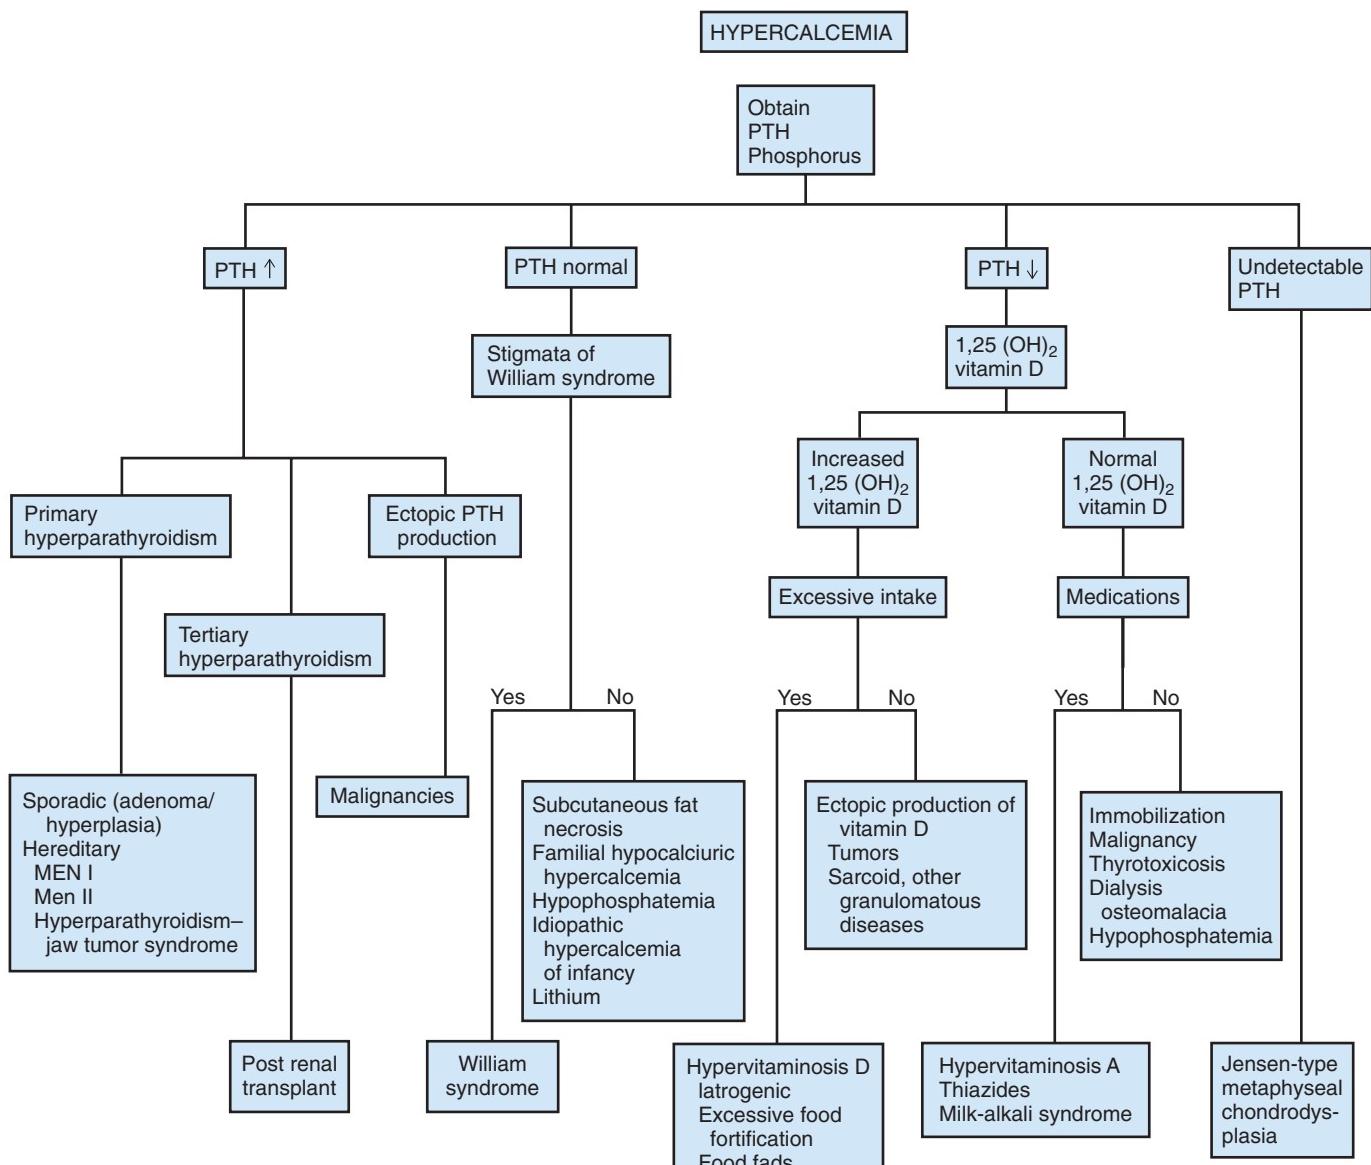

FIGURE 46.4 Causes of Hypercalcemia. MEN, multiple endocrine neoplasia; PTH, parathyroid hormone. (From Pomeranz AJ, Sabnis S, Busey SL, et al. Hypocalcemia. In: Pomeranz AJ, Sabnis S, Busey SL, et al., eds. *Pediatric Decision-Making Strategies*. 2nd ed. Philadelphia: Elsevier; 2016:337.)

There is some variation in the clinical presentation of rickets based on the etiology. Changes in the lower extremities tend to be the dominant feature in X-linked hypophosphatemic rickets. Symptoms secondary to hypocalcemia occur only in those forms of rickets associated with decreased serum calcium (Table 46.12).

Diagnosis of rickets is usually made by radiographic examination of the long bones. Laboratory values can support the diagnosis.

Laboratory values may show decreased calcium and phosphorus, increased alkaline phosphatase, decreased 25-(OH) vitamin D_3 levels, increased 1,25-$(OH)_2$ vitamin D levels, and increased parathyroid hormone (PTH) levels. The increased PTH is indicative of the hormonal response that tries to maintain normal calcium (Table 46.13). The appropriate treatment depends on the underlying etiology.

SUMMARY AND RED FLAGS

Acid–base and electrolyte disturbances have many causes that reflect abnormalities of regulation or compensation of these systems. For many acid–base or electrolyte disturbances, the underlying condition needs to be treated before consideration of the electrolyte or acid-base disturbance. This is true in all causes of shock, such as dehydration, adrenal crisis, or systemic hemorrhage. The circulating blood volume must be quickly reestablished; this is usually performed as part of the resuscitation phase of treating dehydration or shock. Thereafter,

TABLE 46.11 Clinical Features of Rickets

General
Failure to thrive
Listlessness
Protruding abdomen
Muscle weakness (especially proximal)
Fractures

Head
Craniotabes
Frontal bossing
Delayed fontanel closure
Delayed dentition; caries
Craniosynostosis

Chest
Rachitic rosary
Harrison groove
Respiratory infections and atelectasis*

Back
Scoliosis
Kyphosis
Lordosis

Extremities
Enlargement of wrists and ankles
Valgus or varus deformities
Windswept deformity (combination of valgus deformity of 1 leg with varus deformity of the other leg)
Anterior bowing of the tibia and femur
Coxa vara
Leg pain

Hypocalcemic Symptoms†
Tetany
Seizures
Stridor due to laryngeal spasm

*These features are most commonly associated with the vitamin D deficiency disorders.
†These symptoms develop only in children with disorders that produce hypocalcemia.

specific acid–base or, more often, electrolyte abnormalities can be attended to during the replacement phase to correct electrolyte deficits. In general, electrolyte disturbances must be corrected slowly. This is particularly true for sodium abnormalities. The major exceptions are hyperkalemia and acute hypercarbic respiratory acidosis, which must be treated immediately.

Each of the discussed acid–base and electrolyte disturbances are important, and hyperkalemia remains the one of most concern and the most dangerous.

Anuria, hypotension, weight loss, seizures, coma, hypoglycemia or hyperglycemia, apnea, and arrhythmias are additional concerning signs and symptoms. Moreover, the clinician must remain vigilant in identifying the primary reason or reasons for any of these acid–base or electrolyte disturbances.

Congenital Cutaneous Lesions and Infantile Rashes

Yvonne E. Chiu and Stephen R. Humphrey

Neonates and infants can have a variety of congenital birthmarks and transient rashes, some very common and others more rare. The chapter is organized by the primary cutaneous lesion seen on clinical examinations (Table 47.1).

RASHES

Papules and Pustules—Diffuse or Scattered

Erythema toxicum is a benign condition that occurs in 30-70% of white full-term infants. Erythema toxicum occurs less frequently in premature infants. The eruption is characterized by blotchy, erythematous macules or patches with central papules, pustules, or vesicles that give the infant a "flea-bitten" appearance (Fig. 47.1). The lesions develop most commonly between the 2nd and 4th days after birth; however, they may appear during the 1st 2-3 weeks. They are self-limiting and usually resolve within several days. Typical sites of involvement include the face, trunk, and proximal extremities. There may be very few to hundreds of lesions.

A Giemsa or Wright stain of the intralesional contents reveals sheets of *eosinophils* with a relative absence of neutrophils. Peripheral eosinophilia may be present in up to 20% of affected infants. Erythema toxicum is occasionally confused with transient neonatal pustular melanosis, congenital cutaneous candidiasis, impetigo neonatorum, milia, herpes simplex, or miliaria rubra (prickly heat).

Transient neonatal pustular melanosis, seen in up to 4% of neonates, occurs more often in African-American infants. Typically present at birth, the initial lesions are 2- to 5-mm pustules distributed over the face, neck, and upper chest and, less often, on the sacrum, trunk, thighs, palms, and soles (Fig. 47.2). In contrast to the lesions of erythema toxicum, there is no erythema surrounding each pustule, and Wright stain of pustular contents reveals many neutrophils. In both disorders, the pustules are sterile and should be distinguished from those seen in potentially serious infections caused by herpes simplex virus (HSV), *Staphylococcus aureus*, or *Candida* species.

The superficial pustules of transient neonatal pustular melanosis rupture spontaneously within the 1st few days after birth, leaving hyperpigmented macules that have collarettes of fine scale. It is common to see only the hyperpigmented macules at birth. These brown spots slowly fade over several weeks to months.

Miliaria results from sweat retention and is exacerbated by heat and humidity. Affected newborns are frequently in incubators or receiving phototherapy. Keratinous plugging of the eccrine ducts and subsequent release of eccrine sweat into the surrounding skin produces

2 distinct clinical manifestations with different sites of eccrine duct obstruction. In miliaria crystallina, obstruction occurs just below the stratum corneum, resulting in superficial, noninflammatory 1- to 2-mm vesicles. In miliaria rubra, or "prickly heat," obstruction occurs in the mid-epidermis. This is associated with an inflammatory response exhibited by vesicles, papules, or papulovesicles surrounded by a rim of erythema. The lesions occur in clusters on the trunk, face, scalp, and intertriginous regions. Neither type of miliaria warrants therapy, but improvement occurs with cooling of the skin and avoidance of excessive warmth and moisture.

Eosinophilic pustular folliculitis is another disorder of infancy characterized by recurrent crops of vesicles and pustules, beginning in the 1st year of life. Lesions are often present on the forehead and scalp. The condition tends to occur in a cyclic pattern and is very pruritic. Scraped material from the pustules subjected to Wright stain demonstrates a large number of eosinophils but no evidence of infectious organisms. A complete blood cell count may show peripheral eosinophilia. In rare cases, skin biopsy may be necessary. Histopathologic study demonstrates a perifollicular and dermal infiltrate of eosinophils, as well as lymphocytes and histiocytes. Because the clinical condition is very similar to infantile acropustulosis, some authors contend that eosinophilic pustular folliculitis may be part of the same clinical spectrum. This condition is not associated with systemic disease, and the 1st-line treatment is symptomatic with topical corticosteroids and antihistamines. Oral and topical indomethacin has been effective in recalcitrant cases. Eosinophilic pustular folliculitis usually resolves spontaneously by 2-3 years of age.

Acropustulosis of infancy is a condition that may present at birth or during the 1st few weeks or months afterward. The disorder is characterized by recurrent eruptions of pruritic pustules or vesicles involving the hands and feet (Fig. 47.3). On occasion, involvement includes other sites such as the trunk or abdomen. The lesions frequently begin in crops, which typically last approximately 1 week, and resolve with desquamation, followed by postinflammatory hyperpigmentation.

Acropustulosis is often confused with infantile scabies. Family history and examination of scrapings of the involved area may help differentiate between these 2 diagnoses. However there is some thought that it may occur after a previous scabies infection. Scrapings of lesions in acropustulosis often demonstrate neutrophils. Bacterial infection should also be ruled out by wound cultures. Treatment is symptomatic and consists of control of pruritus with low- to mid-potency topical corticosteroids and antihistamines. Parents should be

TABLE 47.1   Neonatal and Infantile Cutaneous Lesions

Rashes

Papules and Pustules

Erythema toxicum	Occurs 1st few days of life. Blotchy red macules with central papule, pustule, or vesicle.
Transient neonatal pustular melanosis	Present at birth. More common in African-American infants. Pustules resolve with hyperpigmented macules.
Miliaria	Associated with overheating. Vesicles and pustules in occluded areas.
Eosinophilic pustular folliculitis	Onset during infancy. Pruritic pustules on the head and neck.
Acropustulosis of infancy	Onset during infancy. Pruritic pustules on the hands and feet.
Neonatal cephalic pustulosis (neonatal acne)	Pink papules, predominately on face.
Langerhans cell histiocytosis	Crusted papules, predominately on the scalp and intertriginous areas.
Herpes simplex virus	Onset from birth to 2 wk. Grouped vesicles and papulopustules favor scalp and trunk.
Varicella	Diffuse vesicles and papules. Associated with sepsis, fever/hypothermia.
Scabies	Pruritic papules, vesicles, and pustules. Can be widespread in infants, but concentrated in intertriginous areas.
Syphilis	Widely scattered scaly red-brown papules and plaques

Patches and Plaques

Neonatal lupus	Bright red annular patches and plaques distributed on cheeks and periorbital skin. Heart block is most common extracutaneous finding.
Seborrheic dermatitis	Pink patches on the scalp, face, ears, and intertriginous areas. May have yellow, greasy scale. Erosions and fissures can be seen.
Diaper dermatitis	Pink patches with erosions in the groin and buttocks. Can be multifactorial.

Fixed Lesions

Macules, Papules, and Pustules

Milia	Pinpoint white-yellow papules without erythema. Typically on face, gingiva, or palate. Resolves with time.
Sebaceous gland hyperplasia	Skin-colored to yellow tiny papules on cheeks and nose. Secondary to maternal androgens. Resolve in 1st few months.

Subcutaneous fat necrosis	Firm, indurated, tender plaques on back, arms, shoulders of newborns. Due to perinatal trauma, hypothermia, or hypoxemia. Monitor for hypercalcemia.
Juvenile xanthogranuloma	Solitary yellow-pink plaques on the face and scalp. May ulcerate and usually resolve spontaneously.
Mastocytoma	Yellow to pink solitary plaques. Can urticate or swell with friction or rubbing. Composed of mast cells. Can be seen in infants but typically more common with toddlers.
Urticaria pigmentosa	Condition with several mastocytomas. Rare in infants. Typically presents with lesions that will urticate. Over time, they become hyperpigmented. Rarely associated with systemic symptoms.
Spider angioma	Rare in infants. Small blanching capillaries with "feeder vessel" on the trunk and face.
Pyogenic granuloma	Solitary, small vascular papules that develop rapidly and bleed profusely. Typically seen in toddlers and occasionally infants.

Patches and Plaques

Pink (Vascular or Other)

Hemangioma	Benign vascular tumors, typically present in 1st month of life. Grow rapidly for 1st several months and then involute slowly over a couple of years.
PHACE/PELVIS	Syndromes associated with hemangiomas in particular locations on the face or back.
Capillary malformation	Stable, pink, vascular patches; typically unilateral. In V1 distribution, can be associated with Sturge–Weber syndrome
Nevus simplex	Pink patches on glabella, eyelids, nape of neck, typically. Usually fade over 1st couple of years.
Cutis marmorata telangiectasia congenita	Lacy, reticulated vascular patches. Do not resolve with rewarming of infant. May have atrophic changes or ulcerate.
Kaposiform hemangioendothelioma	Rare vascular tumor. Firm, violaceous, and tends to proliferate. Can lead to consumptive coagulopathy(Kasabach–Merritt syndrome)
Venous/lymphatic malformation	Slow-flow vascular malformations. Typically present at birth. May be associated with atrophy or overgrowth.

TABLE 47.1	**Neonatal and Infantile Cutaneous Lesions—cont'd**		
Hyperpigmented or Darker Pigment		***Other***	
Congenital melanocytic nevus	Pigmented macules, papules, patches, and plaques. Present in 2–3% of population.	Nevus sebaceus	Sebaceous gland hamartoma, usually present at birth. Yellow-orange and smooth plaque. Thickens during puberty.
Neurocutaneous melanosis	Defined by a giant melanocytic nevus. Associated with melanocytic infiltration of leptomeninges. Clinically symptomatic lesions have worse prognosis.	Dermoid cyst	Typically found in head/neck region. Potential for intracranial connection.
		Aplasia cutis	Congenital absence of skin, typically on scalp. Can resemble scars when child is older.
Café-au-lait macules	Well-demarcated tan macules or patches. Seen in 10–20% of population. Multiple lesions can be associated with neurofibromatosis.	Hair collar sign	Ring of dense, darker hair encircling a scalp lesion. Can be a sign of spinal dysraphism.
Dermal melanocytosis	Large, poorly demarcated, slate-gray to blue patches on buttocks and lumbosacral region. Occurs normally in darker skin tones. Typically fades over time.	Hypertrichosis of lumbar area	Normal variant in certain ethnicities. Can be indicator of spinal dysraphism.
		Sacral dimples	Commonly seen. Large dimples along gluteal crease need to be evaluated for spinal dysraphism. Can be associated with hypertrichosis.
Hypopigmented or Depigmented			
Nevus depigmentosus	Hypopigmented patch that persists through life.	***Transient/Changing Lesions***	
Ash leaf spots	Hypopigmented macules that present in 1st few months to years of life. Typically seen with tuberous sclerosis.	***Patches*** ***Segmental*** Cutis marmorata	Lacy, reticulated vascular patches, often bilateral. Resolve with warming of infant and disappear over time.
Piebaldism	Well-circumscribed areas of depigmentation on the skin. Tends to be symmetric and stable in size.		
Waardenburg syndrome	White forelock, white patches on skin. Can have heterochromia of irides and hearing loss.	***Diffuse*** Harlequin color change	Marked erythema on dependent side. Simultaneous blanching on non-dependent side. Transient.
Albinism	Diffuse congenital hypopigmentation of skin. Usually involves eyes and hair. Should be monitored closely by ophthalmologists. Evaluate for hearing loss. Patients need lifelong photoprotection.	***Distal Extremities*** Acrocyanosis	Bluish-purple discoloration of hands, feet, lips. Occurs with crying and cold stress.

PHACE, posterior fossa malformations, hemangiomas, arterial anomalies, cardiac defects, and eye abnormalities; PELVIS, perineal hemangioma, external genitalia malformations, lipomyelomeningocele, vesicorenal abnormalities, imperforate anus, and skin tag.

FIGURE 47.1 Papules surrounded by erythema are characteristic of erythema toxicum. Typically it is located on the trunk, but can be on the extremities as well.

FIGURE 47.2 Transient neonatal pustular melanosis. Papules and papulopustules that rupture to leave a collarette of fine scales and eventual hyperpigmentation. (From Paller AS, Mancini AJ. Cutaneous disorders of the newborn. In: Paller AS, Mancini AJ, eds. *Hurwitz Clinical Pediatric Dermatology*. 4th ed. Philadelphia: Elsevier; 2011:18.)

FIGURE 47.3 Acropustulosis of infancy. Multiple tense erythematous papules and pustules on the palm of this 4-month-old girl. (From Paller AS, Mancini AJ. Cutaneous disorders of the newborn. In: Paller AS, Mancini AJ, eds. *Hurwitz Clinical Pediatric Dermatology*. 4th ed. Philadelphia: Elsevier; 2011:19.)

FIGURE 47.4 Neonatal acne (cephalic pustulosis) is usually found on the cheeks and scalp in the 1st 2-4 weeks of life; small red papules and pustules without comedones are evident. (Modified from Eichenfield LF, Frieden IJ, Esterly NB. *Textbook of Neonatal Dermatology*. Philadelphia: Saunders; 2001:94.)

advised that lesions tend to occur episodically until approximately 2-3 years of age.

Neonatal cephalic pustulosis (neonatal acne) develops in approximately 20% of newborns. Typically, it is not present at birth, but appears during the 1st few weeks after birth. Characterized by papules and pustules located on the face or trunk, this condition usually resolves within the 1st several months of life (Fig. 47.4). Neonatal acne is a misnomer as neonatal cephalic pustulosis is likely caused by *Malassezia* yeast species. Therapeutic intervention is rarely required, but ketoconazole 2% cream may be of some use.

Langerhans cell histiocytosis (LCH) is a rare disorder, affecting about 5 per 1 million children, which is characterized by a proliferation of clonal dendritic cells, called Langerhans cells. There are 4 main

FIGURE 47.5 "Raccoon eyes" eruption of neonatal lupus erythematosus. (From Eichenfield LF, Frieden IJ, Esterly NB. *Textbook of Neonatal Dermatology*. Philadelphia: Saunders; 2001:297.)

types, 2 of which are most frequently seen in neonates and infants, though there is substantial overlap among the types.

Congenital self-healing reticulohistiocytosis (Hashimoto–Pritzker disease) typically presents at birth or within the 1st few days of life and is limited to the skin. There is a diffuse eruption of red to purple-brown papules and nodules that will crust and remit after several weeks. While it is considered a benign, self-limited condition, it can rarely progress to other more aggressive forms of LCH.

Letterer–Siwe disease is the more acute, diffuse form of LCH that has multisystem involvement. It commonly presents before 1 year of age with the majority of patients having skin findings of small 1- to 2-mm papules, pustules, and vesicles, typically on the scalp, intertriginous areas, and trunk. The lesions are often crusted and may have secondary bacterial infections. Fissures and confluence of papules can be seen. It can be confused with seborrheic dermatitis, and other forms of diaper dermatitis (Table 47.1).

Patches and Plaques

Patches are confluent, flat lesions over 1 cm in size, while plaques are slightly raised lesions over 1 cm in size. Many of these conditions have overlapping features but can often be distinguished by their location, distribution, and response to certain treatments (Table 47.1).

Neonatal lupus erythematosus is a unique annular erythematous eruption during the neonatal period. Lesions of neonatal lupus are often scaly, annular plaques that usually occur on the face and scalp and may affect the periorbital and malar areas, creating a "raccoon eyes" appearance (Fig. 47.5). Other manifestations may include transient hypopigmentation with epidermal atrophy or telangiectasia. Cutaneous lesions may be present at birth but often appear within the 1st 2-3 months of life. The lesions are usually exacerbated by sun exposure and are typically photodistributed. The majority of skin findings are transient, lasting up to 6-9 months.

(See *Nelson Textbook of Pediatrics,* p. 1176.)

Cutaneous findings or congenital heart block are each present individually in approximately 50% of affected infants; some studies have shown congenital heart block to be much less common. An overlap of both is present in approximately 10% of affected infants. The major morbidity and mortality of neonatal lupus result from congenital heart block.

The diagnosis of neonatal lupus includes examination of anti-Ro, anti-La, and anti-U1RNP autoantibodies in both the infant and mother. Ninety-five percent of mothers of infants with neonatal lupus have anti-Ro antibodies. Skin biopsy is usually not necessary. Work-up should include an electrocardiogram (ECG), platelet count, and liver function tests because approximately 5-10% of affected infants have liver disease or thrombocytopenia. Rare reports of multisystem involvement, including neurologic and respiratory findings have been reported.

Mothers with high titers of anti-Ro antibodies or with systemic lupus erythematosus have a higher risk of delivering an infant with neonatal lupus and should be counseled appropriately. Despite high antibody titers, fewer than half of mothers of affected infants are symptomatic at the time of delivery. In most of these mothers, evidence of connective tissue disease, usually Sjögren syndrome or subacute cutaneous lupus, develops over time.

Differential diagnosis should include annular erythema of infancy, tinea corporis, and cutis marmorata telangiectatica congenita (CMTC). Treatment consists of photoprotection and topical steroids. Most cutaneous changes resolve spontaneously by 6-9 months of age as a result of a gradual decrease in maternal antibodies.

Seborrheic dermatitis, common during infancy, typically manifests within the 1st several weeks after birth. Characterized by erythema and a yellow, greasy scale, it usually resolves spontaneously within several months. The eruption occurs at sites where sebaceous glands are concentrated, such as the face, chest, posterior auricular scalp, and intertriginous areas. *Malassezia* colonization plays a part in the development of seborrheic dermatitis. "Cradle cap" is seborrhea that is confined to the scalp. Involvement of the diaper area is characterized by salmon-colored patches that arise in skin folds and spread to the genitalia, suprapubic area, and upper medial thighs. Scale may not be as apparent in intertriginous areas. Unlike atopic dermatitis, this eruption is not very pruritic. Secondary candidal or bacterial infection is common, particularly if erosions or fissures are seen.

The diagnosis is established clinically. The presence of greasy yellow scales and salmon-colored patches, involvement of the scalp and intertriginous areas, early onset, and lack of pruritus or atopic history help distinguish seborrheic from atopic dermatitis. However, some infants have an overlap of seborrheic dermatitis and atopic dermatitis. Seborrheic dermatitis should also be differentiated from LCH, in which the lesions are typically purpuric, erosive, or crusted; and from psoriasis (see Chapter 48). Skin biopsy findings, as well as hepatosplenomegaly, purpura, lymphadenopathy, anemia, thrombocytopenia, external otitis, interstitial pneumonia, and osseous lesions, further distinguish LCH from seborrheic dermatitis.

Treatment of the scalp consists of mild keratolytic shampoos, such as those containing selenium sulfide or zinc pyrithione. Ketoconazole 2% shampoo can be efficacious, particularly with controlling overgrowth of the yeast. Mineral oil may be helpful in removing thick, adherent scales. The scalp and diaper dermatitis may be treated with low-potency topical corticosteroids and barrier ointments. Topical antifungal or antibacterial agents should be used for coexisting candidiasis or impetigo.

Diaper dermatitis is 1 of the most common dermatologic disorders of infants and toddlers (Table 47.2). It comprises a group of inflammatory conditions that involve the lower abdomen, genitalia, upper thighs, and buttocks. Clinical manifestations include erythema, edema, erosions, vesicles, and pustules. Secondary changes of postinflammatory hyperpigmentation or hypopigmentation are common.

Diaper dermatitis is often multifactorial, including irritation from feces/urine, skin breakdown from maceration, and bacterial or fungal components. Although urinary ammonia was thought to be the primary factor in the development of diaper dermatitis, feces now appear to play a more important role. Fecal ureases, by converting urea to ammonia, cause the elevation of skin pH, which in turn, increases fecal protease and lipase activity. These proteases and lipases cause the disruption of the epidermal barrier. Skin wetness, friction, maceration, and contact with feces, urine, and microbes further compromise epidermal integrity. This results in increased permeability of the skin to irritants such as soaps, powders, and detergents. Diaper dermatitis may begin as early as 1-2 months of age and may become a chronic or recurrent problem in older infants as well.

Allergic contact dermatitis is another component to consider, although it is more common in toddlers and children than neonates. Offenders can be dispersed dyes from disposable diapers and methylisothiazolinone in wet wipes. The differential diagnosis may also include seborrheic dermatitis, skin or perianal infections (particularly due to group A streptococcus), and psoriasis (see Chapter 48).

FIXED LESIONS

Macules, Papules, and Pustules

Milia are pinpoint white or yellow papules that are commonly present in 40-50% of neonates. Located predominantly on the face, they may also be seen in the oral cavity, where they are referred to as Epstein pearls (palate) or Bohn nodules (gingiva). The lesions represent keratin-filled epidermal inclusion cysts, which usually resolve spontaneously during the 1st few weeks of life. Unusually widespread or persistent lesions may be associated with defects such as hereditary trichodysplasia, oral–facial–digital syndrome, or particular subtypes of epidermolysis bullosa. Milia may be present in several genodermatoses, including Bazex–Christol–Dupre, Rombo, Brook–Spiegler syndromes, atrichia with papular lesions, and pachonychia congenita, type 2.

Sebaceous gland hyperplasia is characterized by the presence of multiple flesh- to yellow-colored tiny papules primarily on the nose and cheeks of full-term infants. The increased sebaceous cell size and number as well as sebaceous gland volume may result from maternal androgen stimulation. Spontaneous resolution occurs within the 1st 4-6 months of life.

Subcutaneous fat necrosis is a condition of otherwise healthy infants that is associated with preceding trauma, cesarean section, cold injury, or hypoxia. This disorder occurs primarily in healthy full-term and postmature infants. Single or multiple erythematous to violaceous, indurated, tender nodules or plaques arise on the buttocks, thighs, back, cheeks, and arms. In rare cases, lesions liquefy, ulcerate, and drain an oily substance (Fig. 47.6). The diagnosis can be confirmed by the histopathologic findings of fat lobules containing pathognomonic needle-shaped clefts surrounded by a mixed inflammatory infiltrate of lymphocytes, histiocytes, and foreign body giant cells. Intact lesions heal spontaneously within several months, whereas ulcerated lesions may heal more slowly and result in scarring. All patients should be screened for hypercalcemia, which may be present in nearly 70% of patients. Fortunately, hypercalcemia tends to be asymptomatic, without evidence of irritability, hypotonia, or weight loss, though life-threatening hypercalcemia may occur. The hypercalcemia may be delayed, with normal serum calcium early in the course of this disorder but elevated levels arising several weeks later.

(See *Nelson Textbook of Pediatrics,* p. 3116.)

TABLE 47.2	Diaper Dermatitis		
Disease	**Clinical Manifestation**	**Other Features**	**Treatment**
Friction	Inner surface of thighs, genitalia, buttocks, abdomen.	Course waxes and wanes. Aggravated by talc.	Responds well to diaper changes. Avoidance of diapers.
Irritant	Mild erythema with shiny surface and occasional papules. Confined to convex surfaces. Spares intertriginous areas.	Exacerbated by heat, moisture, and sweat retention.	Gentle cleansing. Regular diaper changes. Barrier creams (zinc oxide, Vaseline). Low-potency topical steroids can help.
Allergic contact	Typically confined to convex surfaces. Skin involved is in direct contact with offending agent. Mild cases: diffuse erythema, papules, vesicles, scaling. Severe cases: papules, plaques, psoriasiform lesions, ulcerations, infiltrative nodules.	Often related to topical antibiotics (neomycin, bacitracin). Certain emulsifiers in topical products. Preservatives in wet wipes can be an offender.	Remove offending agent. Judicious use of low-potency topical steroids. Barrier creams/ointments.
Seborrheic dermatitis	Salmon-colored patches. Often have yellow, greasy scale. Fissures, erosions, maceration, and weeping can be seen.	Axillae, ear creases, and neck are often involved. "Cradle cap" on scalp. Hypopigmentation often seen in patients with darker skin tones.	Low-potency topical steroids. If coexistent infection–antifungal or antibacterial agents.
Candidiasis	Usually involves intertriginous areas and convex surfaces. Bright-red papules and plaques. Satellite lesions on abdomen and thighs.	Oral thrush may be present. Often occurs after treatment with systemic antibiotics or local topical steroid use.	Topical anticandidal agent, including nystatin.
Intertrigo	Well-demarcated, macerated plaques with weeping. Gluteal cleft and fleshy folds of thighs.	May be associated with miliaria.	Avoiding excessive heat. Cool clothing.
Psoriasis	Bright red, scaly, well-demarcated plaques. Can persist for months. Less responsive to topical treatment.	Red, sometimes scaly. Can be present on extremities or trunk. Nail changes seen. Family history.	Low-potency topical steroids. Moisturizers.
Staphylococcal infection	Many thin-walled pustules with pink-red base. Collarette of scale after rupturing.		Antistaphylococcal therapy.
Acrodermatitis enteropathica (zinc deficiency)	Early lesions are vesicular and pustular. Become confluent, pink, dry, scaly, crusty plaques.	Perioral skin typically also involved. Irritability or listlessness. Failure to thrive, alopecia, diarrhea.	Secondary to zinc deficiency or inborn error of zinc transporter. Treat with zinc replacement.
Langerhans cell histiocytosis	May mimic candidiasis or seborrheic dermatitis. Persistent, does not improve with standard treatments. Clusters of infiltrative, crusted, hemorrhagic papules. Ulceration can be seen.	Involvement of groin, axillae, periauricular skin, hairline, and scalp. Anemia, thrombocytopenia, hepatosplenomegaly, and osseous lesions.	Chemotherapy.

Juvenile xanthogranulomas (JXGs) are rare, benign, solitary collections of non-Langerhans cell histiocytes, thought to be reactive in nature. They typically present during the neonatal and infantile period and usually resolve over subsequent months or years. Multiple lesions may exist and should raise suspicion for extracutaneous disease. The incidence of extracutaneous JXG is rare, and the eye is thought to be the most common site, occurring in 0.3-0.5% of patients. Multiple JXGs should trigger a thorough review of symptoms, as neurofibromatosis (NF)-1 is associated with multiple JXGs. Recommendations for ophthalmology examinations are somewhat controversial but should be considered in patients with multiple lesions and those younger than 2 years of age. A skin biopsy is diagnostic and shows collections of histiocytes and multinucleated giant cells called Touton giant cells.

A **mastocytoma** is a solitary skin-colored to light red or tan papule or plaque that is often located on the trunk, extremities, or neck. Some lesions may have a yellow or pink hue. The lesion may appear at birth or within the 1st few months of life. Histopathologic study reveals the dermis densely infiltrated with mast cells. The characteristic finding on physical examination is that stroking the lesion causes histamine release that results in tense edema within the lesion and an erythematous flare, known as the Darier sign. A skin biopsy and special stains for mast cells may confirm the clinical diagnosis. Symptoms such as pruritus or flushing, when present, are usually mild. Treatment is not usually necessary unless the patient has symptoms of excessive histamine release. The condition is self-limited and resolves spontaneously over several years. The lesions do not need to be excised.

FIGURE 47.6 Subcutaneous fat necrosis. Indurated, erythematous plaques on the shoulders and back of this 1-week-old boy. (From Paller AS, Mancini AJ. Cutaneous disorders of the newborn. In: Paller AS, Mancini AJ, eds. *Hurwitz Clinical Pediatric Dermatology*. 4th ed. Philadelphia: Elsevier; 2011:14.)

FIGURE 47.7 Urticaria pigmentosa.

Urticaria pigmentosa is characterized by the development of multiple mastocytomas, usually within the 1st 8-12 months of life (Fig. 47.7). The lesions may vary in size from a few millimeters to several centimeters. Some lesions may not become pigmented until the child is approximately 6 months of age or older. Therefore, early lesions of urticaria pigmentosa may resemble recurrent urticaria until pigmentation is noted. The Darier sign, or urtication of the lesions upon rubbing, is seen in urticaria pigmentosa as well. Rarely, these lesions may produce enough histamine release to cause flushing, diarrhea, vomiting, tachycardia, and hypotension. Parents should be counseled about the avoidance of mast cell–degranulating agents.

Antihistamines should be used in any patient who experiences prominent histamine effects. Patients should be monitored closely for any symptoms that suggest systemic mastocytosis. In rare cases, other organs may be involved, including the intestines, bone, liver, spleen, and bone marrow. Intestinal involvement may be manifested by chronic diarrhea. The liver and spleen should be palpated for hepatosplenomegaly, and the patient should be monitored for any symptoms of bone involvement. Routine bone marrow and hematologic examinations are not required. Systemic manifestations are more common

TABLE 47.3 Types of Vascular Tumors and Vascular Malformations

Vascular Tumors	Vascular Malformations
Hemangioma	Capillary malformation
Kaposiform hemangioendothelioma	Venous malformation
Tufted hemangioma	Lymphatic malformation
Non-involuting congenital hemangioma (NICH)	Arteriovenous malformation (AVM)
Rapidly-involuting congenital hemangioma (RICH)	Mixed

TABLE 47.4 Differentiation of Infantile Hemangiomas Versus Vascular Malformations

Infantile Hemangioma	Vascular Malformations
Up to 55% present at birth	90% recognized at birth
Rapid postnatal growth and slow involution	Static malformation of dysplastic vessels that grows proportionally with child
Rapid endothelial cell turnover	Normal endothelial cell turnover and proliferation
Increased incidence in girl-to-boy ratio (3:1–5:1)	Girl-to-boy incidence ratio 1:1

in adults; infants or children with significant systemic symptoms may require further evaluation. In most infants and young children, urticaria pigmentosa remits spontaneously by adulthood. Children who present at an older age tend to have a more persistent condition that is less likely to resolve.

Plaques and Patches
Pink (Vascular or Other)
Vascular birthmarks can be classified into 2 groups: tumors and malformations (Table 47.3). Infantile hemangiomas are the most common of the vascular tumors, and their behavior is characterized by a growth phase (endothelial proliferation), followed by a plateau or stabilization phase and then an involutional phase. Vascular malformations are usually apparent at birth and tend to be relatively stable developmental abnormalities of vessels, including any combination of capillaries, veins, arteries, and lymphatic vessels (Table 47.4).

Infantile hemangiomas are the most common benign tumors occurring in children. These lesions develop in approximately 4% of white infants by 1 year of age. Girls are affected approximately 3 times as often as boys. The incidence is higher in premature infants. Other risk factors for hemangiomas include low birthweight and multiple gestations. The natural course of infantile hemangiomas includes proliferative and involutional phases that end in complete, spontaneous regression in most cases.

There are 3 types of infantile hemangiomas:
1. Superficial hemangiomas, once referred to as strawberry marks, are the most common type (60%). They are bright red with well-demarcated borders (Fig. 47.8). Often, a pale pink stain or bruise-like patch is noted at birth before taking its more characteristic form.

FIGURE 47.8 A superficial hemangioma on the abdomen.

FIGURE 47.9 A mixed hemangioma with prominent deep component on the trunk.

2. Deep hemangiomas, previously known as cavernous hemangiomas, are the least common of the 3 types (15%). They typically have a blue-violaceous to skin-colored surface. These lesions involve the deep reticular dermis and subcutaneous tissue. These may not be noted until the infant is a few months old.

3. Mixed hemangiomas (25%) possess both superficial and deep components (Fig. 47.9).

Most infantile hemangiomas occur on the head and neck, but any area of the body may be involved. Infantile hemangiomas may be indistinguishable from port-wine stains in the early weeks of life. Lesions must be followed closely during the 1st few weeks after birth to determine whether a proliferative phase is present. Although the cause of infantile hemangiomas is not clear, their natural course has been well documented. The initial lesion may be a white macule with central threadlike telangiectases or a red macule resembling a port-wine stain. A peripheral zone of pallor representing vasoconstriction may be noted at this stage. Within the 1st few months of life, the macule becomes raised and enlarges. During the 1st 6 months of life, infantile hemangiomas proliferate at a rapid rate, and after 6 months, the lesions grow at a slower rate. Deep hemangiomas (and to a lesser extent mixed hemangiomas) have a slightly delayed onset of growth, but also have sustained growth when compared to superficial hemangiomas. Involution may begin as early as the 1st year of life and is heralded by a color change from bright cherry red to dull red-violet. Deep hemangiomas start to lose their blue-violet hue. In time, the central portion of the superficial hemangioma develops a grayish-white color that eventually extends to the periphery of the lesion. Lesions on the lips and nose, and deep hemangiomas usually involute more slowly. It is not possible to predict precisely how long an infantile hemangioma will take to involute. Statistically, 50% of lesions are gone by 5 years of age, 70% by 7 years, and more than 90% by 9 years. Once resolved, residual skin changes such as hypopigmentation, atrophy, and telangiectases may be present in up to 10-20% of affected patients. If infantile hemangiomas have grown rapidly during their proliferative phase or were very exophytic, residual fibrofatty tissue may also be seen.

Infantile hemangiomas have many potential complications and associations (Table 47.5). For most, no treatment is needed. Management of infantile hemangiomas is based on a variety of factors. These include the size of the lesion, location of the lesion, age of the patient, rate of growth/involution at the time of presentation, and risk or presence of complications. Steroids used to be the mainstay of treatment, but now β blockers, such as oral propranolol or topical timolol 0.5% solution, are used more frequently, with much improved results. Systematic reviews have shown a response rate in nearly 97% of cases with better efficacy and less toxicity of propranolol compared to steroids. The most common adverse events are sleep changes and cool extremities, but more serious concerns are hypotension, bradycardia, hypoglycemia, and hypoglycemic seizures, though these are rare.

Lesions that may need to be treated include those on the midface, labial, periorbital, genital, or diaper area. These lesions warrant close clinical observation during the rapid growth phase of early infancy. Additional therapeutic modalities that are more rarely used include intralesional steroids, pulsed dye laser therapy, surgery, embolization, and sclerosing agents.

Location of infantile hemangiomas (segmental on face or beard distribution) as well as on the spine and lower back should raise concern for PHACE syndrome or PELVIS/SACRAL syndrome, respectively.

Posterior fossa malformations, hemangiomas, arterial anomalies, cardiac defects, and eye abnormalities (PHACE) syndrome is a rare syndrome that affects a subgroup of infants with infantile hemangiomas. It is likely the most common vascular neurocutaneous disorder. The cutaneous findings tend to be larger hemangiomas (>5 cm) and also tend to be segmental, rather than arising from 1 point. These hemangiomas can be more confluent, have a telangiectatic appearance, or be composed of grouped papules. They are nearly always located on the head or face. It is important to distinguish them from capillary malformations. Approximately 20% of all infants with segmental facial hemangiomas have extracutaneous anomalies.

Criteria for PHACE syndrome include 1 facial hemangioma (>5 cm in diameter) *plus* 1 major criterion or 2 minor criteria. Major and minor criteria involve a group of cerebrovascular, structural brain, cardiovascular, ocular and ventral/midline defects.

TABLE 47.5 Complications and Syndromes of Infantile Hemangiomas

Location	Complication
Lips/perineal/lumbosacral area	Seen in rapidly growing lesions, especially of oral mucosa and genital area Risk for infection, scarring, hemorrhage; can be very painful
High output, extensive lesions	Congestive heart failure; hypothyroidism Extensive lesions with a large vascular supply may compromise cardiac function
"Beard" distribution	Symptomatic subglottic hemangiomas may occur in 50–60% of patients with extensive "beard" involvement Refer for laryngoscopy to evaluate risk for respiratory or airway compromise Often manifests within 1st 2–3 mo of life
Periorbital distribution	Associated ocular complications in up to 80% of patients Screening by an ophthalmologist to rule out astigmatism or amblyopia
Ear lesions	Location can cause the obstruction of auditory canal or decreased auditory conduction Monitor for otitis media or speech delay
Lumbosacral hemangiomas	High risk for spinal dysraphism; imaging of all midline lumbosacral hemangiomas should be considered Increased risk with other lumbosacral abnormalities (e.g., hypertrichosis, dimple, tags) Associated urogenital/anogenital anomalies may be present
Large, extensive cervicofacial hemangiomas	PHACE syndrome
Benign neonatal hemangiomatosis	Multiple cutaneous hemangiomas without evidence of visceral hemangiomatosis History taking/physical examination should be performed thoroughly to rule out systemic involvement Consider liver ultrasound for infants with ≥5 cutaneous hemangiomas Benign clinical course with involution of hemangiomas within 1st year
Disseminated neonatal hemangiomatosis	Multiple cutaneous hemangiomas with evidence of visceral hemangiomatosis Liver most commonly affected; can affect lungs, gastrointestinal tract, eyes, mouth, and tongue Work-up necessary to determine the extent of systemic involvement; aggressive treatment usually needed

PHACE, posterior fossa malformations, hemangiomas, arterial anomalies, cardiac defects, and eye abnormalities.

Cerebral vascular anomalies are the most common extracutaneous manifestation. The changes tend to be arterial, unlike Sturge–Weber syndrome, which involves capillaries. Imaging (magnetic resonance imaging [MRI]/magnetic resonance angiography [MRA] of head and neck) greatly aids in the work-up of a patient with a segmental hemangioma on the face/head, looking for arterial changes, as a subset of patients are at increased risk for vasculopathy and ischemic stroke.

Many congenital brain abnormalities have been noted in patients with PHACE syndrome: The most common ones are malformations of the posterior fossa and cerebellum. Most patients with congenital lesions will have normal neurologic examinations during infancy, thus screening should not be based on abnormalities with the neurologic examination.

Cardiovascular anomalies may be seen on echocardiogram in up to 40% of patients and include coarctation of the aorta (most common), aberrant subclavian aneurysm, ventricular septal defect, and arterial aneurysms. Ocular abnormalities are somewhat rare in PHACE syndrome, but include microphthalmia, optic nerve hypoplasia, persistent fetal vasculature, and morning glory disc anomalies. Midline defects include sternal cleft, supraumbilical abdominal raphe, and subtle changes such as sternal pits, dimples, or papules can be seen.

PELVIS, LUMBAR, and SACRAL syndrome are all different acronyms to describe disorders that include a segmental hemangioma of the perineal area or midline lower back with underlying abnormalities. The acronyms PELVIS (perineal hemangioma, external genitalia malformations, lipomyelomeningocele, vesicorenal abnormalities, imperforate anus, and skin tag) and SACRAL (spinal dysraphism, anogenital anomalies, cutaneous anomalies, renal and urologic anomalies, associated with angioma of lumbosacral localization) have been used to describe associations with occult spinal dysraphism. The risk of a spinal anomaly was 35% with a solitary lumbosacral hemangioma. MRI is more sensitive than ultrasound in evaluating for underlying spinal abnormalities in lumbosacral lesions, such as tethered cord. There seems to be less of a connection with isolated perineal hemangiomas, however.

Capillary malformations (also known as port-wine stains or nevus flammeus) occur in 0.3% of all newborns. They are present at birth and represent progressive ectasia of the superficial vascular plexus. These lesions do not undergo spontaneous resolution. They are usually unilateral and segmental but can be bilateral (Fig. 47.10). The face and neck are the most commonly affected sites. Capillary malformations are typically pink to red during infancy and darken to reddish-purple hues with advancing age. Affected adults frequently have thickened, nodular port-wine stains that may be associated with soft tissue hypertrophy. Capillary malformations occur as isolated cutaneous lesions or in conjunction with other abnormalities.

Sturge–Weber syndrome includes ipsilateral association of a facial capillary malformation, almost always involving the V1 distribution of the trigeminal nerve, eye abnormalities (primarily glaucoma), and vascular malformations of the ipsilateral leptomeninges and brain. The incidence of Sturge–Weber syndrome is approximately 5-10% in infants with a capillary malformation of the V1 distribution of the trigeminal nerve. Consequences of Sturge–Weber syndrome may include seizures, developmental delay, hemiplegia, and glaucoma. Neuroimaging may be helpful in demonstrating the characteristic calcifications of the leptomeninges and the abnormal cerebral cortex, although these changes may be quite subtle with early studies. Newborns at risk for Sturge–Weber syndrome should have careful clinical follow-ups, including monitoring eye pressure for glaucoma.

Other syndromes associated with capillary malformations include Klippel–Trenaunay syndrome and Parkes–Weber syndrome. **Klippel–Trenaunay syndrome** is characterized by a capillary malformation, venous and/or lymphatic malformation, and soft tissue and/or bone overgrowth of the affected limb. **Parkes–Weber syndrome** is the

(See *Nelson Textbook of Pediatrics,* p. 2879.)

FIGURE 47.10 Capillary malformation of the back and flank, extending down the right arm.

association of arteriovenous malformations, limb overgrowth, and the variable presence of lymphedema and multiple arteriovenous shunts. Klippel–Trenaunay syndrome is a slow-flow capillary-venous malformation, whereas Parkes–Weber syndrome is a fast-flow arterial-venous malformation. Both entities can result in overgrowth and hypertrophy of the affected limb; however, Parkes–Weber syndrome usually results in increased morbidity and clinical consequences.

Treatment of a capillary malformation is best accomplished with the pulsed dye laser. Several treatments are generally required over months to years to achieve desired fading. Depending on the location of the capillary malformation, the response to the pulsed dye laser may be limited. Many experts believe that early initiation of pulsed dye laser therapy results in superior cosmetic results.

Nevus simplex (salmon patch) is the most common vascular lesion in infancy. These lesions consist of ectatic capillaries and are present at birth in about 40% of infants. These pink to red macules can be located on the nape of the neck, glabella, forehead, upper eyelids, and nasolabial regions. More atypical locations include the lateral forehead, nose, upper and lower lip, and back. Unusually persistent or prominent nevus simplex can be associated with Beckwith–Wiedemann syndrome, Nova syndrome, nevus simplex with odontodysplasia, macrocephaly–capillary malformation syndrome, and Roberts-SC syndrome.

No treatment is necessary because most of these fade by 1-2 years of age. Persistent lesions can be treated successfully with the pulsed dye laser if cosmetically disturbing.

Cutis marmorata telangiectasia congenita (CMTC) manifests as an erythematous to dark, bluish-purple, reticulated vascular patch that does not resolve with physiologic warming. This disorder is characteristically more segmental and asymmetric than physiologic cutis marmorata. The clinical findings are most often noted within the 1st few days of life. Associated features may include cutaneous atrophy and ulcerations of the skin. CMTC has also been reported to be associated with additional abnormalities, including body asymmetry (hypotrophy or hypertrophy of affected limb), other vascular malformations, psychomotor or mental retardation, and glaucoma

(with lesions in the V1/V2 trigeminal nerve distribution). CMTC may be difficult to differentiate from a reticulated capillary malformation. The clinical course of CMTC is characterized by gradual fading within the 1st 1-2 years of life, and treatment is generally not required.

Kasabach–Merritt phenomenon is the presence of thrombocytopenia, hemolytic anemia, hypofibrinogenemia, and consumptive coagulopathy in association with a vascular tumor. Kasabach–Merritt phenomenon is associated with distinct vascular lesions: namely, kaposiform hemangioendothelioma (KHE) or tufted angioma, but not infantile hemangiomas. KHE and tufted angiomas are rare vascular tumors thought to exist on a spectrum. Clinical examination findings, histologic findings, and the behavior of associated vascular tumors differ from those of conventional infantile hemangiomas. These lesions are often firm and violaceous with a shiny texture and may proliferate for several years. This condition can be life-threatening and may warrant aggressive multimodal therapeutic modalities. Treatment of choice is complete excision, if possible, but may not be feasible given location, size, or tissue infiltration. Vincristine has been considered the 1st-line agent of choice, but complete resolution is rare and is limited by neurotoxicity. Other treatments include sirolimus, high-dose systemic corticosteroids, compression therapy, embolization, irradiation, low-molecular-weight heparin, and interferon-alfa. Unlike infantile hemangiomas, KHE and tufted hemangiomas are not as responsive to propranolol.

Venous and lymphatic malformations are slow-flow vascular malformations that are often present at birth. **Venous malformations** are bluish, poorly demarcated, compressible masses. The characteristic bluish hue is caused by the presence of ectatic venous channels in the dermis. Often there may be associated swelling with changes in position or activity. Venous malformations can be segmental or more generalized, and radiologic imaging may assist in determining the extent of the lesion. Evaluation for central nervous system abnormalities with cranial imaging is recommended for patients with venous malformations of the face, to rule out developmental intracranial venous abnormalities that usually are asymptomatic. Many lesions manifest with pain caused by muscle involvement or with episodes of thrombosis or hematoma. Other associated risks include bone abnormalities (thinning, demineralization, or hypoplasia) and chronic localized intravascular coagulation. Treatment is aimed at correcting disfigurement and functional impairments. Therapy can include sclerotherapy, deep laser surgery, compression, and surgical excision. In many cases, it may be best to not intervene and to treat symptomatically.

Lymphatic malformations, previously referred to as lymphangiomas, are usually skin-colored masses that may have superficial clear or hemorrhagic vesicles that occasionally leak lymphatic fluid. These lesions can be classified as macrocystic, microcystic, or mixed. Macrocystic malformations often occur on the head and neck and are frequently diagnosed by prenatal ultrasonography. When such a large lymphatic malformation occurs on the head and neck region, it is often referred to as cystic hygroma. Microcystic malformations are usually more superficial lesions with a "frog spawn" appearance (hemorrhagic and clear vesicles) that intermittently leak lymphatic fluid. This characteristic lesion was previously referred to as lymphangioma circumscriptum. These lesions usually become more evident in childhood rather than infancy. Large lymphatic malformations may impinge on vital structures and cause severe compromise in the neonatal period. Cellulitis is a potential complication of lymphatic malformations and may require prophylactic antibiotics if recurrent. Treatment includes sclerotherapy and surgery in select lesions, though surgical therapy of these lesions is often difficult and may result in recurrences and complications.

TABLE 47.6	Congenital and Acquired Disorders of Hyperpigmentation	
Disorder	**Congenital or Acquired**	**Clinical Features**
Freckles (ephelides)	Acquired	Small tan to brown, 1- to 5-mm macules. Increase in number and pigmentation in summer and spring due to sunlight. Seen in fair-skinned individuals in sun-exposed areas.
Lentigines	Acquired	Uniform, dark, brown/black 2- to 5-mm macules. No seasonal variation or change with sun exposure. Can be anywhere on the body, including mucous membranes.
Café-au-lait spots	Congenital or acquired	May be seen at birth or later in life. Tan to brown discrete macules or patches. Round or oval. 6 or more lesions >5 mm in prepubertal persons meets diagnostic criteria for neurofibromatosis (NF). NF lesions are smooth and well demarcated McCune–Albright syndrome spots are larger and more jagged.
Dermal melanocytosis (Mongolian spot)	Congenital	Brown, blue-gray patches often seen on lower trunk. Seen usually in African-Americans, Asians, or Native Americans. Usually fades over time.
Nevus of Ota	Congenital or acquired	50% present at birth; 50% develop in 2nd decade. Unilateral, blue-gray pigmentation in trigeminal nerve distribution. Commonly involves ipsilateral sclera. May darken or enlarge over time.
Nevus of Ito	Congenital or acquired	Patchy blue-gray pigmentation of shoulder, supraclavicular area. May increase in size and color over time.
Congenital melanocytic nevus	Congenital	Tan, brown, dark brown macules, patches, plaques, seen at birth or early infancy. Variable color and texture. Large, giant, or multiple nevi increase risk for neurocutaneous melanosis.
Nevus spilus (speckled lentiginous nevus)	Congenital or acquired	Well-demarcated, hyperpigmented patch with smaller, darker macules and papules within larger patch. May be extensive and segmental in distribution. Small risk for malignant transformation.
Acquired melanocytic nevi	Acquired	May start as hyperpigmented macules (junctional melanocytic nevi). Over time, can become elevated papules (compound melanocytic nevi). Peaks in number during 2nd and 3rd decade of life. Abnormalities in color, borders, size, symmetry may suggest malignancy.
Melanoma	Acquired	Variegation in color, texture, or border of congenital or acquired melanocytic nevi. Rare in childhood or infancy. Risk correlated with family history and sun exposure in childhood.

Hyperpigmented or Darker Pigmented Lesions

Several hyperpigmented or darker pigmented lesions can be seen during the neonatal period and infancy, while others can present later in childhood (Table 47.6).

Congenital melanocytic nevi are pigmented macules, papules, patches, or plaques that are present at birth or early infancy in approximately 2-3% of children. The lesions are often tan at birth and become darker and hairier during infancy and childhood. Congenital nevi can be divided into small (<1.5 cm), medium (1.5-20 cm), large (20-40 cm), and giant (>40 cm) lesions on the basis of their final adult size. In neonates and infants, lesions larger than 9 cm on the head and larger than 6 cm on the body constitute giant congenital melanocytic nevi (Fig. 47.11). Most congenital melanocytic nevi are small to medium in size. The incidence of giant melanocytic nevi is approximately 1/20,000 live births.

The malignant potential of congenital melanocytic nevi remains an area of great controversy. The risk for malignant transformation in the general population for small and medium congenital nevi is thought to be less than 1%, and there are no universal guidelines for their

management. For comparison, the overall risk for melanoma in the general population in the United States is 2%. Removal of these nevi can wait until later childhood, when local anesthesia and outpatient surgery are feasible.

The risk for malignant transformation of giant congenital melanocytic nevi is another controversial issue. The incidence of melanoma is approximately 2%. These large lesions warrant close observation and serial photography. Careful annual or semiannual examinations with palpation of the nevi are essential, as melanoma can arise from deep portions of the nevi with little or no apparent surface alterations. Removal of giant congenital nevi is also controversial from a future-melanoma risk standpoint. Removal may require extensive grafting as well as soft tissue expansion procedures.

Neurocutaneous melanosis is defined as the presence of giant (>40 cm) and/or multiple congenital melanocytic nevi, in association with benign or malignant melanocytic infiltration of the leptomeninges. Clinically symptomatic neurocutaneous melanosis substantially worsens the prognosis of large or giant congenital melanocytic nevi and usually presents around or before 2 years of age, but some may

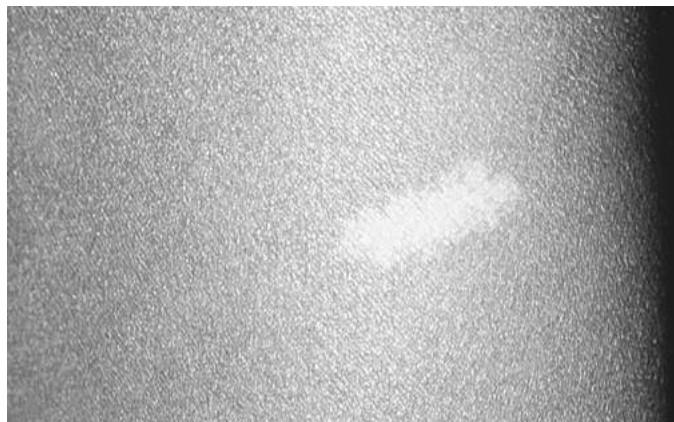
FIGURE 47.11 Giant congenital melanocytic nevus of the lower back. Imaging should be considered to evaluate for tethered cord or spinal dysraphism, as well as melanosis of the spine or brain.

FIGURE 47.12 Ash leaf macule of tuberous sclerosis.

not show symptoms until the 2nd or 3rd decade of life. Most symptomatic patients die within 3 years of the onset of initial neurologic symptoms, typically from central nervous system melanoma or mechanical obstruction. The most frequent clinical manifestations include hydrocephalus, seizures, papilledema, headaches, increase in head circumference, paresis, and developmental delay. Location overlying the axial skeleton and many satellite lesions are predictors of neurocutaneous melanosis.

MRI with contrast of the head *and* spine is suggested in newborns with giant congenital melanocytic nevi, particularly in the posterior axial distribution and especially if satellite nevi are present. MRI abnormalities of the brain have been identified in asymptomatic patients with giant or multiple congenital melanocytic nevi. The most common imaging abnormalities in asymptomatic patients seen were T1 shortening in the cerebellum, temporal lobes, pons, and medulla. Radiologic findings can be very subtle and may be missed by radiologists unfamiliar with this entity. Controversy exists with regard to the need for baseline and follow-up imaging in asymptomatic patients, inasmuch as the implications of these studies are unclear.

Café-au-lait macules are well-circumscribed tan macules that usually measure less than 0.5 cm but may be as large as 15-20 cm in diameter. The lesions are found on any cutaneous site and may be present at birth or appear during early childhood. Although café–au-lait spots are seen in 10-20% of normal individuals, the presence of many macules should raise the clinical suspicion of NF or other genetic disorders (Table 47.6). The presence of 6 or more café-au-lait spots (>0.5 cm in prepubertal children; >1.5 cm in postpubertal children) fulfills 1 of the diagnostic criteria for NF-1. Although the lesions are not pathognomonic, they are present in most patients with NF and tend to be larger and more numerous. Café–au-lait spots have also been associated with tuberous sclerosis, McCune–Albright syndrome, Turner syndrome, Bloom syndrome, ataxia-telangiectasia, Russell–Silver syndrome, Fanconi anemia, epidermal nevus syndrome, Gaucher disease, and Chédiak–Higashi syndrome.

Dermal melanocytosis, also known as **Mongolian spots**, are large, poorly demarcated, slate-gray to blue-black patches usually located over the buttocks or lumbosacral region of normal infants. The condition occurs in approximately 80-90% of black infants, 75% of Asian infants, and 10% of white infants. Mongolian spots may be single or multiple and frequently measure up to 10-20 cm in diameter. This


benign disorder is present at birth, usually fades during early childhood, and necessitates no therapeutic intervention. In rare cases, the lesions may persist into adulthood and may benefit from therapy with lasers that treat dermal pigmentation. These lesions should not be confused with bruises.

The **nevus of Ota** and **nevus of Ito** are special variants of dermal melanocytosis seen most commonly in Asian and black individuals. In contrast to Mongolian spots, these conditions tend to persist throughout adulthood. The nevus of Ota is a slate-gray to blue-black patch located in the distribution of the trigeminal nerve. The condition is usually unilateral and involves the forehead, temple, periorbital region, nose, and cheek. Pigmentation of the sclera occurs in about 50% of affected individuals. The disorder may be cosmetically disfiguring, and laser treatment may be promising in some cases. The nevus of Ito is a similar lesion occurring in the distribution of the lateral supraclavicular and brachial nerves. The condition is usually unilateral and involves the shoulder, neck, upper arm, scapular, and/or deltoid regions. It may be seen alone or in conjunction with the nevus of Ota.

Hypopigmented and Depigmented Lesions

These conditions are often cosmetically disfiguring and persistent. They can be markers of serious systemic diseases. Pigmentary disorders may be localized or generalized; congenital or acquired; and transient, stable, or progressive (Table 47.7).

Nevus depigmentosus is a benign, solitary, hypopigmented macule or patch that is noted at birth. It is not depigmented as the name suggests. It typically remains stable in size and may grow in proportion to the patient as they grow. It should be differentiated from vitiligo.

Ash leaf spots are hypopigmented macules, sometimes present at birth or within the 1st few months or years of life, that allow early identification of individuals with tuberous sclerosis (Fig. 47.12). Although occasionally observed in normal infants, the characteristic lesions are present in up to 90% of patients with tuberous sclerosis. They are usually 2-3 cm in size and are located on the trunk and extremities. The macules may be lancet-shaped or may have a confetti-like or irregularly shaped appearance. *Wood lamp examination may facilitate identification*. Although tuberous sclerosis is an autosomal dominant disorder, spontaneous mutations are responsible for up to 50% of new cases. Other cutaneous findings include facial angiofibromas (adenoma sebaceum), periungual or subungual fibromas, gingival fibromas, shagreen patches (connective tissue hamartomas), and fibrous plaques (typically on the forehead). Systemic manifestations include seizures, intellectual disability, cardiac rhabdomyomas, renal angiomyolipomas and cysts, retinal nodular hamartomas, and pulmonary cysts. Imaging studies of the brain may demonstrate cortical

TABLE 47.7	**Congenital and Acquired Disorders of Hypopigmentation and Depigmentation**	
Disorder	**Congenital or Acquired**	**Clinical Features**
Piebaldism	Congenital	Autosomal dominant inheritance. Leukoderma of frontal scalp. White forelock. Usually involves face, neck, trunk, flank, and extremities. Waardenburg syndrome is a variant, with sensorineural deafness, limb defects, and Hirschsprung disease.
Nevus depigmentosus	Congenital	Well-circumscribed hypopigmented patch (not typically depigmented). May be isolated or segmental. Usually present at birth or infancy. Wood lamp may aid in diagnosis. Often found on trunk or extremities.
Hypomelanosis of Ito	Congenital	Whorls or streaks of hypopigmentation that follow lines of Blaschko. Usually present at birth, but may present in 1st few years of life. Can be associated with CNS, eye, or musculoskeletal abnormalities.
Nevus anemicus	Congenital	Rubbing or temperature change causes erythema of surrounding skin. Often unilateral and on trunk. Not accentuated by Wood lamp. Asymptomatic.
Ash leaf spot	Congenital	Hypopigmented macules/patches often present at birth. Wood lamp may aid in diagnosis. Solitary lesion often of no significance. Multiple lesions are associated with tuberous sclerosis.
Vitiligo	Acquired	Complete loss of pigment in involved areas. May be segmental in distribution. Hyperpigmentation can be seen at the edges of lesions. Infrequently seen with autoimmune disorders, such as hypothyroidism.
Albinism	Congenital	Complete depigmentation or hypopigmentation in skin. Affects eyes and hair. Increased risk for skin cancer.

tubers or subependymal nodules, which are pathognomonic for tuberous sclerosis.

Piebaldism is characterized by circumscribed areas of depigmentation in the newborn. The leukoderma is usually located on the frontal scalp and is associated with a white forelock; however, the depigmented patches characteristically involve the trunk, upper arms, and legs. Hyperpigmented or normally pigmented macules or patches may occur within the depigmented patches. This rare condition is transmitted in an autosomal dominant pattern. The disorder is usually present at birth but may not be recognized until later because of the light color of neonatal skin. A Wood lamp may enhance the contrast between depigmented and normal skin.

Piebaldism is a stable condition throughout life, and most affected individuals are otherwise normal. Sun protection and cosmetic camouflage of the depigmented skin are the mainstays of therapy.

Waardenburg syndrome is a rare genetic disorder characterized by a white forelock, areas of leukoderma, congenital sensorineural deafness, heterochromia of the irides, and lateral displacement of the medial canthi. Other features may include a flattened nasal bridge, confluent eyebrows, hypoplasia of the nasal alae, speech impairment that may or may not be related to presence of a cleft lip or palate, and various skeletal abnormalities. It is most commonly inherited in an autosomal dominant fashion, though autosomal recessive inheritance patterns are sometimes seen.

Albinism is manifested by diffuse congenital hypopigmentation or depigmentation of the skin, hair, and eyes. This heterogeneous group of disorders is composed of approximately 10 types of oculocutaneous albinism and 5 forms of ocular albinism. Most types of oculocutaneous albinism are inherited in an autosomal recessive pattern. The variants of ocular albinism are transmitted in an X-linked or autosomal recessive mode of inheritance.

The various forms of albinism can usually be diagnosed by findings on physical examination. These features include absent or reduced pigmentation of skin and hair and ophthalmologic findings such as foveal hypoplasia, nystagmus, photophobia, transillumination of the irides, fundal depigmentation, and decreased visual acuity. Patients should be monitored closely by ophthalmologists and evaluated for hearing loss. In white persons, the skin is usually milk white and the hair is white, blond, or light brown. The pupils are usually pink, and the irides are blue or gray. In African-Americans, the skin may appear tan or white and is frequently freckled. The hair is usually blond or red, and the eyes are blue or hazel.

Treatment of albinism includes photoprotection and sun avoidance. Individuals are predisposed to severe actinic damage and should be monitored closely for the development of actinic keratoses, basal cell carcinomas, squamous cell carcinomas, and melanomas.

Other

Nevus sebaceus of Jadassohn is a hamartoma of sebaceous gland derivation. Typically present at birth, these lesions are variable in size, usually solitary, and located on the scalp, face, and neck. During infancy, they are well-circumscribed, hairless, yellowish-orange, smooth, velvety, or waxy plaques. These nevi tend to thicken and become verrucous during puberty.

Because up to 15% of these lesions develop secondary benign or malignant neoplasms during adolescence or adulthood, prophylactic surgical excision is recommended before puberty.

Dermoid cysts are nontender, noncompressible, firm, congenital subcutaneous nodules found along sites of closure of embryonic clefts. Dermoids are lined by stratified squamous epithelium that contains mature adnexal structures. Although these lesions can be noted in newborns, they may not be detected until later in infancy or in childhood after the lesion enlarges or becomes inflamed. Lesions are often described as rubbery and may be blue to skin-colored in appearance. A tuft of hair may be seen protruding from an orifice in the dermoid. Dermoid cysts are often found in the head and neck region, often the lateral portion of an eyebrow.

The most important concern with dermoid cysts is the potential for an intracranial connection. Up to 25% of midline or nasal dermoid cysts may have an intracranial connection; all midline head and spinal lesions should be imaged. If a connection is present, the patient is at risk for infection because the dermoid cyst and sinus can serve as a portal of entry for bacteria. These patients should be referred to neurosurgery for removal and repair. Dermoid cysts that are not midline, including those commonly seen at the lateral brow area, should also be excised because of the potential risk for infection and bony erosion. After surgical excision, lesions do not usually recur.

Aplasia cutis congenita is a heterogeneous group of disorders in which there is a congenital absence of skin (Fig. 47.13). This disorder may involve the epidermis, dermis, and subcutaneous tissues. The most common type of aplasia cutis is membranous aplasia cutis. These lesions are well-demarcated, small, oval, 1- to 5-cm defects on the vertex of the scalp. They are easily identified by their classic "punched-out" appearance and may have an atrophic surface with a glistening, membrane-like surface at birth. In older children, these lesions resemble scars. If the lesion is associated with a hair collar or midline in location, the clinician should evaluate for the potential of cranial dysraphism.

The defect is usually solitary; however, in a minority of patients, multiple sites may be affected. Aplasia cutis can also occur on the trunk and limbs, where the defects are often bilateral and symmetric. Aplasia cutis in the midline lumbosacral area is of particular importance because it may be associated with spinal dysraphism.

Lesions of membranous aplasia cutis usually necessitate no further investigation, and gradual epithelialization typically occurs spontaneously. However, large, deep, or widespread lesions with underlying bone defects may necessitate surgical intervention to facilitate healing.

The term **hair collar sign** is a designation for hypertrichosis that usually either partly or completely encircles a congenital scalp lesion (Fig. 47.14). Usually the ring of hair is denser, darker, and coarser in texture than the normal scalp hair. A hair collar sign surrounding a congenital scalp nodule is a marker for cranial dysraphism, including encephaloceles and meningoceles. If a hair collar sign is seen in combination with a capillary malformation or aplasia cutis, the risk for cranial dysraphism is increased substantially. Therefore, all congenital midline lesions with a hair collar sign should be imaged to evaluate for an intracranial connection. MRI is the gold standard, but it occasionally misses a small intracranial connection.

Lumbosacral hypertrichosis may be a normal variant, especially in certain ethnic groups. However, hypertrichosis in this area in association with other stigmata indicative of a neurologic defect is highly suggestive of spinal dysraphism. The area may be poorly circumscribed, and the hair can be light or dark. The hypertrichosis is often present at birth. Complete neurologic examination should be performed. There are no defined parameters to determine further evaluation of isolated hypertrichosis, though suspicion for spinal dysraphism is higher if additional cutaneous markers, such as a vascular stain or a mass, are also present. If a spinal defect is suspected, further evaluation by MRI of the spine is necessary.

Lumbosacral dimples are common findings in neonates. Large, deep dimples that are located in the superior portion of the gluteal crease should be radiologically imaged to rule out dermal sinuses communicating directly with the spinal canal. These dimples should not be probed because of the potential communication with the spinal canal. Sacral dimples seen in association with other cutaneous findings such as hypertrichosis, vascular birthmarks, a mass, or deviated gluteal cleft carry particularly high risk for spinal dysraphism. Imaging should be performed with MRI of the spine as ultrasound has low sensitivity for subtle findings.

Infantile hemangiomas that overlie the midline of the back are strong markers for spinal dysraphism, most often lipomyelomeningocele, intraspinal lipoma, or a tethered cord. Infantile hemangiomas that are larger than 4 cm and overlap the midline appear to carry greater risk for spinal dysraphism, and MRI should be performed. The risk for spinal dysraphism is increased when hemangioma is seen in

FIGURE 47.13 Congenital absence of skin (aplasia cutis congenita) on the scalp of a neonate. As seen here, multiple lesions can be seen.

FIGURE 47.14 A classic hair collar sign (from aplasia cutis).

association with other cutaneous findings such as sacral dimples, hypertrichosis, or a deviated gluteal cleft.

A solitary midline capillary malformation of the back without additional clinical findings may be a marker for spinal dysraphism, but this association is less clear. All affected infants should be evaluated for additional neurocutaneous stigmata. If a lumbosacral capillary malformation is detected with other cutaneous markers of spinal dysraphism, imaging is warranted.

TRANSIENT AND PHYSIOLOGIC CHANGES TO THE SKIN

Many entities unique to newborns are caused by physiologic phenomena in response to the infant's transition to the new environment. Most such entities are benign and self-limited.

Cutis Marmorata

Cutis marmorata is characterized by symmetric reticulated cyanosis involving the trunk and extremities. This marbled appearance usually appears when the skin is cool and resolves upon rewarming of the infant. This benign condition typically improves with age. When this vascular pattern is seen in older infants or children, it may be associated with Down syndrome, Cornelia de Lange syndrome, or hypothyroidism.

Cutis marmorata should be differentiated from Cutis marmorata telangiectasia congenita (CMTC). The persistent cutis marmorata of CMTC is characteristically asymmetric, often segmental, mottled, or marble-like, and more localized than physiologic cutis marmorata. In addition, the reticulated mottling of CMTC is darker in color and does not resolve with rewarming. Although CMTC improves with age, the abnormal vascular pattern is more persistent than that seen in physiologic cutis marmorata. It may be an isolated entity or may have distinct associations, including atrophy or hypertrophy of the affected extremity, ulcerations, or coexistent vascular malformations and tumors, and other extracutaneous anomalies.

Harlequin Color Change

The harlequin color change is a distinctive condition observed in infants lying on their sides. It is characterized by marked erythema on the dependent side of the infant's body with simultaneous blanching of the nondependent side. This phenomenon occurs more often in premature infants but may be observed in full-term newborns. The change may be caused by autonomic immaturity, which results in altered peripheral vascular tone.

Although it typically occurs within the 1st 3 weeks of life, harlequin color change is most often noted at 2-5 days of age. The changes develop abruptly and usually resolve within 20 minutes.

Acrocyanosis

The normal newborn usually displays a bluish-purple discoloration of the hands, feet, and lips. Referred to as acrocyanosis, this typically occurs in association with crying or cold stress and can be seen in greater than 30% of infants. It results from increased peripheral arteriolar tone, which leads to vasospasm and subsequent venous pooling. Acrocyanosis should be differentiated from central cyanosis, which is noted on mucosal surfaces. Physiologic acrocyanosis gradually resolves spontaneously during the neonatal period.

■ SUMMARY AND RED FLAGS

Neonates and infants can have a variety of congenital birthmarks and transient rashes. It is necessary to identify the primary skin lesion, any secondary skin lesions or changes, and the size, color, distribution, and configurations of the lesions to develop an appropriate differential diagnosis. Many entities unique to neonates are benign and self-limited, and often require only reassurance to the parents.

Red flags are lesions consistent with HSV, *S. aureus*, or LCH (Table 47.2), or those consistent with neurocutaneous diseases, such as ash leaf spots, or a capillary malformation in V1 distribution (Table 47.1). The location of infantile hemangiomas in a beard distribution, or on the spine and lower back should raise concern for PHACE syndrome or PELVIS/SACRAL syndrome (Table 47.5). Lesions found on the midline of the back or head such as hemangiomas or hair collar sign can be associated with spinal dysraphism (Table 47.1 and Fig. 47.14).

Acquired Rashes in the Older Child

Kristen E. Holland and Paula J. Soung

Many skin findings in childhood are benign and self-limited conditions. Other dermatologic complaints may be the 1st manifestation of a systemic disease or associated condition, recognition of which facilitates appropriate evaluation and treatment.

HISTORY, PHYSICAL EXAMINATION, AND DIAGNOSTIC PROCEDURES

◆ History

Obtaining a careful and focused history is necessary to establish diagnoses of pediatric skin disorders. It may be helpful to examine the patient first and then proceed with a relevant line of questioning. Important questions to ask include the following:
1. When did the eruption begin?
2. How did the eruption evolve (distribution, spread, change in the structure of individual lesions)?
3. Are the lesions pruritic or painful?
4. Have there been previous similar episodes?
5. Are there associated systemic symptoms?
6. Are there exacerbating or alleviating factors?
7. Has treatment been rendered? If so, what effect has it had?
8. Are there affected family members or close contacts?
9. Is there a family history of skin disease?

◆ Physical Examination

It is necessary to identify the primary skin lesions, secondary skin lesions, or changes, size, color, distribution, and configuration of the lesions. Several specific signs are pathognomonic for certain diseases. Examination of the hair, nails, and mucosal surfaces should be included. Palpation of cutaneous lesions provides additional information, such as firmness, tenderness, mobility, temperature, and ability to blanch with pressure. Precise morphologic descriptions are critical for establishing a differential diagnosis (Figs. 48.1 and 48.2).

Primary Lesions

Macules and Patches. Macules are flat, circumscribed lesions that are detected because of a change in color. Pink or red macules may be caused by inflammation or vasodilatation. Brown, black, or white lesions may be caused by alterations in melanin synthesis. Purple hues may represent extravasation of blood into the skin. Macules greater than 1 cm in diameter are usually described as patches.

Papules, Nodules, Plaques, and Tumors. Papules are circumscribed, palpable, elevated solid lesions. Typically less than 0.5-1 cm in diameter, these lesions may be epidermal or dermal in origin and may be flat-topped or dome-shaped. Papules that are 0.5-2 cm in diameter are described as nodules. Nodules are epidermal, dermal, or subcutaneous lesions that may, in some cases, evolve from preexisting papules. Plaques are elevated flat-topped lesions, larger than 1 cm in diameter, and often formed by the coalescence of papules. Tumors are larger nodules greater than 2 cm in diameter that are usually solid and well circumscribed.

Vesicles and Bullae. Vesicles are elevated fluid-filled lesions. Bullae are large vesicles, usually greater than 1 cm in diameter. The tenseness or flaccidity of the blister indicates whether the level of separation is intraepidermal or subepidermal (Fig. 48.3 and Table 48.1).

Pustules. Pustules are white or yellow well-circumscribed lesions that contain purulent material. Pustules do not always signify an infectious cause.

Wheals. Wheals are edematous, elevated lesions that are transient in nature and variable in shape and size. They may be white or erythematous and often have central pallor.

Telangiectases. These are ectatic, dilated superficial blood vessels of the skin that typically blanch when pressure is applied.

Secondary Lesions

Secondary lesions may represent the natural evolution of primary lesions or changes that result from external manipulation, such as scratching.

Crusts. Crusts represent serum, pus, blood, or exudate that has dried on the skin surface.

Scales. Scales appear as yellow, white, or brownish flakes on the skin surface that represent desquamation of stratum corneum.

Erosions. Erosions are moist, erythematous, circumscribed lesions that result from partial or complete loss of the epidermis. They often result from rupture of a blister. Erosions do not involve the dermis or subcutaneous tissue; therefore, they heal without scarring.

Ulcers. Ulcers are deeper than erosions and penetrate the dermis or fat and usually heal with scarring.

Lichenification. Lichenification, or thickening of the skin, usually results from chronic scratching or rubbing. Accentuation of skin markings or hyperpigmentation is observed.

Fissures. A fissure is a linear crack in the epidermis extending to the dermis.

Atrophy. Atrophy represents loss of substance of the skin. Epidermal atrophy is characterized by loss of skin markings, increased wrinkling, and transparency with visibility of underlying vasculature. Dermal or subcutaneous atrophy results in depression of the skin with minimal, if any, epidermal changes.

Excoriations. Excoriations are linear erosions on the skin caused by scratching.

◆ Diagnostic Techniques
Potassium Hydroxide Test

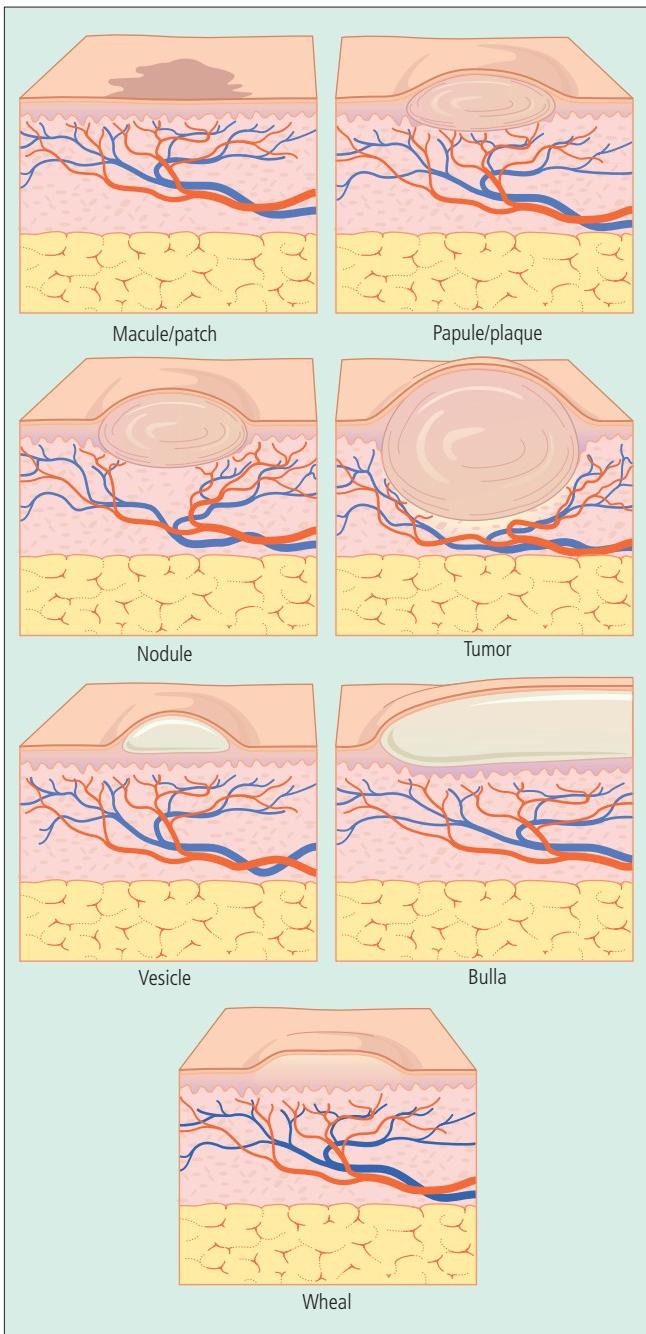
This simple and rapid test can confirm the diagnosis of dermatophyte or candidal infections. Scale is scraped with a curved blade onto a microscope slide. Hair or nail fragments can also be examined. A glass


FIGURE 48.1 Primary skin lesions. (From Cohen BA. Introduction to pediatric dermatology. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013.)

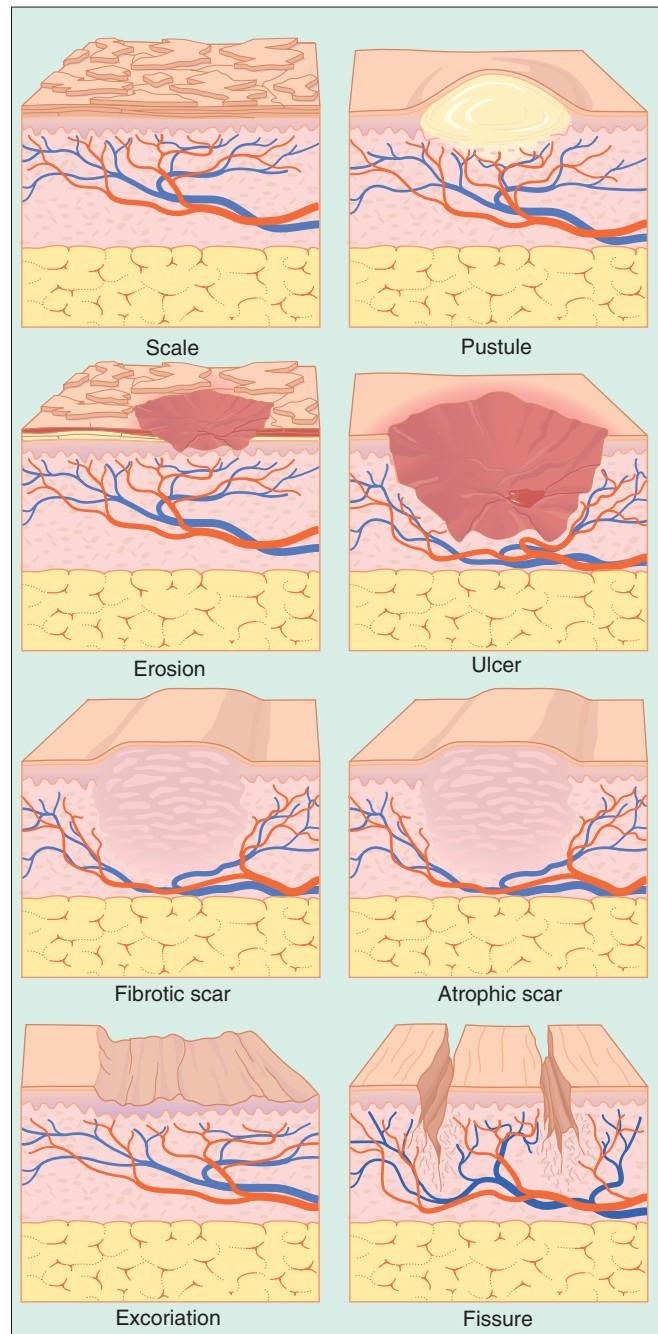

FIGURE 48.2 Secondary skin lesions. (From Cohen BA. Introduction to pediatric dermatology. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:1-13.)

coverslip is then placed on the slide after 1-2 drops of 10-20% KOH are added. The slide is heated gently but not boiled, which can result in KOH crystallization and subsequent difficulty in interpretation. Dermatophyte infections are confirmed by identifying **fungal hyphae**, which appear as long, branching septate filaments. **Pseudohyphae** or **budding spores** are characteristic of candidiasis. Short, broad hyphae and clusters of budding cells resembling "spaghetti and meatballs" are diagnostic of tinea versicolor.

Tzanck Smear

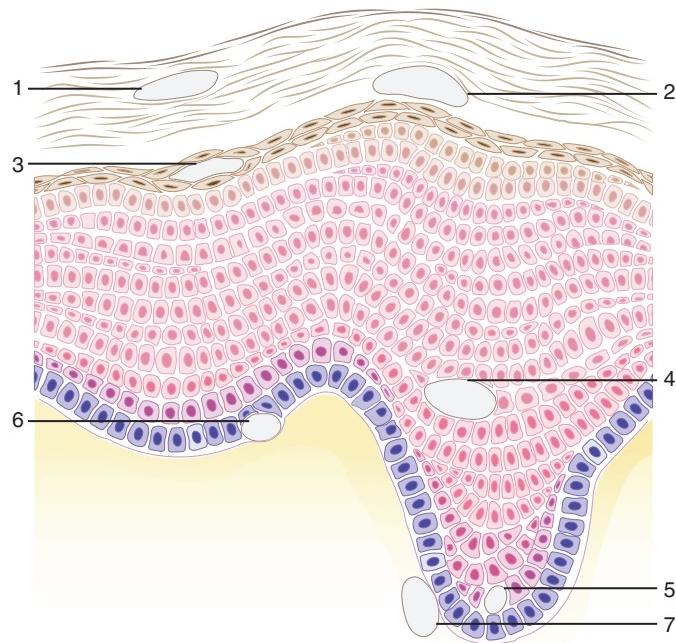
A Tzanck smear is useful for the diagnosis of varicella-zoster virus and herpes simplex virus (HSV) infections. The smear is prepared by unroofing a blister with a curved blade and gently scraping the blister base and underside of the roof. The material is spread in a thin layer onto a glass slide. The slide is air-dried and stained with Giemsa or Wright stain. Identification of **multinucleated giant cells**, a syncytium of epidermal cells with multiple overlapping nuclei, establishes the


FIGURE 48.3 Blister cleavage sites in the skin. *1,* Intracorneal. *2,* Subcorneal. *3,* Granular layer. *4,* Intraepidermal. *5,* Suprabasal. *6,* Junctional (between the basal cell membrane and basement membrane). *7,* Subepidermal. IgA, immunoglobulin A.

diagnosis. These cells may have 2-15 nuclei and are much larger than other inflammatory cells. Although a positive result of Tzanck preparation is confirmatory, a negative test result does not rule out herpes viral infection. Viral specimens should be obtained for culture or polymerase chain reaction (PCR) to differentiate HSV from varicella-zoster virus infections.

Scabies Test

A scabies preparation exhibiting the mite, egg, or feces (scybala) confirms the diagnosis of scabies infestation with *Sarcoptes scabiei*. The mite is most often found within burrows (serpiginous or elongated papules), which may have a vesicle or pustule at one end. A drop of mineral oil should be applied to the lesion so that the scraped material adheres to the blade. The site is then scraped firmly with a curved blade, which occasionally induces minimal bleeding. The material is applied to a microscope slide, another drop of mineral oil is added, and a glass coverslip is placed. Mites are 8-legged arachnids that are easily identified under low magnification. Eggs are frequently observed as smooth ovals approximately half the size of the mite. Feces are smaller than ova and appear as red-brown pellets, often in clusters.

Gram Stain

A Gram stain can be useful in the diagnosis and treatment of suspected bacterial infections. After the site is disinfected, the pustule or blister roof is carefully removed with a needle or straight blade. The contents of the pustule are removed in a sterile manner and spread thinly onto a glass slide. The specimen is air-dried or heat-fixed, stained, and examined microscopically. Results help determine which antibiotic, if any, is indicated. Bacterial cultures are typically obtained simultaneously.

Wood Lamp Examination

A Wood lamp emits low-intensity ultraviolet light at 365 nm and is useful for accentuating pigmentary alterations such as those of piebaldism or ash leaf macules in the newborn and detecting several fungal or bacterial infections. The examination is performed in a darkened room, and the lamp is held 4-6 inches from the patient's skin. Characteristic color changes of infectious etiologies are outlined in Table 48.2.

Skin Biopsy

A skin biopsy can be performed when a clinical diagnosis is unclear. Histologic evaluation of a small skin specimen may reveal changes in the epidermis, dermis, or subcutaneous tissue that confirm or rule out specific disorders. Direct immunofluorescence testing can be extremely helpful in the diagnosis of collagen vascular and autoimmune bullous diseases (Table 48.3).

DERMATOLOGIC DISORDERS IN OLDER INFANTS AND CHILDREN

Many forms of skin lesions are acquired during childhood and adolescence with a range from benign asymptomatic dermatoses to infectious or chronic skin disorders. A thorough history to understand the symptomatology and time course, as well as a detailed skin examination to evaluate the morphology of the lesions, can help distinguish between childhood dermatoses.

Scaling Disorders

The term *papulosquamous* refers to conditions in which the primary lesions are papules or plaques associated with scale. These disorders are typically benign but can be chronic and therapeutically challenging.

Pityriasis Rosea

Pityriasis rosea is an acute, common, self-limited eruption that has no gender predilection. Although the precise cause is unknown, a viral origin is suspected because there have been reports of epidemics, clusters of cases among closely related individuals, and low recurrence

TABLE 48.2	Wood Lamp Examination Findings	
Fluorescence	**Clinical Appearance**	**Organisms/Disease**
Coral, red, pink	Brown or red thin plaques on the groin, axillae, or toe webs	Erythrasma (*Corynebacterium minutissimum*)
Pale green or yellow	Hypopigmented or hyperpigmented macules and plaques on the trunk	Tinea versicolor (*Pityrosporum orbiculare, P. ovale, Malassezia furfur*)
Bright yellow-green	Infection of the toe web space; often in burn patients	*Pseudomonas aeruginosa*
Yellow-green	Scaling of the scalp with patchy hair loss	Tinea capitis (*Microsporum canis, M. audouinii*) Not *Trichophyton tonsurans*

TABLE 48.3	Immunofluorescent Findings in Immune-Mediated Cutaneous Diseases				
Disease	**Involved Skin**	**Uninvolved Skin**	**Direct IF Findings**	**Indirect IF Findings**	**Circulating Antibodies**
Dermatitis herpetiformis	Negative	Positive	Granular IgA ± C in papillary dermis	None	IgA antiendomysial and transglutaminase antibodies
Bullous pemphigoid	Positive	Positive	Linear IgG and C band in BMZ, occasionally IgM, IgA, IgE	IgG to BMZ	IgG anti-BP180 and anti-BP230
Pemphigus (all variants)	Positive	Positive	IgG in intercellular spaces of the epidermis between keratinocytes	IgG in intercellular spaces of the epidermis between keratinocytes	IgG antidesmoglein 1 and 3 (pemphigus vulgaris and foliaceus). IgA antidesmocollin 1 (IgA pemphigus)
Linear IgA bullous dermatosis (chronic bullous dermatosis of childhood)	Positive	Positive	Linear IgA at BMZ, occasionally C	Low titer, rare IgA, anti-BP180	None
Discoid lupus erythematosus	Positive	Negative	Linear IgG, IgM, IgA, and C3 at BMZ (lupus band)	None	Usually ANA-negative
Systemic lupus erythematosus	Positive	Variable; exposed to sun, 30–50%; nonexposed, 10–30%	Linear IgG, IgM, IgA, and C3 at BMZ (lupus band)	None	ANA Anti-Ro (SSA), anti-La (SSB) Anti-RNP Anti-dsDNA Anti-Sm
Henoch–Schönlein purpura	Positive	Positive	IgA around vessel walls	None	None

ANA, antinuclear antibody; BMZ, basement membrane zone at the dermal–epidermal junction; BP, bullous pemphigoid; C, complement; dsDNA, double-stranded deoxyribonucleic acid; IF, immunofluorescence; Ig, immunoglobulin; Sm, Smith; SSA/SSB, Sjögren syndrome A/B; RNP, ribonucleoprotein.

rates. Pityriasis rosea has been associated with systemic reactivation of human herpesvirus 6 (HHV-6) and HHV-7. Furthermore, a prodrome of malaise, headache, and respiratory symptoms is occasionally observed.

The eruption usually begins with a solitary oval, pink scaly plaque approximately 3-5 cm in diameter, typically located on the trunk or proximal extremities (Fig. 48.4). Referred to as the **herald patch**, this finding is observed in 50-70% of cases. When the herald patch has an elevated red border and central clearing, it resembles tinea corporis. Performing a KOH preparation can differentiate these two conditions. Within 1-2 weeks after appearance of the herald patch, numerous small, pink scaly papules or plaques arise over the trunk and proximal extremities, sparing the face and distal extremities. The lesions classically have a fine cigarette paper–like peripheral collarette of scale. These oval 0.5- to 2-cm lesions have their long axis oriented along skin lines, and when present on the trunk, result in a "Christmas tree" pattern on the back (Fig. 48.4). Young children, particularly African-Americans, may have an "inverse" type of pityriasis rosea, with most lesions distributed on the distal extremities, face, neck, and intertriginous regions. Other variants seen in children demonstrate lesions that are papular, vesicular, pustular, purpuric, or lichenoid.

The duration of the eruption varies from 2-12 weeks. Therapy is unnecessary; emollients, topical corticosteroids, or oral antihistamines help relieve pruritus. In addition, pityriasis rosea improves significantly with exposure to ultraviolet light. Postinflammatory hypopigmentation or hyperpigmentation may persist for weeks to months, especially in dark-skinned patients. There are many other dermatoses that can resemble pityriasis rosea (Table 48.4). In sexually active adolescents, a rapid plasma reagin (RPR) test should be obtained to rule out the possibility of secondary syphilis, especially if the palms and soles are involved. Persistence of the eruption after 3-4 months necessitates an evaluation for another diagnosis.

FIGURE 48.5 Well-demarcated erythematous, scaly plaques of psoriasis. (From Kliegman RM, et al. Diseases of the epidermis. In: Kliegman RM, et al, eds. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2015:3160-3162.)

Psoriasis

Psoriasis is an immune-mediated inflammatory skin condition characterized by well-demarcated, erythematous scaly papules and plaques located most often on the scalp, elbows, knees, genitalia, and lumbosacral regions. The course is more chronic and unpredictable than that of pityriasis rosea. Psoriasis occurs in approximately 1-3% of the population and is estimated to manifest before the age of 20 years in about 30% of patients. It affects both genders equally in adulthood, but childhood psoriasis has a slight female predominance. The cause is multifactorial, but there is a genetic predisposition in many affected individuals and about 50% have a positive family history when onset occurs during childhood. The association between psoriasis, obesity, and metabolic syndrome has been described in both adult and pediatric patients with psoriasis, and screening for individuals with moderate-to-severe involvement should be considered.

Psoriasis encompasses a broad spectrum of clinical manifestations, ranging from mild, asymptomatic, virtually undetectable disease to extensive, chronic, debilitating disease. The course is usually marked by recurrent flares and remissions and is often exacerbated by stress, trauma, infection, climate, hormonal factors, and particular medications.

Although morphologic variations exist, the classic lesions of **plaque psoriasis** are well-demarcated erythematous papules or plaques with a silvery-white scale (Fig. 48.5). The lesions usually begin as small erythematous papules that gradually enlarge and coalesce to form plaques up to several centimeters in diameter. The micaceous (micalike) scale of the psoriatic plaque is more adherent centrally than peripherally. Removal of this scale results in multiple small bleeding points. This is referred to as the *Auspitz sign* and is secondary to disruption of the dilated blood vessels that are located high in the papillary dermis. Although this finding is seen in psoriasis, it is not pathognomonic.

The **Koebner phenomenon**, another characteristic feature of psoriasis, although observed in a number of dermatologic conditions, is an isomorphic response (development of new or larger lesions) occurring at sites of injury or trauma such as scratching, sunburn, or surgery (Fig. 48.6). Psoriatic lesions tend to be distributed symmetrically. Although extensor surfaces are typically involved, a variant of psoriasis known as inverse psoriasis affects flexural surfaces, such as the axillae and groin.

FIGURE 48.6 Koebner phenomenon in psoriasis with linear plaques formed in the pattern of excoriations. (From Papulosquamous eruptions. In: Cohen BA, ed. *Pediatric Dermatology.* Philadelphia: Saunders; 2013:68-103.)

FIGURE 48.7 Small droplike plaques of guttate psoriasis. (From Cohen BA, Davis HW, Gehris RP. Dermatology. In: Zitelli BJ, et al, eds. *Atlas of Pediatric Physical Diagnosis.* Philadelphia: Saunders; 2012: 299-368.)

Scalp lesions are present in most children with psoriasis. Diffuse, thick white scale may be accompanied by erythema. In contrast to seborrhea, psoriasis often extends beyond the hairline, affecting the forehead, ears, and neck. The lesions are variably pruritic and are generally not associated with hair loss. Scalp psoriasis tends to be more resistant to therapy than seborrheic dermatitis.

Nail abnormalities are seen in 25-50% of patients with psoriasis. Nail pits are the most common finding, identified by multiple pinpoint depressions that are irregularly distributed over the nail plate. Although nail pitting is characteristic of psoriasis, it is not a pathognomonic sign; it is also associated with atopic dermatitis, alopecia areata, and trauma. Other nail changes include separation of the nail plate from the nail bed (onycholysis), subungual hyperkeratosis, discoloration, crumbling, and yellowish-brown "oil spots" on the nail plate.

Guttate psoriasis, characterized by numerous droplike lesions, is a variant commonly seen in children and young adults (Fig. 48.7). The round-to-oval, pinkish-red, somewhat scaly papules arise in crops and are widely distributed, particularly on the trunk. Two-thirds of affected patients have a history of an upper respiratory tract infection, usually streptococcal in origin, which was present 1-3 weeks before the onset of lesions. Clinical improvement is often seen after appropriate antibiotic therapy; however, the clinical course may range from spontaneous resolution to chronic disease.

Psoriasis is usually diagnosed from the clinical appearance of skin lesions. However, when the diagnosis is unclear, a skin biopsy may be helpful. Differential diagnosis of psoriasis includes seborrheic dermatitis, dermatophytosis, pityriasis rosea, lichen planus, atopic dermatitis, and subacute cutaneous lupus erythematosus (Table 48.4).

The course of psoriasis is marked by recurrent flares and remissions. Although it is unpredictable, there appears to be a subset of individuals whose disease gradually improves over time. Management of psoriasis varies depending on a number of factors including age of the child, extent of involvement, functional limitations, and psychosocial impact. For limited disease, topical therapy (emollients, corticosteroids, vitamin D derivatives, retinoids, tar, keratolytics) alone may afford control. For more extensive or debilitating disease, the addition of phototherapy or a systemic agent (immunosuppressants, retinoids, "biologic" therapy) may be necessary.

Pityriasis Lichenoides

Pityriasis lichenoides can manifest in two forms: pityriasis lichenoides et varioliformis acuta (PLEVA) or pityriasis lichenoides chronica. These diseases most commonly affect children between ages 5 and 15 years. Both diseases are believed to be part of the same clinical spectrum. **PLEVA** is characterized by an abrupt eruption of multiple, 2- to 4-mm, nonpruritic, variably scaly erythematous macules and papules that may progress to vesicular, necrotic, or crusted lesions. The lesions often occur in crops, and are thus present in different stages most commonly on the trunk, but may spread to the extremities. The condition may resolve spontaneously within several months, or recurrences and relapses may occur episodically for several years.

Pityriasis lichenoides chronica manifests more gradually and is characterized by pink-to-brown 2- to 5-mm papules with central adherent scale, found primarily on the trunk and proximal extremities. The clinical course is variable, and the lesions may last from months to years. After the papules recede, postinflammatory hypopigmentation or hyperpigmentation commonly occurs. Sequelae are uncommon, and the lesions usually heal without a scar. Pityriasis lichenoides chronica may initially resemble pityriasis rosea and other papulosquamous eruptions (Table 48.4). Reports of cutaneous T-cell lymphoma (**mycosis fungoides**) in the setting of pityriasis lichenoides chronica exist, and the patient with a persistent or atypical eruption should be evaluated with consideration of a skin biopsy (Fig. 48.8).

Treatment may be limited to lubricants in an asymptomatic patient. If treatment is required, first-line agents include oral antibiotics with antiinflammatory properties (erythromycin, doxycycline) for several weeks, which have shown benefit in some children.

Lichen Planus

Lichen planus occurs in patients of all ages but is less commonly seen in children than in adults. It is characterized by the "**5 Ps**": purple, polygonal, planar, pruritic papules. The primary lesion is a shiny, violaceous, flat-topped papule, often with angulated borders, measuring from 2 mm to more than 1 cm in diameter. The lesions are very pruritic and demonstrate the Koebner phenomenon, which results in the development of new lesions (often in a linear configuration) at sites of scratching. The distribution may be localized or generalized, and lesions may number from few to numerous. Sites of predilection include the volar wrists, forearms, legs, genitalia, and mucous membranes. A reticulated pattern of delicate white lines or streaks (**Wickham striae**) seen on the buccal mucosa or skin aids in confirming the diagnosis.

Nail changes are seen in approximately 10% of patients. These include longitudinal ridging, generalized nail destruction, red or brown discoloration, subungual hyperkeratosis, and thinning of the

nail plate. Pterygium formation results from the overgrowth of fibrous tissue, which extends from the proximal nail fold to the tip of the nail, obliterating the nail plate.

Common **medications** that can produce a lichenoid eruption that is indistinguishable from lichen planus include antihypertensives (β blockers, angiotensin-converting enzyme inhibitors), diuretics (hydrochlorothiazide), antimalarials, penicillamine, and gold salts. Rarely, tetracycline, griseofulvin, nonsteroidal antiinflammatory medications, phenytoin, and carbamazepine can be causes. Unlike other cutaneous medication reactions, the lichenoid reaction may not occur for months or years after medication initiation.

FIGURE 48.8 Asymptomatic, hypopigmented, minimally scaly patches on the trunk of a child, which were present for several years and found to be cutaneous T-cell lymphoma. (From Papulosquamous eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:68-103.)

It is often possible for the experienced clinician to diagnose lichen planus strictly on clinical grounds. If necessary, a skin biopsy specimen can reveal specific findings. The clinical differential diagnosis most often includes psoriasis and drug eruptions (Table 48.4). If oral lesions are present, the clinician must consider the possibility of aphthous stomatitis, erythema multiforme (EM), herpes simplex, or leukoplakia.

Topical corticosteroids are the treatment of choice in most cases. Lichen planus often resolves spontaneously over 1-2 years, but some cases may persist for many years. Generalized eruptions may respond to a short course of systemic corticosteroids. Oral antihistamines provide symptomatic relief.

Seborrheic Dermatitis

Seborrheic dermatitis is characterized by an erythematous, scaly, symmetric eruption that occurs most often in hair-bearing and intertriginous regions. Seborrhea of infancy is discussed in Chapter 47. In adolescents, yellowish, greasy scale of the scalp, eyebrows, nasolabial folds, nasal bridge, posterior auricular regions, and midchest may be accompanied by mild erythema (Fig. 48.9). Immunodeficiency disorders and neurologic dysfunction may be associated with severe, recalcitrant seborrheic dermatitis. Although patients usually respond well to therapy, it is a chronic condition characterized by recurrences. It is often responsive to low-potency topical corticosteroids or topical antifungals (azoles, ciclopirox, selenium sulfide). These preparations may be available in a number of vehicles, including solutions or shampoos for the scalp. Keratolytics may be added when thicker scale is present.

Atopic Dermatitis

Atopic dermatitis (**eczema**) is a chronic condition characterized by pruritus, a personal or family history of atopy, and an age-dependent distribution. It is common during infancy and childhood. Up to 95% of affected individuals have signs before the age of 5 years.

Typical lesions are pink-to-red crusted or scaly plaques or papules. Some individuals have follicular accentuation, particularly on the trunk, manifested by a goosebump-like texture. **Lichenification** (thickened skin with exaggerated skin markings) is a feature of chronic atopic dermatitis and results from repeated rubbing and scratching.

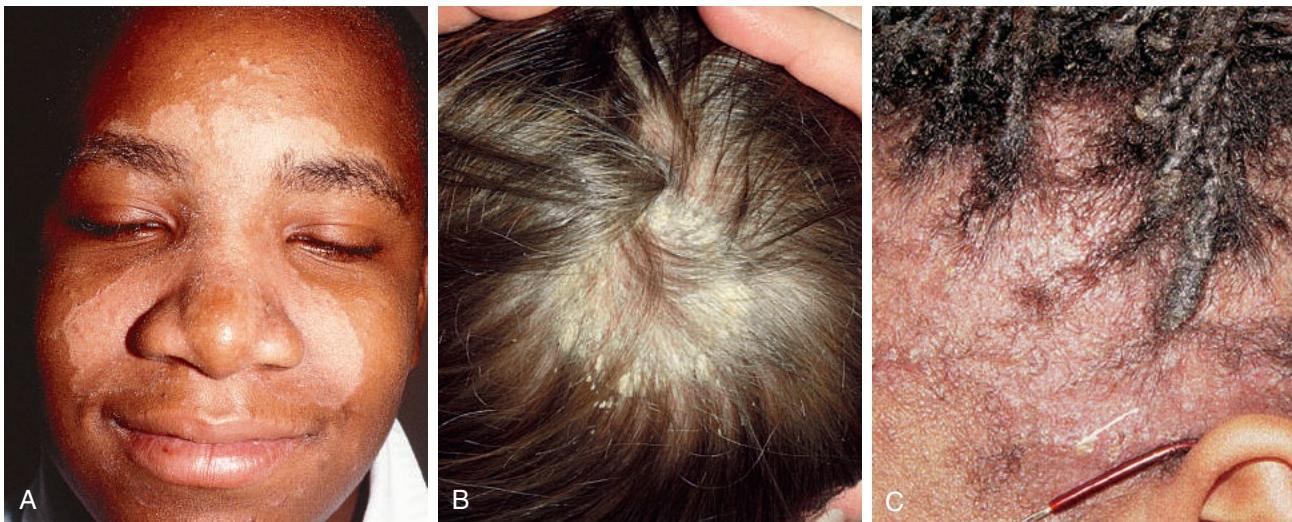

FIGURE 48.9 Seborrheic dermatitis in the older child or adolescent. *A,* Scaly, hypopigmented lesions on the face involving eyebrows, nasolabial folds, and nasal bridge. *B,* Thick, yellow, adherent scale in the scalp. *C,* Confluent, scaly patches on the scalp with mild erythema. (From Papulosquamous eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:68-103.)

Excoriations are secondary lesions caused by scratching. Postinflammatory pigmentary changes are frequently noted, especially in dark-skinned individuals (Fig. 48.10). Associated findings are noted in Table 48.5.

The distribution of the lesions tends to be age dependent. The cheeks, face, scalp, trunk, and extensor surfaces of the arms and legs are characteristically involved in the infant form. Between the ages of 2 and 10 years (childhood atopic dermatitis), the distribution predominately involves the neck, wrists, ankles, and flexural surfaces of the extremities (Fig. 48.11). After puberty, atopic dermatitis has a predilection for the face, neck, hands, and feet. The clinical features of the skin lesions are not specific to this condition, as other eczematous eruptions (contact dermatitis, seborrheic dermatitis) have a similar appearance. Laboratory tests are of limited value, and histologic findings reveal nonspecific spongiotic dermatitis. The distribution of lesions, age at onset, and history are most important for establishing the diagnosis. Obtaining a complete personal and family history of atopic diatheses is necessary.

Secondary infections are the most common complication. Individuals with atopic dermatitis have increased colonization with *Staphylococcus aureus.* Most affected children need occasional treatment with antibiotics to eradicate secondary infection, and dilute sodium hypochlorite bleach baths can help reduce infection with *S. aureus.* The presence of pustules, extensive excoriations, or weeping and crusted lesions suggests the need for antibiotic therapy. Topical therapy with mupirocin may be sufficient for limited areas; however, widespread involvement may necessitate the use of oral antimicrobial agents. The

increase in methicillin-resistant *S. aureus* (MRSA) infections has limited therapeutic options in some patients. Secondary infection with HSV is referred to as **eczema herpeticum** or **Kaposi varicelliform eruption** (Fig. 48.12). Transmission may occur during routine child care from a caretaker with a herpetic fever blister, whereby the eczematous skin becomes inoculated with HSV. The hallmark of this condition is the rapid development of numerous umbilicated vesicles and pustules. Later in the course, multiple erosions are seen, and identification of an intact vesicle may be difficult. The infection may be associated with fever and other constitutional symptoms, and expedient treatment with acyclovir is required. Hospitalization may be necessary in young infants or severely affected individuals. Recurrences of eczema herpeticum can be problematic.

Other dermatologic conditions to consider in the differential diagnosis of a rash that looks like atopic dermatitis are presented in Table 48.6.

An overview of the management of atopic dermatitis is presented in Table 48.7.

LUMPS AND BUMPS

The presence of cutaneous or subcutaneous **nodules** and **tumors** can present a diagnostic challenge. They are also a source of great concern to parents, who fear the possibility of malignancy. Fortunately, most

FIGURE 48.10 Postinflammatory pigment changes of the ankles *(A)* and hands *(B).* (From Papulosquamous eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:68-103.)

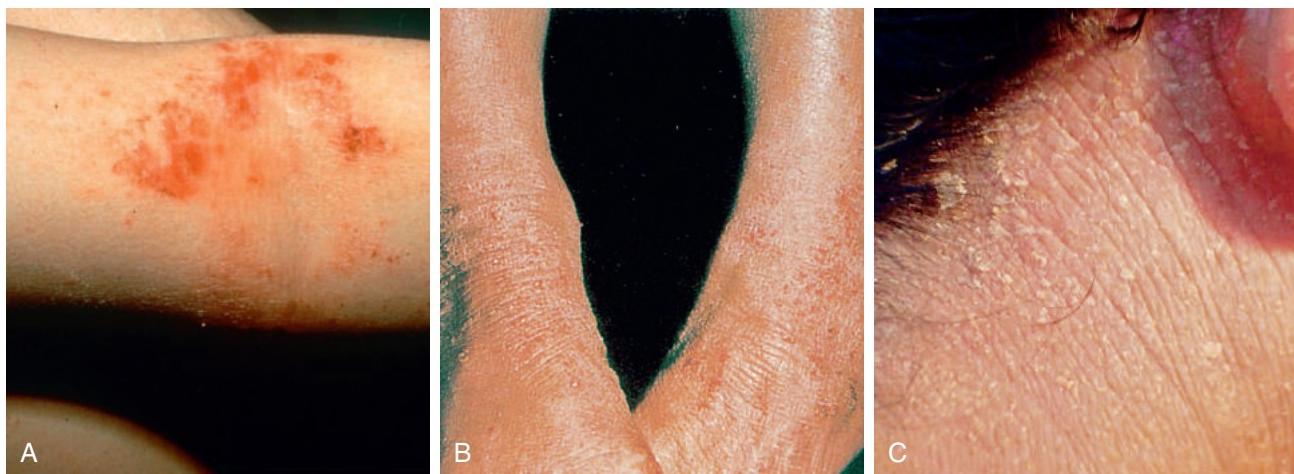
| TABLE 48.5 **Atopic Dermatitis: Associated Findings**	
Ichthyosis vulgaris	Affects 20% of patients with atopic dermatitis. Primarily involves the legs and trunk
Keratosis pilaris	Asymptomatic hyperkeratotic follicular papules found mainly on the extensor surfaces of the upper arms and anterior thighs, also on the face in children
Pityriasis alba	Hypopigmented patches on the cheeks and occasionally upper body
Hyperlinear palms/soles	Common physical finding
Dennie–Morgan fold	A double line found under the lower eyelids. Not pathognomonic
Lichen spinulosus	More commonly seen in darker skin. Pruritic grouped hyperkeratotic follicular spires
Eye findings	Keratoconjunctivitis, cataracts, keratoconus (abnormally shaped cornea), retinal detachment (rare)
Dyshidrotic eczema	Firm vesicles found on the palms and soles and lateral aspects of digits. Frequently associated with hyperhidrosis
Nummular eczema	Well-demarcated, scaly, coin-shaped lesions usually on the lower extremities. Associated with xerosis
Juvenile plantar dermatosis	Occasionally exudative lesions. Painful erythema, scaling, cracking, and fissuring of weight-bearing surfaces of the feet. Often associated with hyperhidrosis. Improvement after puberty


FIGURE 48.11 Atopic dermatitis in childhood with lesions of the arm *(A)*, ankles *(B)*, and neck *(C)*. (From Papulosquamous eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013: 68-103.)

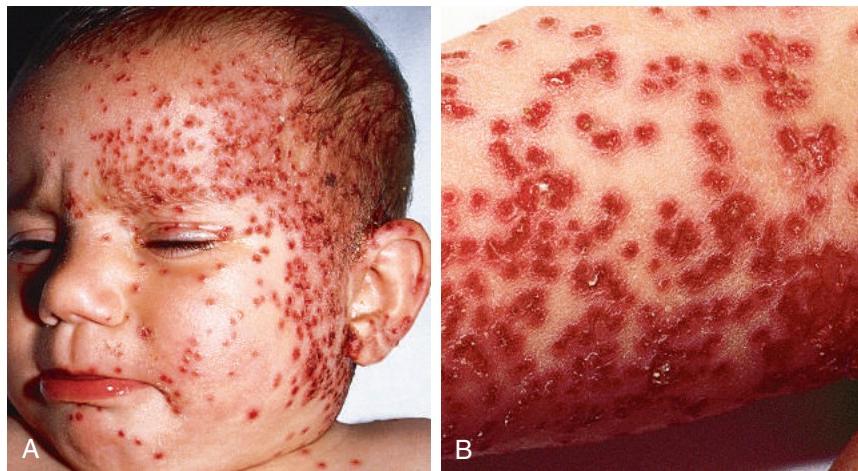

FIGURE 48.12 Eczema herpeticum infection in a patient with atopic dermatitis. Numerous punched out vesicles and erosions involving the face *(A)* and extremities *(B)*. (From Papulosquamous eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:68-103.)

nodules and tumors in children are benign, and cutaneous malignancies are rare (Table 48.8).

Granuloma Annulare

Granuloma annulare is characterized by skin-colored to mildly erythematous dermal papules and nodules that may expand and coalesce into rings. These asymptomatic annular plaques measure 1-4 cm in diameter and appear most commonly on the dorsal hands and feet or extensor surfaces of the extremities (Fig. 48.13). The centers of these lesions usually appear normal but are occasionally hyperpigmented or violaceous in color. The overlying epidermis is unaffected. Multiple lesions are common, particularly in children. Granuloma annulare may be seen in all age groups, but at least 40% of cases occur before 15 years of age. The etiology remains unknown. Some cases have been associated with preceding trauma, such as insect bites. Histologically, there is dermal infiltration of lymphocytes and histiocytes surrounding degenerated collagen. Some authorities postulate that the condition may result from a cell-mediated immune response. In children, this condition is less commonly associated with systemic diseases such as diabetes, as has been reported in adults. The eruption is most

FIGURE 48.13 Ring of confluent dermal papules with a depressed center typical of granuloma annulare. (From Kliegman RM, et al. Diseases of the dermis. In: Kliegman RM, et al, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2015:3176.)

TABLE 48.6	**Differential Diagnosis of Atopic Dermatitis**	
Condition	**Similarities**	**Differences**
Seborrheic dermatitis	Scaly plaques Erythroderma may be seen when severe	Earlier onset is typical, can be seen in older children Increased severity associated with immunodeficiency disorders and neurologic dysfunction Pruritus minimal or absent Well-demarcated lesions Characteristic yellowish-salmon greasy lesions with intertriginous distribution
Contact dermatitis		
Primary irritant	Common in infants, young children May have similar distributions depending on the irritant (i.e., cheeks, chin, neck)	Usually less pruritic and less eczematoid Diaper area distribution uncommon in atopic dermatitis
Allergic	Pruritic Erythematous, papulovesicular eruption	Well circumscribed Uncommon in 1st few months of life Involutes spontaneously after the removal of the offending agent
Psoriasis	Scaly, red lesions	Deeper red-violaceous hue Thick micaceous scale Characteristic nail changes Sharply demarcated lesions Distinct distribution Pruritus may be less intense
Scabies	Frequent eczematous changes secondary to scratching, rubbing, or irritating therapy Can be very difficult to distinguish in infancy	Presence of hyperpigmented nodules Presence of burrows Isolation of a mite from skin scrapings Acute onset Affected household members
Langerhans cell histiocytosis	Scaly, erythematous eruption Usually begins during 1st yr of life	Primarily children <3 yr of age Presence of purpuric papules Associated hematologic abnormalities, hepatosplenomegaly
Acrodermatitis enteropathica	Vesiculobullous eczematoid lesions Onset during infancy	Acral, periorificial distribution Associated features: failure to thrive, diarrhea, alopecia, nail dystrophy, low serum zinc levels
Wiskott–Aldrich syndrome	Severe eczematous dermatitis	X-linked recessive disorder Associated features of thrombocytopenia, defects in cellular and humoral immunity, bloody diarrhea
Phenylketonuria	Eczematous eruption	Hereditary Intellectual disabilty, seizures Diffuse hypopigmentation, blond hair, photosensitivity Elevated blood phenylalanine levels
Hyper-IgE syndrome	Symptoms begin in 1st 3 mo of life Eczematous dermatitis involving the face and extensor surfaces Personal or family history of atopy	Coarse facial features, irregularly proportioned jaw and cheeks, broad nasal bridge, prominent nose, severe oral mucositis Lifelong history of severe streptococcal or staphylococcal infections of the skin, limbs, joints Exceptionally high serum IgE levels Diminished neutrophil chemotaxis

IgE, immunoglobulin E.

commonly confused with that of tinea corporis, but tinea has epidermal changes such as scaling, vesiculation, or pustules.

There are several variants of granuloma annulare. Generalized granuloma annulare is characterized by many asymptomatic papules symmetrically distributed. The ringlike lesions may coalesce into reticulated or circinate forms. The features of subcutaneous granuloma annulare are single or multiple deep hard nodules on the extremities, buttocks, and scalp. This entity is most frequently mistaken for rheumatoid nodules; however, the latter are usually larger.

Granuloma annulare resolves spontaneously over several months to years. Although more than 50% of cases clear within 2 years, recurrences are common. Treatment is generally unnecessary, but the use of topical or intralesional corticosteroids may hasten resolution.

Juvenile Xanthogranuloma

Juvenile xanthogranulomas (JXGs) are papules, nodules, or plaques within the skin that are solitary or multiple; well demarcated; rubbery to firm; and yellow, orange, brown, or red in color. One of the most

TABLE 48.7   Atopic Dermatitis Management

Therapeutic Modality	Indications and Recommendations
Bathing	Recommended daily for 10–15 min with warm, not hot, water. May use fragrance-free bath oils. Hydrates the skin.
Soaps	Mild, fragrance-free cleansers, such as Dove, Basis, Aveenobar, Olay, Cetaphil, or Aquanil, are essential.
Emollients	Best applied immediately after bathing/showering. Should be used as often as possible. Petroleum jelly is an ideal emollient: contains no water, additives, or preservatives and prevents evaporative water loss from the skin. Thick creams such as Eucerin, Nivea, Aquaphor, Vanicream, and Cetaphil are some alternatives.
Bleach (sodium hypochlorite)	Depending on the size of the bathtub/amount of water used, 0.25–0.5 U.S. cup (60–120 mL) of common bleach solution (6% sodium hypochlorite) is added to a full bath (40 gallon tub). Performed 2–3 times/wk to reduce *S. aureus* colonization.
Compresses	Indicated for acute weeping lesions. Helps cool and dry the skin, reduces inflammation. Use cool tap water or aluminum acetate solutions for 20 min, 2–4 times daily. Follow with topical corticosteroid application.
Topical corticosteroids	Indicated to reduce pruritus and inflammation. The potency of the topical corticosteroid is determined by the age of patient, site of involvement, severity of dermatitis, and duration of therapy. Facial and intertriginous skin should be treated with low-potency preparations. Apply before emollient. Use the lowest potency that is effective. Monitor closely for potential side effects, such as striae and cushingoid features.
Topical Immunomodulators	Tacrolimus and pimecrolimus may be effective steroid-sparing agents for more severe involvement.
Antihistamines	Controversial whether effective in this condition. Topical formulations should be avoided. May help some patients sleep. Hydroxyzine often more effective than diphenhydramine. May induce drowsiness. Nonsedating antihistamines include cetirizine, loratadine and fexofenadine.
Antibiotics	Patients have increased colonization with *S. aureus*. Use if multiple weeping excoriations, crusts, or pustules suggest secondary infection or if severe or resistant eczema is present. Treat with antistaphylococcal antibiotics; specific antibiotic is based on local sensitivities.
Ultraviolet light	Useful for severe, uncontrollable atopic dermatitis. May administer narrowband ultraviolet B light (NBUVB).
Tars	Useful for chronic, dry, lichenified lesions, not for acute dermatitis.
Environmental conditions	Environmental factors may influence the severity of the dermatitis. Some helpful measures: • Avoid fragrances in all topicals and laundry products. • Avoid wool, feathers, dust exposure. • Reduce house dust mites. • Eliminate animal dander. • Use plastic mattress covers. • Reduce stress/anxiety. • Increase environmental humidity to reduce skin evaporative losses. • Avoid smoking.
Systemic immunosuppressants	Oral corticosteroids should be avoided. Cyclosporine, methotrexate, mycophenolate mofetil, and azathioprine have shown some benefit in the management of atopic dermatitis, but given the side effect profile, should be prescribed under the direction of a dermatologist.

S. aureus, Staphylococcus aureus

distinct clinical features of a JXG is its characteristic yellow color. On examination, an overlying telangiectasia may be visualized. Lesions are of variable size, usually 0.5-2 cm, and are most commonly located on the head and neck region. The differential diagnosis should include Spitz nevus, solitary mastocytoma, and occasionally nevus sebaceous. Biopsy demonstrates the characteristic histopathologic features of lipid-laden histiocytes and Touton giant cells. Most JXGs are asymptomatic, but occasionally they cause pruritus or pain. The lesions may be present at birth or within the 1st years of life. JXGs are usually benign, and treatment of cutaneous lesions is generally not required. After a brief period of growth, the lesion often stabilizes and involutes spontaneously in months to years.

Multiple lesions should prompt a search for the rare possibility of extracutaneous involvement. The eye is the most common extracutaneous site. Lesions may be found in the iris, and JXG is the most

common cause of anterior chamber hemorrhage in children. The incidence of ocular disease in JXGs is approximately 0.3-0.4%. Ophthalmologic examination is recommended if a JXG is present near the eye or with multiple lesions. Involvement has also been described in other organs including the testes, lungs, liver, spleen, heart, and central nervous system. An increased risk of juvenile myelomonocytic leukemia has been reported in the setting of patients with both neurofibromatosis type 1 and JXGs.

Vascular Lesions
Spider Angioma (Nevus Araneus)
Telangiectases are dilated capillaries that appear as red linear stellate or punctate lesions. There are many causes of *primary* telangiectasia (spider angiomas, hereditary hemorrhagic telangiectasia syndrome) and *secondary* telangiectasia, such as collagen vascular diseases. Spider

TABLE 48.8 **Lumps and Bumps: Distinguishing Features**

Diagnosed Lesion	Usual Onset	Color	Size	Site	Comments	Therapy
Epidermal cyst	Birth, childhood, adolescence	Skin-colored	1–3 cm	Face, scalp, neck, trunk	Potential for inflammation and infection	Elective excision vs observation
Dermoid cyst	Birth	Skin-colored	1–4 cm	Face, scalp, lateral eyebrow	When midline, may have sinus tract	Elective excision
Pilomatricoma	Any age, 50% before adolescence	Skin-colored, reddish-blue, bluish-gray	0.5–3 cm	Head, neck	Malignant transformation possible but rare	Elective excision vs observation
Dermatofibroma	Adulthood, 20% before age 20 yr	Skin-colored, tan brown, black	0.3–1 cm	Extremities	May follow trauma	Elective excision vs observation
Neurofibroma	Occasionally at birth Usually childhood or adolescence	Usually skin colored Also pink, blue	2 mm to several centimeters	Any body site	May be associated with neurofibromatosis May see café-au-lait spots	Elective excision vs observation
Juvenile xanthogranuloma	Birth Childhood	Yellow to reddish-brown	0.5–4 cm	Head, neck, trunk, proximal extremities	Extracutaneous lesions involving eye, other organs	Ophthalmology consult; resolves spontaneously
Keloids	Peak between puberty and age 30	Pink to violaceous	Variable	Any site of injury Commonly earlobes after piercing	Often tender or pruritic Familial tendency	Difficult; intralesional steroids, excision
Granuloma annulare	Childhood Adolescence	Skin colored to red	1–4 cm	Distal extremities	May be generalized in approximately 15% of cases	Observe, self-limited Topical steroids if needed
Lipoma	Puberty, adulthood	Skin colored	Variable May be >10 cm	Any, but usually neck, shoulders, back; abdomen	Malignant change Very rare	Observe, excision
Solitary mastocytoma	Birth Early infancy	Skin colored to light brown or tan Occasionally pink or yellowish hue	1–5 cm	Any site; but most often on arms, neck, trunk	Positive Darier sign Urticaria with stroking	Usually resolves spontaneously; antihistamines may be helpful
Erythema nodosum	Usually >10 yr of age Peak in the 3rd decade	Begins bright to deep red, then develops a brownish-red to violaceous bruiselike appearance	1–5 cm	Symmetric distribution over pretibial region, legs Occasionally arms	Tender Association with many infectious agents (group A streptococci, tuberculosis, mycoplasma), inflammatory diseases (sarcoidosis, inflammatory bowel disease), medications (birth control pills)	Thorough evaluation and treatment of underlying cause, antiinflammatory agents Bed rest/elevation of legs

FIGURE 48.14 Pyogenic granuloma. Hemorrhagic nodule with a central crust. (From Nodules and tumors. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:126-147.)

angiomas are the most common of the telangiectasias. In the pediatric age group, these lesions are typically not associated with systemic disease. Spider angiomas are seen most often on the face and tops of hands. They usually develop after 2 years of age. Small vessels radiate from a central punctum (arteriole), giving the appearance of a "spider." When pressure is applied to the central punctum, the lesion blanches. Treatment, if desired, consists of gentle electrodesiccation or pulsed dye laser therapy. In some cases, spider angiomas clear without treatment.

Pyogenic Granuloma

Pyogenic granulomas are acquired vascular lesions that arise from the connective tissue of the skin or mucous membranes. These vascular nodules may be associated with antecedent trauma and represent a reactive, proliferative process. They are usually solitary, but multiple lesions occur in rare cases (Fig. 48.14). Arising as small red papules, pyogenic granulomas grow rapidly and can ulcerate, leading to profuse bleeding. Histologically, these lesions resemble infantile hemangiomas (IH). Unlike IH, onset after the 1st year of life is typical and spontaneous regression is rare and recurrences may be seen. Treatment involves destruction by pulsed dye laser therapy, electrodesiccation, surgical removal, or cryotherapy.

DISORDERS OF PIGMENTATION

These conditions are often cosmetically disfiguring and persistent. They can be markers of serious systemic diseases. Pigmentary disorders may be localized or generalized; congenital or acquired; and transient, stable, or progressive (see Chapter 47).

Acquired Disorders of Hypopigmentation or Depigmentation
Postinflammatory Hypopigmentation

Postinflammatory hypopigmentation is a common form of acquired hypopigmentation and may follow any inflammatory skin condition, including bullous disorders, infections, eczema, psoriasis, pityriasis rosea, secondary syphilis, insect bites, acne, pityriasis lichenoides chronica, and burns. More frequently detected in dark-skinned individuals, the clinical findings consist of irregularly shaped hypopigmented patches of variable size, often ill-defined, located at sites of preceding inflammation. Postinflammatory hypopigmentation usually resolves gradually over several months, and no treatment is necessary other than photoprotection.

FIGURE 48.15 Poorly demarcated areas of hypopigmentation in pityriasis alba. (From Papulosquamous eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:66-103.)

Pityriasis Alba

Pityriasis alba is characterized by oval but poorly demarcated, slightly scaly, hypopigmented macules or patches located on the face (typically the cheeks), upper trunk, or extensor surfaces of the arms (Fig. 48.15). The lesions generally vary from 0.5-2 cm in diameter, are often multiple, and are usually asymptomatic. Sun exposure may increase the contrast with normal skin, prompting patients to seek treatment. An association with atopic dermatitis may be seen, and differentiating this from postinflammatory hypopigmentation associated with patches of atopic dermatitis may be difficult. In contrast to postinflammatory hypopigmentation, the histology of pityriasis alba demonstrates low-grade inflammation. Pityriasis alba may resemble tinea versicolor or tinea corporis but can be differentiated by negative KOH results. The hypopigmentation typically persists for several months to years. Although no therapeutic intervention is required, the use of emollients and low-potency topical corticosteroids may be effective.

Vitiligo

Vitiligo is an acquired disorder characterized by complete loss of the pigment of the involved skin. The condition often manifests during childhood and is believed to be linked to specific genetic mutations. Many authorities believe that vitiligo is an autoimmune process with circulating antibodies that destroy melanocytes. There is an increased incidence of autoimmune diseases in affected individuals and their families. The incidence of vitiligo in persons with diabetes mellitus is also higher than that in the general population.

The onset of vitiligo may be precipitated by sunburn or other trauma. Physical findings are usually sufficient for establishing the diagnosis. Well-demarcated depigmented macules and patches that are often bilateral and symmetric are distributed on the extremities, on the periorificial areas, and within skin folds. In some cases, depigmentation may have a segmental distribution. This variant is seen more commonly in children than in adults. The clinical course is unpredictable. Spontaneous complete repigmentation is unusual; however,

partial repigmentation may be seen, especially within lesions of less than 2 years' duration. Repigmentation proceeds gradually and is more likely to occur in children than in adults.

Treatment response often takes months. For limited involvement, topical corticosteroids are most frequently used, but calcineurin inhibitors provide an option in places where corticosteroids may be preferable to avoid. For more widespread involvement in motivated, compliant patients, phototherapy may provide the best chance of repigmentation. Other interventions may consist of camouflage with cosmetics to reduce the contrast between affected and unaffected sites and careful photoprotection to prevent the development of cutaneous malignancy. Bleaching agents are another option in individuals with depigmentation of greater than 50% of their cutaneous surface.

Disorders of Hyperpigmentation
Lentigines
Lentigines are 1- to 5-mm macules that are darker than freckles and may occur on any cutaneous site, including the mucous membranes. Lentigines have no seasonal variance, and those that manifest during early childhood often disappear during adulthood. A lentigo may be clinically indistinguishable from a junctional nevus (mole); however, these lesions are histologically distinct.

Several syndromes are associated with multiple lentigines. *Lentiginosis profusa* is an entity characterized by multiple deeply pigmented macules that are usually present at birth or in early infancy. These individuals have no associated systemic or developmental abnormalities, unlike children with **LEOPARD syndrome** (multiple lentigines, electrocardiograph abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, growth retardation, and neural deafness), which also manifests during infancy. Multiple lentigines located on the mucous membranes, especially the vermilion border of the lips and buccal mucosa, should alert the clinician to the possibility of **Peutz–Jeghers syndrome**, which is characteristically associated with intestinal polyposis and subsequent risk of malignant transformation and intussusception. **Solar lentigines** occur in sun-exposed areas in older children.

Café-Au-Lait Macules
Café-au-lait macules are well-circumscribed tan macules that usually measure less than 0.5 cm and may be as large as 15-20 cm in diameter. The lesions are found on any cutaneous site and may be present at birth or appear during early childhood. Although café-au-lait spots are seen in 10-20% of normal individuals, the presence of many macules should raise the clinical suspicion of **neurofibromatosis** (Table 48.9). The presence of 6 or more café-au-lait spots (>0.5 cm in prepubertal children; >1.5 cm in postpubertal children) fulfills 1 of the diagnostic criteria for neurofibromatosis type 1. Although the lesions are not pathognomonic, they are present in most patients

TABLE 48.9	**Neurocutaneous Syndromes**		
Syndrome	**Mode of Inheritance**	**Cutaneous Findings**	**Systemic Findings**
Tuberous sclerosis	Autosomal dominant	Ash leaf macules Angiofibromas (adenoma sebaceum) Shagreen patches Periungual/subungual fibromas Gingival fibromas	CNS involvement (seizures, intellectual disabilty, cortical tubers) Cardiac rhabdomyomas Retinal gliomas Renal carcinoma or hamartoma Renal or pulmonary cysts Skeletal abnormalities
Neurofibromatosis (NF) (NF1 >85% of cases)	Autosomal dominant	Café-au-lait macules (>6 measuring ≥1.5 cm) in adults and >0.5 cm in children Axillary, inguinal freckling (Crowe sign) Neurofibromas Blue-red macules and pseudoatrophic macules (involuted neurofibromas) Lisch nodules (melanocytic hamartomas of the iris)	Acoustic neuroma in NF2 Optic glioma may result in exophthalmos, decreased visual acuity Intellectual disability (rarely) Seizure disorders (rarely) Tumors (astrocytomas) Hyperactivity, macrocephaly Learning disabilities, speech delay Osseous defects (up to 50%) Intestinal neurofibromas Endocrine disorders
Incontinentia pigmenti	X-linked dominant	Phase 1: inflammatory vesicles/bullae in crops over trunk and extremities, may persist weeks to months Phase 2: irregular linear verrucous lesions on ≥1 extremity, resolves spontaneously within several months Phase 3: brown to blue-gray hyper-pigmentation, swirl-like formations on extremities and trunk; increases in intensity through 2nd yr of life, then remains stable or fades over many years Phase 4: streaked hypopigmented lesions	Eosinophilia CNS involvement (seizures, spasticity, ↓IQ) in 30% Spasticity Ophthalmic changes (strabismus, cataracts, optic atrophy, retinal damage) Alopecia Skeletal abnormalities Dental abnormalities

CNS, central nervous system; IQ, intelligence quotient.

with neurofibromatosis and tend to be larger and more numerous. Café-au-lait spots have also been associated with tuberous sclerosis, McCune–Albright syndrome, Turner syndrome, Bloom syndrome, ataxia-telangiectasia, Russell–Silver syndrome, Fanconi anemia, Gaucher disease, and Chédiak–Higashi syndrome.

Postinflammatory Hyperpigmentation

Postinflammatory hyperpigmentation is the most common cause of acquired hyperpigmentation in children. This pigmentary alteration can follow any inflammatory insult and is seen commonly after insect bites, acne, drug reactions, or other skin trauma. The clinical features are usually more striking in darkly pigmented individuals and often may be more pronounced than the original inflammatory lesions. The increased pigmentation usually resolves gradually over several months to years.

Acquired Melanocytic Nevi

Acquired melanocytic nevi arise during early childhood as 1- to 2-mm brown macules occurring most often on sun-exposed skin. These early flat nevi usually represent junctional nevi, in which nests of nevus cells are located along the dermoepidermal junction. Over time, some nevus cells may spread into the dermis, forming compound melanocytic nevi, which clinically appear somewhat larger and more papular than junctional nevi. In some nevi, the nevus cells may become restricted to the dermis. These intradermal nevi are usually fleshy or even pedunculated in appearance. Located usually on the head, neck, or upper trunk, these nevi may clinically resemble skin tags.

There is a gradual increase in the number of nevi during childhood and adolescence. The average individual acquires approximately 20-40 melanocytic nevi. This number peaks at 25 years of age. In general, fair-skinned persons have a greater number of nevi than do darkly pigmented persons.

Melanoma

Although melanomas are very rare in childhood, their incidence is increasing and can present with atypical features compared to the classic criteria of adult cases. The overall lifetime risk of melanoma in white persons in the United States is currently approximately 1 in 50 individuals. Melanoma can arise de novo or from preexisting congenital or acquired melanocytic nevi. Nevi should be observed for specific changes that may be indicative of malignancy. These alterations include:

1. Rapid growth of the nevi
2. Changes in texture, including nodularity, crusting, ulceration, bleeding, or loss of normal skin lines
3. Changes in pigmentation, especially the development of red, white, or blue hues
4. Border irregularity, especially notched or scalloped edges
5. Symptoms of itching, tenderness, or pain

In general, melanomas occur more frequently in light-pigmented individuals, in individuals with a high nevus count, and in those with a family history of melanoma. Melanomas usually appear as darkly pigmented nodular masses, often with color variegation, larger than 6 mm in diameter. They are often asymmetric and tend to have irregular borders and surface characteristics. Melanomas must be differentiated from other benign pigmented lesions, including congenital and acquired melanocytic nevi, blue nevi, Spitz nevi, vascular lesions such as hemangiomas and pyogenic granulomas, and pigmented lesions caused by trauma. Suspect lesions should be referred to a dermatologist.

The mortality rate of melanoma is estimated to be between 10% and 20%. The prognosis depends on the thickness of the lesion. For lesions less than 0.75 mm in depth, the prognosis is excellent. Surgical excision is the treatment of choice. Patients should be educated on the importance of photoprotection with broad-spectrum (ultraviolet A and B) sunscreens.

REACTIVE ERYTHEMAS

Morbilliform Drug Eruption

Morbilliform (measles-like) eruptions are the most common cutaneous manifestations of drug-induced eruptions in children. In this eruption, fine erythematous macules and papules are distributed over the trunk. The rash often spreads centripetally from the trunk to the extremities. Lesions may coalesce into large plaques and are usually pruritic. Morbilliform drug eruptions are often difficult to differentiate from viral exanthems. It is believed that concomitant viral infections may predispose susceptible individuals to develop an allergic morbilliform drug eruption.

Many agents, including common antibiotics, can trigger a morbilliform drug eruption. These medications include penicillins, sulfonamides, thiazides, sulfonylureas, nonsteroidal antiinflammatory drugs (NSAIDs), aromatic anticonvulsants, and gold. Treatment includes prompt diagnosis with discontinuation of the offending medication and symptomatic care with antihistamines and emollients. The rash may last an average of 1-2 weeks and sometimes progresses despite discontinuation of the offending medication. In rare cases for which discontinuation of the offending medication is not possible, continuation of the medication with close monitoring for the development of a more severe reaction may be considered as tolerance may develop with subsequent resolution of the eruption.

Although this eruption is usually self-limited, it may be an early manifestation of a more severe reaction such as **Stevens–Johnson syndrome (SJS)**, **toxic epidermal necrolysis (TEN)**, or **DRESS** (drug reaction with eosinophilia and systemic symptoms). Worrisome signs and symptoms of these life-threatening entities may include high fever, mucous membrane involvement, lymphadenopathy, and other systemic involvement. Signs of visceral involvement may include elevated hepatic transaminases, hematologic changes, or renal manifestations.

Fixed Drug Eruption

A fixed drug eruption is characterized by the sudden development of solitary or multiple well-demarcated, annular, erythematous, or hyperpigmented plaques. One of the distinguishing features is persistent postinflammatory hyperpigmentation, which may last weeks to months after the eruption subsides. The size of the lesion may vary, and the sites of predilection include the lips, trunk, legs, arms, and genitals. In some cases, the lesion may have a central bulla. Systemic symptoms are rare, although the patient may complain of local pruritus or a burning sensation.

Discontinuation of the offending medication causes a decrease in the intensity of the erythema and edema; repeated challenge with the same agent causes a reappearance of the lesion in the same location and may produce new lesions. Future outbreaks may be progressively more severe. The most common agents inducing fixed drug eruption include barbiturates, sulfonamides, tetracyclines, phenolphthalein, paracetamol, salicylates, NSAIDs, and even certain foods that contain yellow dye No. 5. Treatment is aimed at discontinuation and avoidance of the offending agent.

When numerous lesions occur, the condition may resemble erythema multiforma (EM), and the clinical history becomes paramount in establishing the diagnosis, particularly as there is significant histologic overlap.

HYPERSENSITIVITY REACTIONS

Urticaria

Urticaria is characterized by transient, edematous, erythematous, often annular wheals (Fig. 48.16). Central clearing may be seen but is not always present. The eruption is often sudden and pruritic, and each lesion rarely lasts longer than a few hours. Although the lesions are transient, they may continue to appear in new locations, and the entire urticarial episode may last hours to years.

Giant annular urticarial lesions are usually large, up to 20-30 cm, and polycyclic. A centrally bruised appearance is common within these lesions. Lesions may be of different sizes with bizarre shapes and patterns. Affected patients are often irritable and may have edema of the hands, eyelids, or feet. **Angioedema** is a form of urticaria that manifests with marked edema affecting deeper tissue planes and frequently involves the lips, dorsum of the hands or feet, scalp, scrotum, or periorbital tissue.

Giant annular lesions are often confused with the target lesions of EM. However, there are key features by which to differentiate the 2 disorders. Urticarial lesions, by definition, are transient and individual lesions last less than 24 hours, whereas lesions in EM are fixed and usually last 1-2 weeks in the same anatomic location. Outlining the lesions with a marker may help determine whether the lesions are fixed or transient. Another differentiating feature is that the lesions in EM usually have a dusky, necrotic center or blister. A skin biopsy may also aid in differentiating between the 2 disorders (Table 48.10).

Urticaria may be defined as either acute or chronic. **Acute** urticaria lasts less than 6 weeks. When hives continue to develop for more than 6 weeks, urticaria is considered to be chronic. Acute urticaria has numerous etiologies but is often caused by medications (particularly antibiotics), foods, infections, or environmental stimuli such as stinging insects (Table 48.11). The cause of **chronic** urticaria is typically difficult to determine and there is a broad list of etiologies

(Table 48.11). A thorough history and a careful physical examination are the most helpful tools for determining the cause. There is no routine battery of laboratory tests that should be obtained for the evaluation of urticaria. However, evaluation for infection and other causes as suggested by the history and physical examination findings should be pursued.

Urticaria is usually self-limited. Treatment of pruritus consists of elimination of identifiable causes and administration of antihistamines. Hydroxyzine and diphenhydramine are often used but produce drowsiness. Nonsedating antihistamines are popular, but prescribers must be aware of potential interactions with concurrent medications. H_1- and H_2-blockers may be combined as needed. Systemic steroids are usually not indicated unless there is airway involvement or anaphylaxis.

Erythema Multiforme

Erythema multiforme (EM) is a distinct hypersensitivity eruption that has numerous implicated etiologies but is most often associated with HSV infection. Additional etiologies include other infections, and less commonly medications (Table 48.12). This self-limited condition lacks internal organ involvement and has minimal complications. EM may not be preceded by a clinically recognizable herpetic lesion, but PCR and in situ hybridization techniques have demonstrated HSV DNA and antigens in the lesions of EM.

The clinical picture in EM may be variable. The typical lesion in EM is an erythematous papule with a dusky, purpuric, or necrotic center (Fig. 48.17). The lesions are described as targetoid with concentric zones of color change: a dusky center or blister, a peripheral ring of pale edema, and an erythematous halo. Some lesions may not demonstrate the characteristic concentric changes, and the appearance of the lesions may be variable depending on the stage at which the lesion is visualized. Lesions start as red macules or urticaria and expand to form the target appearance. The Koebner phenomenon may be seen with lesions occurring in areas of injury. The lesions present abruptly and symmetrically. They are commonly distributed on the upper extremities and may appear on the dorsa of the hands, feet, palms, and soles (Table 48.10).

Erythema multiforme minor is often differentiated from *erythema multiforme major*. EM minor consists of mainly cutaneous lesions with 0-1 areas of mucosal involvement, typically orolabial. EM major has a similar cutaneous eruption with 2 or more sites of mucosal involvement with more extensive oral involvement. The mucous membranes most commonly involved are the conjunctiva and oral mucosa. Patients with EM major associated with *Mycoplasma* infection usually have

FIGURE 48.16 Acute urticaria. Giant annular urticaria with large, bizarre shapes. (From Lee AD, Jorizzo JL. Acute urticaria. In: *Dermatologic Signs of Internal Disease*. 2009:53-62.)

TABLE 48.10 **Urticaria Versus Erythema Multiforme**	
Urticaria	**Erythema Multiforme**
Transient lesions: usually last for hours	Fixed lesions: lasting several days in the same location
Asymmetric, variable, and bizarre shapes	Usually round or oval
No epidermal change: may have central clearing	Epidermal change: usually central necrosis, duskiness, blistering or crusting
Continued appearance of new lesions	All lesions present within 1st few days
Associated edema of hands/feet, eyelids	No edema
Generalized	Acral distribution

TABLE 48.11 Etiology of Acute and Chronic Urticaria

Etiology of Acute Urticaria	
Foods	Eggs, milk, wheat, peanuts, tree nuts, soy, shellfish, fish, strawberries, food additives (direct mast cell degranulation)
Medications	Suspect all medications, even topical, nonprescription or homeopathic (examples include penicillin, aspirin, sulfonamides, codeine)
Insect stings	Hymenoptera (honeybee, yellow jacket, hornets, wasp, fire ants), biting insects (papular urticaria)
Infections	Bacterial (streptococcal pharyngitis, *Mycoplasma*, sinusitis); viral (hepatitis, mononucleosis [Epstein–Barr virus], coxsackieviruses A and B); fungal (dermatophytes, *Candida*); parasitic (*Ascaris, Ancylostoma, Echinococcus, Fasciola, Filaria, Schistosoma, Strongyloides, Toxocara, Trichinella*)
Contact allergy	Latex, pollen, animal saliva, nettle plants, caterpillars
Transfusion reactions	Blood, blood products, or IVIG administration
Etiology of Chronic Urticaria	
Idiopathic/ autoimmune	Approximately 30% of chronic urticaria cases are physical urticaria and 60–70% are idiopathic. Of the idiopathic cases approximately 35–40% have anti-IgE or anti-FcεRI (high-affinity IgE receptor α chain) autoantibodies (autoimmune chronic urticaria)
Physical	Dermatographism Cholinergic urticaria Cold urticaria Delayed pressure urticaria Solar urticaria Vibratory urticaria Aquagenic urticaria
Autoimmune diseases	Systemic lupus erythematosus Juvenile idiopathic arthritis Thyroid (Graves, Hashimoto) Celiac disease Inflammatory bowel disease Leukocytoclastic vasculitis
Autoinflammatory/ periodic fever syndromes	NOMID (neonatal-onset multisystem inflammatory disease) Muckle-Wells syndrome Familial cold autoinflammatory syndrome Cold urticaria, immunodeficiency, autoimmunity as a result of *PLCG2* deficiency
Neoplastic	Lymphoma Mastocytosis Leukemia
Angioedema	Hereditary angioedema (autosomal dominant inherited deficiency of C1-esterase inhibitor) Acquired angioedema Angiotensin-converting enzyme inhibitors

IVIG, intravenous immunoglobulin.

TABLE 48.12 Precipitating Factors in Erythema Multiforme-Like Reaction*

Infection (90% of cases)	Viral	**Herpes simplex virus (HSV-1, HSV-2)** Parapoxvirus Vaccinia (smallpox vaccine) Varicella-zoster virus Adenovirus Epstein–Barr virus Cytomegalovirus Hepatitis virus Coxsackievirus Parvovirus B19 Human immunodeficiency virus
	Bacterial	***Mycoplasma pneumoniae*** *Chlamydophila (formerly Chlamydia) psittaci* *Salmonella* *Mycobacterium tuberculosis*
	Fungal	*Histoplasma capsulatum* Dermatophytes
Medications		Nonsteroidal antiinflammatory drugs Sulfonamides Anticonvulsants Other antibiotics Allopurinol
Exposures (unusual)		Poison ivy
Systemic disease (rare)		Inflammatory bowel disease Lupus erythematosus Behçet disease

*Most common causes are bolded.

lesions in a predominantly acral distribution, and the eruption tends not to be as generalized as in SJS.

Histopathologic study of the lesions usually demonstrates a perivascular lymphocytic infiltrate with individual keratinocyte necrosis. There may be vacuolar degeneration of the basal layer, spongiosis, papillary dermal edema, and junctional or subepidermal cleft formation. In general, patients with EM major tend to have increased inflammation and decreased epidermal necrosis in comparison with patients with SJS.

The disease is usually self-limited and necessitates supportive treatment with analgesics, topical steroids, and antihistamines for symptomatic relief. Systemic steroids are not indicated. Lesions often heal within 1-3 weeks and may leave residual hyperpigmentation. In children with recurrent HSV-associated EM, antivirals may prove helpful. Antimicrobial treatment is warranted if *M. pneumoniae* is diagnosed.

Stevens–Johnson Syndrome/Toxic Epidermal Necrolysis Complex

Most authorities consider SJS and TEN to be part of a continuum of disease. They are severe reactions most often elicited by medications with frequent internal organ involvement and an increased incidence of complications and sequelae. SJS and TEN differ in the severity of body surface involvement. In SJS, there is less than 10% body surface involvement; with 10-30% body surface involvement, the condition is labeled *SJS/TEN overlap*; and TEN refers to cases with more than 30% body surface involvement.

FIGURE 48.17 Target lesions of erythema multiforme with characteristic dusky centers on the palms *(A)* and dorsum of the hand *(B)*. (*A,* From Kliegman RM, et al. *Nelson Textbook of Pediatrics.* 20th ed. Philadelphia: Elsevier; 2015:3142; *B,* From Bolognia JL, et al. Erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. In: Bolognia JL, et al. *Dermatology Essentials.* Elsevier; 2014: 140-150).

SJS is a unique hypersensitivity reaction. Although many factors have been implicated in the origin of SJS/TEN, medications are the most common causes in children. In particular, sulfonamides, anticonvulsants (phenytoin, carbamazepine, lamotrigine, phenobarbital), and NSAIDs are cited as some of the most common triggers. The nature of the reaction is not clearly understood, but it is believed to be a cytotoxic immune reaction aimed at the destruction of keratinocytes expressing drug-related antigens. In children, infections are also associated with SJS. Classifications such as ***Mycoplasma pneumoniae-associated mucositis*** have been used when children have documented *M. pneumoniae* infection with predominant mucosal involvement and limited SJS/TEN cutaneous involvement.

SJS usually begins with a nonspecific prodrome followed by generalized blisters, erosions, erythema, and hemorrhagic crusting of mucous membranes of the mouth, nose, eyes, and/or genitalia as well as the trunk and extremities (Fig. 48.18). At least 2 mucous membranes must be involved to establish this diagnosis. Lesions are usually roundish, irregularly shaped, and less targetoid with numerous erythematous to violaceous macules and papules with dusky centers. The macules may then quickly progress to bullae with skin necrosis. Involvement usually begins more proximally, with a predilection for the face, chest, and neck. There is a striking tendency for coalescence, reminiscent of a diffuse erythema. The eruption in SJS is more generalized and tends to be more truncally distributed than that of EM major.

Histopathologic findings in SJS are characterized by prominent epidermal necrosis with minimal inflammation. Epidermal injury and subepidermal separation may be observed. Spongiosis and dermal edema are usually absent.

TEN is the most severe hypersensitivity reaction, with an estimated mortality rate of 5-20%. Patients experience tender erythema of the skin that progresses rapidly to blistering and subsequent denudation. Malaise and prolonged fever often accompany these skin changes. Sheets of necrotic epidermis may slough off and leave denuded patches in areas of pressure, such as the back and shoulders. Mucous membranes are typically involved, and lesions are similar to those seen in SJS with flaccid, hemorrhagic blisters. In severe cases of TEN, sheets of necrotic epidermis may include skin appendages such as fingernails and toenails.

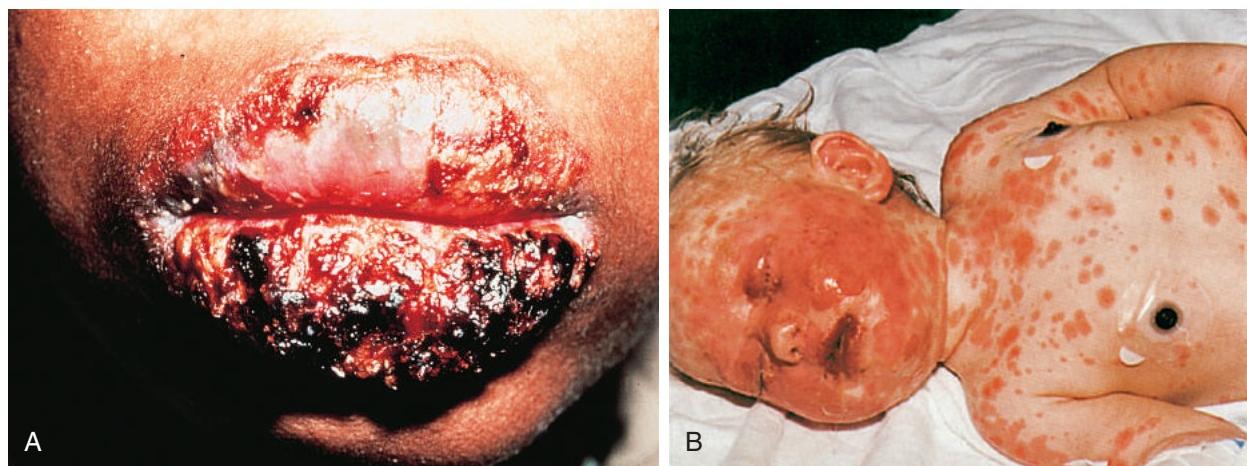

FIGURE 48.18 *A,* Erosions and crusting of the lips in Stevens–Johnson syndrome. *B,* Widespread blistering and erosions of the skin and mucous membranes. (From Vesicopustular eruptions. In: Cohen BA, ed. *Pediatric Dermatology.* Philadelphia: Saunders; 2013.)

Systemic signs such as fever, weakness, and arthralgia occur commonly. SJS/TEN may be complicated by dehydration, electrolyte imbalance, and bacterial infection or sepsis. TEN is often accompanied by a systemic toxic state with increased morbidity and mortality. Generalized lymphadenopathy and hepatosplenomegaly may be present. Internal organ involvement, manifesting as tracheal and bronchial symptoms, pneumonitis, hepatitis, acute kidney injury, myocarditis, confusion, and coma, can be prominent in TEN.

Supportive therapy is the mainstay of treatment. Some physicians believe that systemic corticosteroids are helpful in SJS/TEN, although this remains a topic of controversy as studies have not shown it to be efficacious with reports of increased morbidity and mortality. Removal of the offending medication or triggering factor is of utmost importance. Careful *ophthalmologic* monitoring is necessary because corneal scarring may lead to blindness. Affected patients are cared for as if they sustained a severe burn; fluid and electrolyte balance, temperature control, protein loss, and prevention of infection are serious concerns. Affected children usually require initial management in a pediatric intensive care unit or burn center. Intravenous immunoglobulin (IVIG) may be considered because its use has shown some improved outcomes.

With meticulous supportive care, most children survive; however, there is a high morbidity. Poor prognostic factors include neutropenia, impaired renal function, and extensive skin lesions. Recovery is slow; skin lesions require several weeks to heal, depending on the extent of involvement. Scarring and stricture formation may occur at mucosal sites, as well as postinflammatory hypo- or hyperpigmentation.

Allergic Contact Dermatitis

Allergic contact dermatitis is an example of a type IV delayed hypersensitivity reaction. This T cell–mediated immune response occurs after contact of the responsible antigen with the skin. The reaction becomes apparent 7-14 days after the 1st antigenic exposure. Future contact with the same antigen provokes an inflammatory response within hours to 1-3 days.

Acute contact dermatitis is usually characterized by the sudden onset of erythema, vesiculation, edema, and intense pruritus. Chronic contact dermatitis results in the development of lichenification, scaling, and hyperpigmentation and can be complicated by secondary bacterial infection. **Poison ivy** is the most common cause of allergic contact dermatitis (*Rhus* dermatitis) in the United States. Direct contact of the skin with the sap of poison ivy, oak, or sumac may result in dermatitis. Contact with clothing or pets that have been exposed to the plant resin or smoke from the fire of such plants being burned are other forms of exposure. The eruption is usually seen as linear vesicles and papules or plaques. The spread to body sites is caused by exposure to the plant resin, not by the blister fluid. Therefore, scratching affected skin or contact with affected individuals should not result in spreading of the eruption. Other common forms of allergic contact dermatitis result from exposure to cosmetics, fragrances, hair dyes, and nickel.

Nickel dermatitis often results from prolonged contact with the nickel in jewelry or belt buckles (Fig. 48.19). The eczematous changes are usually localized to the sites of contact, including the earlobes, neckline, wrists, and waistline, although generalized lichenoid papular id reactions have been described. The diagnosis of contact dermatitis can usually be determined from history and clinical examination findings. The distribution of linear or well-demarcated areas may be helpful in confirming the diagnosis. When allergic contact dermatitis is suspected but the responsible agent is unclear, patch testing with a selected group of antigens may provide useful information. Prevention of future exposure to inciting antigens is necessary.

FIGURE 48.19 Nickel contact dermatitis. Wrist lesions in the distribution of the nickel bracelet clasp. (From Cohen BA, Davis HW, Gehris RP. Dermatology. In: Zitelli BJ, et al, eds. *Atlas of Pediatric Physical Diagnosis*. Philadelphia: Saunders; 2012:299-368.)

Usually, treatment with topical corticosteroids, emollients, and antihistamines is sufficient to control the eruption. However, widespread dermatitis or severe involvement of the face may necessitate administration of systemic corticosteroids. Wet compresses with aluminum acetate aid in the drying of weeping, vesicular lesions and provide symptomatic relief.

BULLOUS LESIONS

Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome (SSSS) (Table 48.13) is an exfoliative dermatitis produced by staphylococcal epidermolytic toxins associated with *S. aureus* phage group II. The condition is most common in children younger than 5 years. The condition may be localized, as in the case of bullous impetigo, or become more generalized as the result of hematogenous spread of the epidermolytic toxin from localized sites of infection. The diagnosis of SSSS should be considered in children with generalized tender erythema. The onset of the erythema may be preceded by fever, skin tenderness, malaise, and irritability. The initial sites of involvement are the flexural (neck, groin, and axillae) and periorificial skin. Circumoral erythema with radial crusting and fissuring around the mouth, eyes, and nose is characteristic (Fig. 48.20). A positive **Nikolsky sign**, the ability to laterally spread a blister or slough the skin with the application of light tangential pressure, is seen in most cases. Flaccid bullae, sheets of desquamating skin, or moist red erosions may be present, with the desquamation phase typically beginning 2-5 days after the onset of erythema. Healing without residual scarring occurs within 1-2 weeks. Patients may have conjunctivitis and superficial lip erosions, but in contrast to SJS or TEN, the mucosal surfaces are usually unaffected. The diagnosis is usually established from the clinical presentation. *S. aureus* may be isolated from a minority of blood cultures. The organism is more likely to be isolated from distant sites, such as the nares, throat, and conjunctivae, than from the bullae themselves. In some children, the toxin may be produced by an underlying infection, such as pneumonia, osteomyelitis, or septic arthritis.

Oral antibiotics may be indicated in localized SSSS. Children with widespread involvement usually require hospitalization and treatment with intravenous antistaphylococcal antibiotics with antibiotic choice

TABLE 48.13 Childhood Skin Eruptions Categorized by Etiology

Entity	Clinical Clues	Entity	Clinical Clues
I. Hereditary		E. Dermatitis herpetiformis	Intensely pruritic Associated with Celiac disease Extensor surfaces of elbows, knees, buttocks, shoulders, neck Hemorrhagic lesions on palms and soles DIF shows granular deposition of IgA in dermal papillae
A. Epidermolysis bullosa (AR, AD)	Bullae at birth in more severe forms Localized or widespread Dystrophic nails in some forms Bullae induced by trauma, friction; may occur spontaneously Mucosal involvement in severe forms		
B. Incontinentia pigmenti (X-linked recessive)	Crops of blisters at birth or early infancy Often linear May have coexistent streaky hyperpigmentation Eosinophilia Associated CNS, dental, ocular, cardiac, skeletal abnormalities Girls affected; boys may have Klinefelter syndrome	**III. Infectious** **A. Bacterial** 1. Staphylococcal scalded skin syndrome (SSSS)	Generalized, tender erythema Positive Nikolsky sign Occasionally associated with underlying infection such as osteomyelitis, septic arthritis, pneumonia Desquamation, moist erosions observed More common in children <5 yr of age
C. Porphyria cutanea tarda (AD or acquired)	On dorsal hands, other sun-exposed skin Heal with milia formation Increased fragility of skin Hypertrichosis	2. Bullous impetigo	Localized SSSS Transparent flaccid bullae initially, then moist erythematous shallow erosions once bullae disrupted Covered sites of trunk and perineum likely, can occur on face and extremities
D. Epidermolytic hyperkeratosis (bullous congenital ichthyosiform erythroderma) (AD)	Bullae within the 1st wk after birth Verruciform scales on flexural surfaces Hyperkeratosis after the 3rd mo Collodion membrane at birth in some cases	**B. Viral** 1. Herpes simplex virus	Grouped vesicles on erythematous base May be recurrent at the same site: lips, eyes, cheeks, hands Reactivated by fever, sunlight, trauma, stress Positive Tzanck smear, herpes PCR
II. Autoimmune A. Linear IgA disease (chronic bullous disease of childhood)	Onset usually before the age of 6 yr Sites of predilection: perioral, periocular, lower abdomen, buttocks, anogenital region Annular or rosette configuration of tense blisters: "cluster of jewels" Mucous membranes commonly involved Spontaneous remission DIF shows linear deposits of IgA at DEJ	2. Varicella	Crops of vesicles on erythematous base: "dewdrops on rose petal" Highly contagious Multiple stages of lesions may be present simultaneously Associated with fever Positive Tzanck smear, varicella-zoster PCR
B. Bullous pemphigoid	Large, tense subepidermal bullae Lower abdomen, thighs, face, flexural areas Oral lesions common; rare in children DIF shows linear deposits of C3 and IgG at DEJ	3. Herpes zoster	Grouped vesicles on erythematous base, limited to 1 or several adjacent dermatomes Usually unilateral Burning, pruritus Positive Tzanck smear, varicella-zoster PCR Thoracic dermatomes most commonly involved in children
C. Pemphigus vulgaris	Flaccid bullae, persistent erosions Seborrheic distribution Mucosal involvement very common, usually the initial manifestation Positive Nikolsky sign DIF with intercellular (desmosomal) deposits of IgG, C3	4. Hand-foot-mouth syndrome (coxsackievirus)	Prodrome of fever, anorexia, sore throat Oval blisters in acral distribution, usually few in number classically, but more generalized eruptions or concentration in the diaper area may be seen Shallow oval oral lesions on erythematous base Highly infectious Peak incidence: late summer, fall
D. Pemphigus foliaceus	Small flaccid bullae or shallow erosions with scaling, crusting Back, scalp, face, upper chest, abdomen; photodistribution Oral lesions uncommon May resemble a generalized exfoliative dermatitis DIF shows intercellular deposition of IgG, C3 in superficial epidermis

TABLE 48.13 Childhood Skin Eruptions Categorized by Etiology—cont'd

Entity	Clinical Clues	Entity	Clinical Clues
C. Fungal		**V. Extrinsic**	
1. Tinea corporis	Annular scaly plaques, usually with central clearing Pustule formation common Positive KOH, fungal culture Vesicles and erosions on instep	A. Contact dermatitis	Irritant or allergic Distribution dependent on the irritant/allergen Distribution helpful in establishing diagnosis
2. Tinea pedis	Interdigital fissuring Positive KOH, fungal culture Burrow formation	B. Insect bites	Occur occasionally after flea or mosquito bites May be hemorrhagic bullae Often in linear or irregular clusters Very pruritic
D. Scabies	Interdigital web spaces, genitalia, ankles, lower abdomen, wrist Intensely pruritic; vesicles on palms and soles Very contagious Positive scabies preparation	C. Burns	Irregular shapes and configurations May be suggestive of abuse Vary from 1st–3rd degree; bullae with 2nd and 3rd degree
		D. Friction	Usually on acral surfaces May be related to footwear Often activity related
IV. Hypersensitivity		**VI. Miscellaneous**	
A. Erythema multiforme (EM) major (Stevens–Johnson syndrome [SJS])	Prodrome of fever, headache, malaise, sore throat, cough, vomiting, diarrhea EM major with involvement of 2 mucosal surfaces; hemorrhagic crusts on lips usually present Target lesions progress from central vesiculation to extensive epidermal necrosis; sheets of denuded skin may be present SJS has <10% body surface involvement Associated with infection (e.g. HSV, *Mycoplasma*), medications	A. Urticaria pigmentosa	Positive Darier sign Coexistent pigmented lesions Usually manifests during infancy Dermatographism commonly seen
B. Toxic epidermal necrolysis	Possible extension of SJS involving >30% of body surface Severe exfoliative dermatitis Affects older children, adults Frequently related to medications (e.g., sulfonamides, anticonvulsants) Positive Nikolsky sign	B. Miliaria crystallina	Seen in the setting of fever or overheating Clear, 1–2-mm superficial vesicles occurring in crops, rupturing spontaneously Intertriginous areas, especially the neck and axillae

AD, autosomal dominant; AR, autosomal recessive; C, complement; CNS, central nervous system; DEJ, dermoepidermal junction; DIF, direct immunofluorescence; HSV, herpes simplex virus; IgA and IgG, immunoglobulins A and G; KOH, potassium hydroxide; PCR, polymerase chain reaction.

to be based on local resistance patterns given the emergence of MRSA. Clindamycin may be added to inhibit bacterial protein (toxin) synthesis. Supportive management should be undertaken with close monitoring for fluid and electrolyte imbalances, signs of sepsis, or underlying focal infections. The skin should be handled very carefully. Aluminum acetate wraps may be used with skin care and adhesive bandages should be avoided. Application of an emollient in the desquamation phase may help lubricate the skin and reduce discomfort. Pain control is frequently necessary. The prognosis is good in immunocompetent children.

Epidermolysis Bullosa

Epidermolysis bullosa is a heterogeneous group of inherited blistering disorders characterized by spontaneous and posttraumatic bulla formation. It is estimated to occur in approximately 1 in 50,000 births; the severe variants are seen less frequently. There are several distinct variants that are distinguished by the inheritance pattern, cutaneous manifestations, histologic findings, and ultrastructural abnormalities.

In **epidermolysis bullosa simplex (EBS)**, the level of blister cleavage is intraepidermal (see Fig. 48.3). This form results from a defect in the basal cell keratins 5 and 14, which have been localized to chromosomes 12 and 17, respectively, and are necessary for epidermal integrity. Most of the simplex forms are relatively mild and are autosomal dominant conditions. Bullae formation may be localized or generalized, but it is usually worst in areas of frequent trauma, such as the hands, feet, and joints.

In the **localized form of EBS** (formerly *Weber–Cockayne*), blisters are usually confined to the hands and feet and develop after significant friction or trauma. This form may not become apparent until adolescence or adulthood and may manifest after strenuous activities such as hiking, military training, or golf. There are also generalized forms of EBS in which the bullae are much more extensive and usually apparent at birth and during early infancy. In general, the various EBS subtypes are characterized by bullae that heal without scarring, mild or no nail changes, and minimal mucosal involvement. There are usually no associated extracutaneous manifestations.

In **junctional epidermolysis bullosa (JEB)**, the cleavage plane occurs at the level of the lamina lucida of the dermoepidermal junction. The junctional form is transmitted in an autosomal recessive mode of inheritance. There is a wide spectrum of subtypes, including

FIGURE 48.20 Staphylococcal scalded skin syndrome. Perioral crusting and generalized tender erythematous skin with areas of desquamation. (From Vesicopustular eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:104-125.)

Herlitz and non-Herlitz types, ranging from moderate involvement to a more severe, potentially fatal variant. The majority of JEB subtypes results from defects in the protein laminin 5, which is localized to the anchoring filaments, fibrillar structures within the lamina lucida. Other JEB variants occur as the result of mutations in collagen XVII, an important component of the hemidesmosome. There are subsets of epidermolysis bullosa associated with pyloric atresia classified under both EBS and JEB resulting from altered expression of plectin and $\alpha_6\beta_4$ integrin, respectively. Ureterovesical obstruction may produce recurrent urinary tract infections. Most forms are clinically apparent at birth.

In general, there are widespread bullae that heal with atrophy, not scarring. Dysplastic nails, severe oral lesions, and enamel dysplasia are usually seen. The most severe variant has been referred to as JEB, **generalized severe** (formerly junctional epidermolysis bullosa, Herlitz type). Often fatal by 2 years of age, this variant is characterized by exuberant granulation tissue on the face and around the mouth. Extracutaneous manifestations include pyloric atresia, chronic anemia, and laryngeal involvement that often necessitate tracheostomy.

In **dystrophic epidermolysis bullosa (DEB)**, tissue separation occurs below the dermoepidermal junction at the level of the lamina densa. The lamina densa is made up of anchoring fibrils composed of type VII collagen. Individuals with the dystrophic form have qualitative or quantitative abnormalities caused by mutations in the gene for type VII collagen. DEB is further separated into variants that may be inherited in either an autosomal dominant or recessive pattern. They are usually apparent at birth; there is a wide array of clinical manifestations, but the condition is generally characterized by nail dystrophy and generalized blisters that heal with scarring and milia formation. In the more severe recessive dystrophic form, affected individuals usually have severe interdigital scarring, which results in syndactyly between fingers and eventual encasement of fingers and thumbs known as the mitten deformity. Severe mucosal involvement is a constant feature of recessive DEB, and esophageal stenosis and obstruction

are significant causes of morbidity and mortality. Chronic malnutrition, growth failure, and increased susceptibility to infection may lead to sepsis and death in children with this epidermolysis bullosa subset. Affected patients have multiple extracutaneous manifestations, as well as a very high frequency of aggressive and recurrent squamous cell carcinomas. The dominant dystrophic forms are usually more localized and have a better prognosis than does recessive DEB.

It is usually impossible to distinguish the variants of epidermolysis bullosa on the basis of clinical manifestations alone; skin biopsies are generally necessary. Immunofluorescence antigen mapping (IFM) and/or transmission electron microscopy on newly induced blisters are used to begin to classify epidermolysis bullosa subtypes. Monoclonal antibodies directed toward the skin basement membrane zone and epidermal antigens may provide further data. Mutational analysis directed by the results of IFM is recommended for the most precise subclassification.

Treatment modalities are dependent on the severity of the particular variant. In general, the emphasis is on wound care, prevention of infection, and prevention of mechanical factors likely to induce blister formation. Topical antibiotics and nonadhesive semipermeable dressings may be necessary for recalcitrant wounds. All adhesives should be avoided. In patients with the severe variants of epidermolysis bullosa, a multidisciplinary approach is imperative and should focus on preventive care. All affected patients should undergo genetic counseling.

PURPURA AND PETECHIAE

Purpura results from leakage of blood from vessels into the skin or mucous membranes associated with diverse causes (Table 48.14). Purpuric lesions do not blanch when pressure is applied. Small lesions that are pinpoint-sized or a few millimeters in diameter are called **petechiae**. Large lesions may be referred to as *ecchymoses*. Raised or palpable purpura is diagnostic of vasculitis and can be seen in conditions such as Henoch–Schönlein purpura (HSP), lupus erythematosus, and Rocky Mountain spotted fever. Inflammation and destruction of blood vessel walls are responsible for the raised quality of these lesions. Nonpalpable purpura can be seen with platelet abnormalities, leukemia, and other thrombocytopenic conditions (see Chapter 38), capillaritis (pigmented purpuras), scurvy, viral exanthems, and physical exertion. Petechiae on the upper body (above the nipple line) can result from crying, vomiting, or coughing. Careful clinical examination is important for detecting these lesions and establishing a proper diagnosis.

Henoch–Schönlein Purpura

HSP is a small-vessel vasculitis that usually occurs in children and young adults with most cases occurring between 3 and 10 years (Table 48.15). HSP is the most common vasculitis of childhood. It is a leukocytoclastic vasculitis and is characterized by perivascular immunoglobulin A deposition in affected tissues. The skin, joints, kidneys, and gastrointestinal tract can be involved. Given the seasonality and frequency of preceding upper respiratory infections, bacterial (such as streptococcal infections) and viral etiologies are suspected, although the precise nature of the pathogenesis is unclear.

The classic presentation is that of **nonthrombocytopenic palpable purpura** predominately on the lower extremities and buttocks (Fig. 48.21). However, urticarial and ecchymotic lesions may appear as well. Hemorrhagic bullae and ulcerations can also be present. Edema of the hands, feet, genitalia, and face is common. Systemic involvement is present in approximately two-thirds of affected patients with abdominal pain from bowel angina and arthritis or arthralgias occurring as the most common extracutaneous symptoms. Arthritis most frequently affects the lower extremities; joint effusions are rare.

TABLE 48.14   Causes of Purpura

Infections
Rocky Mountain spotted fever
Sepsis
Bacterial endocarditis
Streptococcal infection
Gonococcemia
Meningococcemia
Hepatitis
Atypical measles
Varicella
Parvovirus 19
Epstein–Barr virus

Collagen Vascular Diseases*
Lupus erythematosus
Dermatomyositis
Rheumatoid arthritis
Ehlers–Danlos syndrome

Hematologic Disorders
Idiopathic thrombocytopenic purpura
Acute lymphocytic leukemia
Aplastic anemia
DIC
Thrombotic thrombocytopenic purpura
Clotting factor deficiencies
Warfarin or heparin use
Malignancy

Medications
Aspirin
Corticosteroids
Penicillins
Sulfonamides
Thiazides
Antiepileptics (phenytoin, valproic acid)

Vasculitis
Henoch–Schönlein purpura
Polyarteritis nodosa
Polyangiitis with granulomatosis
Cryoglobulinemia

Other
Scurvy
Trauma

*Usually livedo pattern.
DIC, disseminated intravascular coagulation.

Gastrointestinal features may include vomiting, colicky abdominal pain, nausea, diarrhea, bleeding, and, in rare cases, intussusception or bowel perforation (see Chapter 10). Renal involvement is the most serious complication and can be manifested by hematuria and/or hypertension (see Chapter 20). Patients with HSP require close monitoring for nephritis as renal manifestations can develop several months after diagnosis.

The diagnosis of HSP is usually made on clinical grounds, but a skin biopsy confirms the presence of leukocytoclastic vasculitis in atypical or severe cases. Direct immunofluorescence staining of the skin biopsy specimen reveals immunoglobulin A deposition around the blood vessels in the superficial dermis (Table 48.3).

Treatment includes supportive care and analgesics for joint pains. Systemic corticosteroids may be indicated when there is significant gastrointestinal or joint pain as well as renal involvement, but this treatment remains controversial as it does not alter the renal prognosis. Systemic corticosteroids are generally not indicated for skin involvement alone. The clinical course is characterized by acute onset of cutaneous lesions, often associated with fever and malaise. Systemic symptoms usually last for several weeks. Recurrences are common, but spontaneous resolution almost always occurs. The prognosis is excellent, with the primary factor being the extent of renal involvement. Mortality is rare and is usually caused by chronic renal disease.

HAIR LOSS

Alopecia (hair loss) is the most common hair abnormality seen in children. Hair loss can have a number of presentations ranging from focal patches to diffuse thinning. An accurate history alone can often lead to a presumptive diagnosis. Information regarding duration of loss, rate of shedding, medications, trauma, family history of hair disorders, symptoms such as pruritus or burning, breakage, and hair care is particularly important. The scalp should be examined for the pattern and distribution of hair loss, erythema, scaling, scarring, pustules, and crusts. Abnormal or broken hairs, as well as texture, length, and color should be noted. Associated abnormalities of the teeth, nails, and sweat glands may occur. Hair pulls (gentle pulling on small tufts of hair) and microscopic examination of removed hairs should be performed. Appropriate tests (KOH, fungal culture, scalp biopsy) may be necessary to confirm the clinical suspicions.

Classification of alopecia is somewhat arbitrary, but it is helpful to determine whether hair loss is acquired or congenital and localized or diffuse. Congenital alopecia usually results from aplasia cutis, intrauterine injury, or nevus sebaceous. Five common disorders responsible for most cases of childhood hair loss are (1) alopecia areata, (2) tinea capitis, (3) traction alopecia, (4) trichotillomania, and (5) telogen effluvium.

Alopecia Areata

Alopecia areata is a common disorder that affects all ages, particularly children. Although several hypotheses have been proposed, it is generally thought to be an autoimmune condition linked to specific genetic mutations. There is a family history of alopecia areata for approximately 20% of affected individuals. Clinically, there is acute onset of hair loss that is occasionally preceded by burning or itching of the scalp. In most cases, well-demarcated, localized areas of alopecia result, and the scalp is usually normal without epidermal changes. The **exclamation point hairs** are pathognomonic and are caused by breakage of abnormally growing hairs. Exclamation point hairs, when pulled out, appear as a tapered or attenuated bulb secondary to atrophy of that portion. When the disease is active, dystrophic anagen hairs can be easily pulled from the periphery of lesions. Nail pitting, often seen in rows, is seen in some cases. Factors that portend a poor prognosis for regrowth include extensive loss, early onset, nail involvement, atopic background, and an ophiasis pattern (involvement of the temporal and occipital hairline).

Treatment consists of topical, intralesional corticosteroids; topical minoxidil; anthralin; and sensitization to contact allergens. Other supportive measures include camouflage, hairpieces, and support groups. In some cases, hair regrows without medical intervention. Although the course is unpredictable, about half of affected patients have a recurrence.

TABLE 48.15 Types of Vasculitis and Associated Skin Lesions

Type of Vasculitis	Blood Vessels Involved	Type of Skin Lesion
Leukocytoclastic or hypersensitivity angiitis: Henoch–Schönlein purpura, cryoglobulinemia, hypocomplementemic vasculitis	Dermal capillaries, venules, and occasional small muscular arteries in internal organs	*Purpuric papules*, hemorrhagic bullae, cutaneous infarctions
Rheumatic vasculitis: systemic lupus erythematosus, rheumatoid vasculitis	Dermal capillaries, venules, and small muscular arteries in internal organs	*Purpuric papules*: ulcerative nodules; splinter hemorrhages; periungual telangiectasia and infarctions
Granulomatous vasculitis Churg–Strauss allergic granulomatous angiitis	Dermal small and larger muscular arteries and medium muscular arteries in subcutaneous tissue and other organs	Erythematous, *purpuric*, and ulcerated nodules, plaques, and *purpura*
Granulomatosis with polyangiitis (Wegener)	Small venules, arterioles of dermis, and small muscular arteries	Ulcerative nodules, peripheral gangrene
Periarteritis: classic type limited to skin and muscle	Small and medium muscular arteries in deep dermis, subcutaneous tissue, and muscle	Deep subcutaneous nodules with ulceration; livedo reticularis; *ecchymoses*
Giant cell arteritis: temporal arteritis, polymyalgia rheumatica, Takayasu disease	Medium muscular arteries and larger arteries	Skin necrosis over scalp

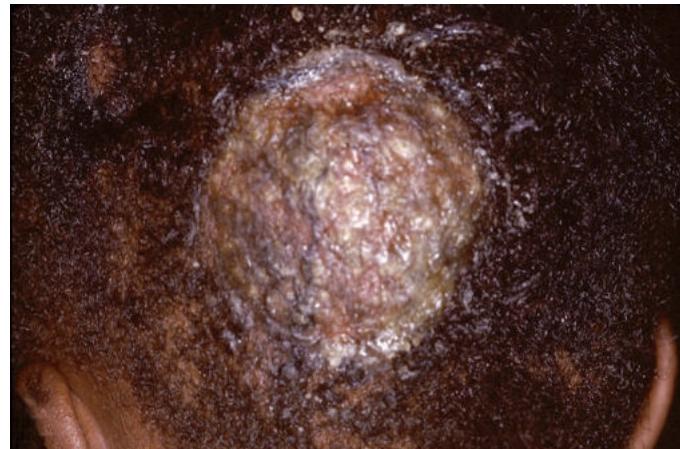

FIGURE 48.22 Boggy, purulent mass of the scalp typical of kerions. (From Kliegman RM, et al. Cutaneous fungal infections. In: Kliegman RM, *Nelson textbook of pediatrics*. 20th ed. Philadelphia: Elsevier; 2015:3215.)

Tinea Capitis

Tinea capitis (**ringworm**) is another common cause of alopecia in children, although it may not always be associated with hair loss or breakage. The "seborrheic" type of tinea capitis is manifested by diffuse scaling without scalp inflammation. Alopecia is often not noted, but broken hairs are occasionally present. This type of alopecia is frequently misdiagnosed as dandruff. Tinea capitis can also manifest as localized scaly patches, kerions, and "black-dot" patches. This latter type features hairs that have broken at the surface of the scalp, resulting in a black-dot appearance. **Kerions** are boggy, inflammatory plaques on the scalp that are caused by hypersensitivity to the offending dermatophyte (Fig. 48.22). Pustules and drainage are common, but the

purulent material is often sterile. Cervical lymphadenopathy, fever, and elevated white blood cell counts may accompany kerions. The differential diagnosis of tinea capitis includes psoriasis, alopecia areata, trichotillomania, folliculitis, and seborrheic dermatitis.

The most common etiologic agent of tinea capitis is *Trichophyton tonsurans*, a dermatophyte that produces endothrix infections. Because spores are not present on the surfaces of the hair shafts, Wood lamp examination is not useful. If, the infection is caused by *Microsporum canis* or another dermatophyte that produces an ectothrix infection, Wood lamp examination results in positive fluorescence (Table 48.2). Fungal cultures should be performed in all suspected cases of tinea capitis. Fungal culture can be performed with a standard toothbrush and Petri dish. KOH preparations can be useful if positive, but false-negative results are common. Some children may be asymptomatic carriers.

Traditional therapy consists of oral griseofulvin for 6-8 weeks. Selenium sulfide 2.5% shampoo or 2% ketoconazole shampoo should be used to decrease surface spores and reduce spread to other individuals. On occasion, there is a secondary bacterial infection that necessitates antibiotic therapy. Kerions typically respond to griseofulvin; but in

severe cases, systemic corticosteroids may be added to decrease inflammation and reduce the risk of scarring. Antifungal agents that may be useful include oral fluconazole, itraconazole, and terbinafine. Incision and drainage are not indicated. A follow-up fungal culture may be obtained to confirm adequacy of treatment.

Traction Alopecia

Traction alopecia is seen in individuals whose hair is tightly braided or pulled into ponytails or cornrows for long periods of time. Chronic tension on the hair shafts leads to breakage and gradual hair loss. Damaging hairstyle procedures such as straightening and waving may also result in hair breakage if performed improperly. On clinical examination, the clinician sees linear areas of hair loss at the part line or throughout the scalp. The alopecia is reversible in most cases. However, if the traction is maintained for years, the alopecia may become permanent secondary to scarring. Treatment is aimed at avoiding all tension-producing trauma. The patient should be advised to stop all hair chemical procedures, wear loose styles with no braids, avoid wearing heavy objects in the hair or ponytails, and handle hair as gently as possible.

Trichotillomania

In trichotillomania, individuals pull, break, or twist hair from the scalp, eyebrows, eyelashes, and/or pubic hair. In younger children, this form of hair pulling is usually a harmless habit that is outgrown. Trichotillomania in older children and adolescents may represent a more serious psychologic problem with a less favorable prognosis. Psychiatric assistance may be required, and the disorder may be refractory to treatment. On physical examination, there are hairs of varying length in bizarre, often geometric, patterns. The occiput is often spared. Hairs have blunt tips because of mechanical breakage. Scalp biopsy may be necessary if the diagnosis is unclear. Treatment is aimed at identifying underlying psychologic stressors. Supportive therapy and psychologic and/or psychiatric evaluation are usually needed.

Telogen Effluvium

Telogen effluvium is characterized by excessive shedding of telogen (resting) hairs. This may result from medications, febrile illness, crash diets, parturition, surgical procedures or anesthesia, endocrine disorders, or severe emotional stress. A large number of growing hairs enters the resting phase, resulting in a 3-fold to 5-fold increase in the number of resting hairs. Gradually, these numerous telogen hairs are shed over 6-24 weeks. Affected individuals notice increased hair loss and sparser scalp hair 2-4 months after exposure to the inciting factor. The prognosis for this type of diffuse alopecia is excellent. Patient education is important, as is reassurance that regrowth can be expected within approximately 6 months. No treatment is indicated.

INFECTIONS AND INFESTATIONS

Impetigo

Impetigo is the most frequently diagnosed bacterial skin infection. It is a contagious superficial skin infection, occurring most often in infancy and early childhood. The 2 major pathogens, *S. aureus* and group A β-hemolytic streptococcus *(Streptococcus pyogenes)*, can cause lesions at any body site.

Nonbullous Impetigo

Nonbullous impetigo accounts for the majority of cases and is secondary to infection with either of the aforementioned pathogens. The lesions of nonbullous impetigo caused by either organism are indistinguishable. The lesions typically arise on the face or extremities after trauma such as insect bites, cuts, and abrasions, or after varicella infection. The primary lesion is usually a vesicle or a pustule that develops secondary changes of honey-colored crusting, the clinical hallmark of this condition. In general, the lesions are smaller than 2 cm and may be single or multiple (Fig. 48.23). Although the lesions are generally asymptomatic with little surrounding erythema, regional lymphadenopathy may be present.

The differential diagnosis includes HSV infections, nummular eczema, varicella, kerions, and scabies, which all may become secondarily infected. Nonbullous impetigo usually resolves spontaneously within 2 weeks. It is highly contagious to other parts of the body and to close contacts, however, and should therefore be treated with appropriate antimicrobial agents.

Bullous Impetigo

Bullous impetigo develops on intact skin and is a localized form of SSSS. The initially transparent flaccid bullae are more likely to occur on covered body sites such as the trunk and perineum than are the lesions of nonbullous impetigo. They can, however, occur on the face and extremities as well. Intact vesicles or bullae may be observed, or moist, erythematous shallow erosions may be the sole clinical finding after disruption of the bullae (Fig. 48.24). Bullous impetigo should be differentiated from early SSSS, herpetic infection, allergic contact dermatitis, burns, EM, and inflammatory bullous diseases.

Impetigo may be treated with topical or oral antibiotics depending on the number and locations of the lesions. Topical antibiotics may be acceptable for localized disease.

Systemic therapy is indicated for streptococcal infections or staphylococcal infections with an extensive number of lesions or more severe soft tissue involvement. One of the more cost-effective 1st-line choices includes cephalexin. However, the incidence of MRSA has increased dramatically and local resistance patterns should be taken into account. If MRSA is suspected, initial medication choices including clindamycin, doxycycline (over age 8 years), or sulfamethoxazole-trimethoprim are recommended. A culture should be obtained and antibiotic choice should be based on sensitivity patterns when available. Recurrent impetigo is often secondary to carriage of *S. aureus*. Although intranasal carriage is common, colonization can also involve the axillae and perineum. Intranasal application of mupirocin may eradicate the

FIGURE 48.23 Multiple honey-colored crusted lesions of impetigo. (From Kliegman RM, et al. Cutaneous bacterial infections. In: Kliegman RM. *Nelson textbook of pediatrics*. 20th ed. Philadelphia: Elsevier; 2015:3203.)

FIGURE 48.24 Thin-walled vesicles and shallow erosions with surrounding erythema seen with bullous impetigo. (From Paller AS, Mancini AJ, eds. *Hurwitz Clinical Pediatric Dermatology*. Philadelphia: Elsevier; 2015:334-359.)

organism; however, recolonization occurs over time. Of note, there are reports of increasing resistance with prolonged use of mupirocin. Dilute bleach baths (sodium hypochlorite) may help reduce recurrent skin infections by decreasing bacterial carriage.

Potential but rare complications of impetigo include pneumonia, cellulitis, osteomyelitis, septic arthritis, and septicemia. More specifically, streptococcal infections can result in scarlet fever, guttate psoriasis, lymphadenitis, and lymphangitis. Furthermore, nephritogenic strains of group A β-hemolytic streptococcus can result in poststreptococcal glomerulonephritis (see Chapter 20). The latency period after impetigo is approximately 3 weeks. Treatment does not prevent poststreptococcal glomerulonephritis but does prevent the spread of the organism to other people.

Molluscum Contagiosum

Molluscum contagiosum, caused by a large DNA poxvirus, is most often seen in children and adolescents. The characteristic well-circumscribed, skin-colored to pearly papules usually arise in crops on the face, trunk, and extremities but have a predilection for the axillary, antecubital, and crural regions (Fig. 48.25). Generally ranging in size from 1-5 mm, these asymptomatic papules have a central umbilication, often with a central core. In some individuals, eczematous changes develop at sites of the molluscum lesions, probably representative of a delayed hypersensitivity response. This so-called "molluscum dermatitis" may be localized or more extensive, is not an uncommon finding, and in fact may be more prominent on examination than the molluscum papules, which are occasionally missed. The associated eczematous dermatitis may resemble nummular eczema or tinea corporis. Molluscum lesions often become inflamed or appear infected shortly before spontaneous involution. The diagnosis is made by the clinical appearance of the lesions. However, skin biopsies or microscopic examination of the cores of the lesions can confirm the diagnosis by revealing molluscum bodies, which are masses of virus-infected epidermal cells. The condition should be differentiated from warts, closed comedones, and milia.

Molluscum contagiosum is both contagious and autoinoculable. The incubation period ranges from 2 weeks to 6 months, and multiple family members are often affected. Immunosuppressed persons are at risk for more aggressive disease, especially patients infected with

FIGURE 48.25 The characteristic umbilicated lesions of molluscum contagiosum. (From Nodules and tumors. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013.)

human immunodeficiency virus. Patients with preexisting atopic dermatitis are also at greater risk for widespread molluscum.

Treatment options include curettage, topical cantharidin, liquid nitrogen, immunotherapy with *Candida* or *Trichophyton* antigen, topical retinoids, and imiquimod cream. Most pediatric dermatologists avoid application of cantharidin to facial or genital lesions because of concerns of a possible aberrant reaction. As with other poxvirus infections, these lesions occasionally result in scarring or pits as the lesions resolve.

Warts

Warts are intraepidermal tumors caused by human papillomavirus (HPV), a small DNA virus. They may be present in up to 10% of the general population. There are more than 200 types of human papillomavirus. The virus produces 4 major types of warts: common, flat, plantar, and genital (condyloma acuminatum). The incubation period generally varies from 1-6 months, depending on HPV type, the size of the inoculum, the site of infection, and the host's immune status. The duration of the wart is variable as well; approximately 65% of the lesions resolve spontaneously within 2 years. Warts can be spread between persons and between body sites by direct or indirect contact. Most warts are located on the fingers, hands, and elbows because trauma to these sites promotes inoculation of the virus. Warts also display the Koebner phenomenon, which results in linear configurations of lesions at sites of shaving or scratching.

Common Warts

Verruca vulgaris, or the common wart, is found most commonly on the dorsal surface of the hands or fingers, although it may be located at any body site. The lesions may be solitary or multiple and measure from several millimeters to more than 1 cm. Varying in color from yellowish-tan to grayish-black, the common wart has a distinct rough, papillated surface. Punctate thrombosed capillaries, clinically manifested as black dots, may be seen on the surface.

Flat Warts

Verrucae plana, or flat warts, are 2- to 5-mm flat-topped papules that are typically skin-colored, tan, or brown. They are distributed on the face, neck, and extremities. They often appear grouped, especially when the Koebner phenomenon has occurred secondary to shaving or other trauma. These lesions are most often confused with lichen planus or lichen nitidus because these disorders also feature flat-topped papules.

Plantar Warts

Verrucae plantaris, or plantar warts, develop on the weight-bearing areas of the toes, heels, and the midmetatarsal region. The lesions are pushed into the skin in such a manner that the verrucous surface is even with the surrounding skin. These warts are often very tender and may produce significant discomfort with ambulation. Plantar warts may be difficult to distinguish from corns and calluses.

Genital Warts

Condylomata acuminata, or genital warts, are fleshy papillomatous growths found on the genitalia. In early or mild cases, the only physical finding may be subtle skin-colored, flat-topped papules. Their growth can be exuberant in some patients when untreated, resulting in cauliflower-like masses. These genital warts should be differentiated from moist papular or nodular lesions of secondary syphilis (condylomata lata). Although nonvenereal transmission may occur, such as spread from cutaneous warts, the presence of genital warts in young children is usually associated with sexual abuse.

Treatment of Warts

Treatment of warts is designed to be cytodestructive and varies depending on the type of wart, site of the lesion, age and immune status of the patient, and extent of involvement. Topical treatments include keratolytic preparations, such as salicylic acid, ammonium lactate, and 5-fluorouracil. In-office treatments include topical cantharidin, cryotherapy with liquid nitrogen, or immunotherapy with *Candida* or *Trichophyton* antigen. In children with numerous warts, cryotherapy may be limited by discomfort and immunotherapy may be preferable. Podophyllin is reserved for the treatment of genital warts because it is most effective on mucosal surfaces. Imiquimod (Aldara) has been approved for the treatment of genital warts, although it is not approved by the US Food and Drug Administration for use in children. Cimetidine has been used in children with multiple lesions that have failed other treatment options. Extremely recalcitrant warts may necessitate surgical or laser (pulsed dye or carbon dioxide) treatment. Multiple or serial treatments may be necessary, and recurrences are common. A conservative approach is often best for this self-limited infection because the treatment may be worse than the condition. Prolonged periods of applying duct tape to the wart (plantar, finger) have also resulted in resolution.

Herpes Simplex Virus

HSV is a large DNA virus that is divided into two major antigenic subtypes. Type 1 (HSV-1) has been traditionally associated with oral and skin nongenital herpes infections; type 2 (HSV-2) is generally responsible for genital and neonatal infections. The clinical lesions are indistinguishable but can be differentiated by serologic tests. HSV infections are categorized as either primary or recurrent. Primary manifestations usually follow an incubation period of approximately 1 week. They range from subclinical infections to localized or generalized vesicular eruptions to life-threatening systemic infections. Primary herpetic infections can involve any cutaneous or mucosal surface.

The classic clinical manifestation consists of grouped thin-walled vesicles on an erythematous base (Fig. 48.26). The lesions usually begin

FIGURE 48.26 A cluster of vesicopustular lesions on an erythematous base in herpes simplex virus. (From Vesicopustular eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:104-125.)

as papules, which evolve into vesicles or, sometimes, pustules within approximately 48 hours. The vesicles rupture and form a crust over the next 5-7 days and generally heal within 2 weeks. The cutaneous eruption is often accompanied by fever, regional lymphadenopathy, or flulike symptoms (Table 48.13).

After the primary infection, the virus remains dormant until reactivated. Recurrent infections are characterized by localized vesicular eruptions and symptoms such as itching or burning at the same site. Recurrent HSV infections are usually less severe than primary herpes. Reactivation of the virus may be triggered by sunburn, cutaneous trauma, febrile illnesses, menstruation, or emotional stress. Oral antivirals, if administered during the prodromal period before the onset of lesions, may abort or shorten recurrent episodes.

Herpetic gingivostomatitis is typically seen in infants and toddlers. Multiple vesicles and subsequent erosions develop on the lips, gingivae, anterior portion of the tongue, or hard palate. The condition is very painful and is often accompanied by inability to eat and drink. Fever, irritability, and cervical lymphadenopathy are frequently observed. The fever typically resolves within 3-5 days, whereas the oral lesions may persist for up to 2 weeks. The lesions may resemble aphthae, which are usually more localized and are not accompanied by systemic symptoms. Enteroviruses may produce similar oral manifestations; however, they tend to spare the gingivae and often affect the posterior pharynx.

The test of choice to confirm the diagnosis of HSV infection is PCR for HSV. Tzanck smear can suggest HSV, but is not specific. Treatment is supportive, with an emphasis on pain control and fluid replacement. Systemic antivirals may hasten resolution of the lesions and shorten the course of the illness.

Neonatal herpes is a potentially fatal infection, often with severe central nervous system involvement. Vigilant evaluation to determine extent of infection, intravenous acyclovir, and supportive care are required. Immunocompromised children who develop a herpetic infection should receive intravenous acyclovir and be monitored carefully for evidence of pulmonary, hepatic, and central nervous system involvement.

Another high-risk group consists of children with underlying atopic dermatitis who, if exposed to HSV, are susceptible to rapid spread of herpetic blisters. This condition, referred to as **eczema herpeticum** or **Kaposi varicelliform eruption**, may be accompanied by fever and malaise (see Atopic Dermatitis). Oral or intravenous antivirals and supportive care are indicated.

Varicella

Varicella (**chickenpox**) is a very contagious, but usually self-limited infection caused by the varicella-zoster virus. Since the introduction

of the varicella vaccine, mild and atypical variants of this disease have been common.

Transmitted by close contact and respiratory droplets, varicella has an incubation period of 10-21 days. The cutaneous manifestation in healthy children is characterized by crops of lesions (usually 2 or 3 crops of 50-100 lesions each) that initially appear as 2- to 3-mm red macules and then evolve through papular, vesicular, and finally pustular stages within approximately 24 hours. The vesicular stage has traditionally been described as resembling "dewdrops on a rose petal" (Fig. 48.27). The presence of lesions in various stages is characteristic of varicella. Varicella lesions often appear first on the scalp, face, or trunk, and then progress to the extremities. All vesicles become crusted and resolve over several days. Chickenpox usually heals without scarring, except for lesions that have been excoriated or secondarily infected. The eruption is usually accompanied by fever, intense pruritus, and malaise (Table 48.13). The exanthem may be more extensive in children with skin disorders.

When the diagnosis is unclear, confirmatory tests include PCR, immunofluorescent staining, and viral culture. A positive Tzanck smear supports the diagnosis but is not specific for varicella. Symptomatic treatment consists of oral antihistamines, aluminum acetate soaks, oatmeal baths, calamine lotion, and cool compresses. Lesions should be observed for signs of secondary bacterial infection. Antiviral therapy is not routinely recommended in otherwise healthy children. Oral antivirals, if given, should be administered within 24 hours of the onset of the eruption. Immunosuppressed individuals usually require intravenous acyclovir.

High-risk individuals (immunosuppressed, immunocompromised, those with malignancies) who have been exposed to varicella should receive gamma globulin prophylaxis as soon as possible. If varicella develops in a pregnant woman within 5 days before delivery or in a mother 48 hours after delivery, the infant should also be treated with gamma globulin prophylaxis. Complications may include visceral organ involvement, coagulopathy, hemorrhage, pneumonia, or encephalitis.

Herpes Zoster

Similar to HSV, the varicella-zoster virus remains dormant in the dorsal root ganglia after initial infection. Reactivation of the virus results in the clinical manifestations of herpes zoster, or shingles. The infection usually manifests as a linear or bandlike papulovesicular eruption affecting 1 or several dermatomes (Fig. 48.28; see also Table 48.13). Commonly, there is a prodrome of burning, pruritus, or pain of the affected skin that may last several days before the appearance of cutaneous lesions. Vesicles become crusted, and all lesions resolve within a few weeks. The most common dermatomes involved are within the thoracic regions. Up to 10 **satellite lesions** may be encountered outside the primary dermatomes in uncomplicated zoster. An increased number of satellite lesions is observed in **generalized zoster**, which carries a greater risk of systemic involvement. Widespread vesicles should raise the suspicion of an underlying immunodeficiency disorder.

Immunocompromised patients, especially children with lymphoreticular malignancies, are at increased risk for zoster and should be treated with either oral or intravenous acyclovir. As with HSV infection, lesions around the eyes, nose, and forehead require careful ophthalmologic examination. Ocular complications occur in approximately 50% of the patients with ophthalmic zoster. The potential for deep keratitis, uveitis, secondary glaucoma, and loss of vision warrants prompt ophthalmologic evaluation. Patients with zoster should avoid contact with high-risk individuals who are susceptible to development of varicella.

Scabies

Scabies is an extremely common eruption. It occurs in persons of all ages and results from infestation of the superficial layers of skin by the human mite *Sarcoptes scabiei*. The infestation is highly contagious and is therefore seen frequently among individuals living in crowded conditions. Humans are the only source of the mite, which can be passed from 1 person to another. Fomites can also play an important role in transmission. In previously unexposed individuals, the incubation period varies from 2-6 weeks. The incubation period is significantly shortened in individuals who have been previously exposed to the mite.

Although the morphologic appearance of scabies can vary dramatically, the hallmark lesion is the burrow. A burrow is a serpiginous or linear papule caused by movement of the mite through the epidermis. Although considered to be characteristic of scabies, the burrow is

FIGURE 48.27 Lesions in various stages of development including the dewdrop on a rose petal appearance characteristic of varicella. (From Vesicopustular eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:104-125.)

FIGURE 48.28 A dermatomal distribution of umbilicated vesicles is characteristic of herpes zoster. (From Vesicopustular eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:104-125.)

apparent in only a minority of patients. Other typical lesions include papules, vesicles, and pustules, the distribution of which is age dependent. Nodules may appear during active infection and may persist for several weeks to months after treatment; these are common in infantile scabies and on the penis and scrotum of affected males. These persistent nodules are referred to as postscabetic nodules and may be a manifestation of an ongoing hypersensitivity response. In infants, the distribution is generalized and involves the trunk, scalp, face, neck, axillae, palms, and soles. Because the eruption is extremely pruritic, secondary infection and eczematization are common, leading to misdiagnoses of impetigo and atopic dermatitis. In affected older children, adolescents, and adults, the lesions characteristically involve the volar aspects of the wrists, ankles, interdigital web spaces, buttocks, genitalia, groin, abdomen, and axillae (Fig. 48.29). Unlike infantile scabies, the lesions always spare the head.

The diagnosis can be confirmed by scraping the newer lesions, ideally a burrow, with a blade after the application of mineral oil. The scraping may be viewed microscopically, and the presence of mites, ova, or feces is considered diagnostic. Although the yield may be low, suspect lesions should be scraped and an attempt to identify evidence of the mite should be made. In prolonged cases of scabies, which have been appropriately treated, the diagnosis of acropustulosis of infancy needs to be considered.

Topical 5% permethrin cream (Elimite) is the treatment of choice for infants over 2 months and children. Permethrin cream is applied to the entire body from the neck down and thoroughly washed off after 8-12 hours. Scalp and neck treatment is often necessary for infants. This treatment should be repeated 1 week later. Lindane is not recommended as 1st-line treatment for scabies because of its potential for neurotoxicity. Six percent sulfur ointment should be used as an alternative therapy in infants younger than 2 months and in pregnant women. Topical and oral ivermectin are options for resistant infestations. Because scabietic lesions are the result of a hypersensitivity reaction, itching may persist for several weeks despite treatment, which can be relieved with emollients, topical corticosteroids, and antihistamines.

It is critical that all household members as well as close contacts be treated simultaneously to prevent reinfestation. All linens and clothes should be washed and dried in an electric dryer because heat kills the mite. Bulkier linens and stuffed toys can be placed in plastic bags for several days. Mites do not survive without a human host for more than 2-3 days.

FIGURE 48.29 Papulopustular eruption of scabies with burrows visible on the palms and wrist of a child. (From Papulosquamous eruptions. In: Cohen BA, ed. *Pediatric Dermatology*. Philadelphia: Saunders; 2013:68-103.)

Pediculosis

Lice are ectoparasitic insects. *Pediculus humanus capitis*, the head louse, causes the most common form of louse infestation. This occurs more often in whites; girls are more susceptible than boys. Because the head louse can survive for more than 2 days off the host's scalp, the condition can be transmitted via shared hats, combs, brushes, towels, or bedding. On physical examination, the nits (ova) can be found close to the scalp on the proximal hair shafts. They appear as small, oval, whitish bodies approximately 0.5 mm in length. They adhere tightly to the hair shaft and are not easily removed. The nits can be more readily identified by their fluorescence under a Wood lamp. Microscopic examination of the proximal hair shaft may further aid in recognition of the nits. The infestation is characterized by intense pruritus, especially at night.

Some sources start treatment of pediculosis capitis with over-the-counter topical application of 1% permethrin shampoo or pyrethrin combined with piperonyl butoxide products, both of which have good safety profiles. However, resistance to these products has been documented. In treatment failures or known resistance, additional topical agents such as malathion 0.5%, benzyl alcohol, spinosad, and ivermectin lotions are options. Oral ivermectin may be used when lice are resistant to all topical agents. However, each agent's recommended age, weight, and safety profile need to be considered.

It is extremely important to wash and dry (on a hot cycle) all exposed bedding and clothing. All combs and brushes should be soaked in the pediculicide for 15 minutes, and all items that cannot be machine-washed with hot water or dry-cleaned should be placed in plastic bags for 2 weeks. All household members should be treated at the same time. Nits must be removed with a fine-toothed comb after application of a damp towel to the scalp.

Candidiasis

Candidal species, particularly *Candida albicans*, may be considered part of the normal cutaneous flora in most individuals. However, predisposing factors such as endocrinologic disorders, genetic disorders, immunosuppressive conditions, and the administration of systemic corticosteroids or antibiotics may allow for overgrowth of this organism and subsequent infection. Candidiasis refers to an acute or chronic infection of the skin, mucous membranes, or internal organs caused by this pathogenic yeast. Other conditions, such as warmth, moisture, and disruption of the epidermal barrier, further promote invasion and overgrowth. Cutaneous candidiasis can have a variety of clinical manifestations, depending on the site of infection. Some of the most common manifestations include (1) oral candidiasis (thrush), (2) candidal diaper dermatitis, (3) vulvovaginitis, and (4) paronychia.

Oral candidiasis is a common condition of infancy and in immunosuppressed individuals. It is characterized by painful inflammation of the oral cavity with multiple, often confluent, white plaques on an intensely erythematous base. The disorder usually responds to treatment with oral nystatin suspension, which is applied to the oral mucosa 4 times daily until 2 days after the lesions have completely resolved. Oral fluconazole is another therapeutic option for more extensive or resistant cases. Extensive involvement or failure to respond to treatment may suggest an underlying immunodeficiency disease. Cutaneous lesions in the intertriginous and diaper areas are frequently coexistent with thrush.

Candidal paronychia manifests with erythema and edema of the proximal and lateral nail folds, which is usually not associated with tenderness, in contrast to acute bacterial paronychia. The nail is often dystrophic, crumbly, and thick. The condition is seen commonly in thumb suckers. Treatment with topical antifungal creams with yeast

coverage, applied nightly under occlusion for several weeks, usually results in clinical resolution.

Dermatophytoses

The dermatophytes are a group of fungi that infect the hair, skin, and nails and result in a collection of clinical syndromes referred to as dermatophytoses. The clinical conditions are referred to as tinea (or ringworm), and the affected body site determines the name of the entity. This group of infections is caused by species of *Trichophyton*, *Microsporum*, and *Epidermophyton*. Dermatophyte infections are usually confined to the epidermis.

Tinea Capitis

Tinea capitis is discussed in the section on alopecia.

Tinea Corporis

Tinea corporis is characterized by 1 or multiple annular erythematous patches that can occur anywhere on the body. The lesions typically have a papular scaly border and demonstrate central clearing (Fig. 48.30). Vesiculation and pustulation, especially peripherally, are commonly observed. The borders are usually sharply demarcated. Identification of fungal hyphae by KOH examination of scrapings of the lesion's scaly border confirms the diagnosis. Psoriasis, nummular eczema, secondary syphilis, the herald patch of pityriasis rosea, and the annular plaques of granuloma annulare may resemble tinea corporis.

Tinea Pedis

Tinea pedis is diagnosed most often in postpubertal adolescents. The clinical manifestation is variable, but multiple vesicles or erosions on the insteps are characteristic. Other findings include fissures and maceration of the web spaces and "moccasin foot" tinea pedis, in which there is generalized scaling of 1 or both soles with extension onto the lateral aspect of the foot. The differential diagnosis includes atopic or contact dermatitis, juvenile plantar dermatosis, psoriasis, and scabies. The clinician should have increased suspicion for tinea pedis if unilateral involvement is present. A positive KOH scraping or fungal culture rules out these other entities.

Tinea Faciei

Tinea faciei, a dermatophyte infection of the face, is commonly seen in children. Erythematous, scaly, and often in a malar distribution, the condition may resemble lupus erythematosus but is less symmetric. Atopic, contact, and seborrheic dermatitis may have similar cutaneous manifestations. Again, the diagnosis can be confirmed by a positive KOH scraping or fungal culture.

Tinea Cruris

Tinea cruris, uncommon before adolescence, is an erythematous, scaly eruption involving the inguinal creases and medial thighs. The eruption is usually symmetric, and sometimes the margins are papular. This infection may resemble candidiasis, in which there is also scrotal erythema. *Erythrasma*, an uncommon superficial bacterial infection caused by *Corynebacterium minutissimum*, may also mimic tinea cruris. The coral red fluorescence seen on Wood lamp examination is diagnostic of erythrasma, which can be further differentiated from tinea cruris by a negative KOH preparation and fungal culture.

Dermatophyte infections of the skin can usually be successfully managed with topical antifungal agents such as clotrimazole, econazole, ciclopirox, tolnaftate, or terbinafine creams or lotions. These medications are applied twice daily for approximately 2-4 weeks. They should be continued for several days after clinical resolution is apparent. Widespread eruptions or treatment failures may necessitate systemic antifungal therapy, such as griseofulvin, fluconazole, itraconazole, or terbinafine.

Tinea Versicolor

Occurring more frequently in adolescents and adults, tinea versicolor is a superficial fungal infection characterized by multiple slightly scaly macules and patches located on the upper trunk, neck, proximal extremities, and, on occasion, the face. The macular lesions vary in hue (pink, tan, brown, white), hence the name "versicolor." In darkly pigmented or tanned individuals, the macules appear hypopigmented; in fair-skinned persons or during winter months, the lesions usually appear tan-brown. Tinea versicolor is caused by *Pityrosporum orbiculare*, also called *Malassezia furfur*, a dimorphic fungus that is a skin saprophyte. It is generally present in its yeast form, which does not produce a rash. When proliferation of the filamentous form occurs, the organism produces the characteristic lesions of tinea versicolor. Usually asymptomatic or only slightly pruritic, tinea versicolor is primarily a cosmetic disturbance that occurs most commonly in warm and humid environments.

Although the diagnosis is established by the distinctive clinical presentation, a KOH scraping of the fine scale reveals multiple round spores and short, curved hyphae, giving the characteristic "spaghetti and meatballs" appearance typical of this disorder. Wood lamp examination may demonstrate yellow to yellow-green fluorescence, further

FIGURE 48.30 Annular erythematous, scaly plaques with central clearing as seen in tinea corporis. (From Cohen BA, Davis HW, Gehris RP. Dermatology. In: Zitelli BJ, et al, eds. *Atlas of Pediatric Physical Diagnosis.* Philadelphia: Saunders; 2012:299–368.)

supporting the diagnosis (Table 48.2). The differential diagnosis includes postinflammatory pigment alteration, pityriasis alba, vitiligo, contact dermatitis, seborrheic dermatitis, and pityriasis rosea. Tinea versicolor is a chronic condition.

Although usually responsive to therapy, recurrences are common. Application of 2.5% selenium sulfide shampoo to the affected skin can be very effective. Other topical treatments include broad-spectrum antifungal creams or lotions. In extremely widespread or recalcitrant cases, or in immunosuppressed individuals, oral treatment with fluconazole, itraconazole, or terbinafine may be indicated. After successful treatment, the lesions remain temporarily hypopigmented or hyperpigmented.

ACNE VULGARIS

Acne is a very common condition in adolescents, but all age groups can be affected. Open and closed comedones, inflammatory papules, pustules, and nodules are characteristic primary lesions. Scarring and sinus tracts are present in moderate-to-severe forms. Androgens stimulate the hair follicle unit leading to hyperkeratosis of the follicular epithelium and increased sebum production resulting in follicular plugging. The microscopically plugged follicle is clinically apparent as a comedo. With further accumulation of keratin and sebum, the follicle wall may rupture and elicit an inflammatory reaction as contents are released into the surrounding dermis. Clinically, this corresponds to inflammatory lesions ranging from inflammatory papules and pustules to nodules or cysts. *Propionibacterium acnes*, an anaerobic follicular diphtheroid, contributes to the inflammatory process.

The diagnosis of acne is a clinical one; skin biopsies and other diagnostic studies are not necessary. In some cases of midchildhood acne (1-7 years of age), or associated signs or symptoms of androgen excess (e.g., hirsutism, irregular menses), endocrinologic evaluation may be needed to further elucidate the hormonal factors contributing to formation of acne lesions. Medication-induced acne can be seen in all age groups; the offending medications include glucocorticoids, androgens, hydantoin, and isoniazid.

Treatment of acne varies depending on the types of lesions present and individual tolerance to acne medication. Patients should be instructed to use mild cleansers and oil-free, noncomedogenic moisturizers, sunscreen, and makeup. Antibacterial soaps and cleansers may help reduce surface bacteria. Topical medications include benzoyl peroxide, retinoids, antibiotics and combination products. Retinoids are most effective in decreasing new comedo formation and promoting expulsion of existing comedones by reducing and preventing abnormal keratinization of the follicular canal. Benzoyl peroxide has mostly anti-inflammatory activity as the result of its antibacterial activity with mild comedolytic effects, and can be used as an adjunct to retinoid therapy.

Inflammatory acne, particularly with evidence of scarring, often requires the use of antibiotics, either topically or systemically. Oral contraceptives may also provide a significant benefit for the treatment of acne in women, particularly in those with a perimenstrual flare. **Nodulocystic acne** or recalcitrant severe inflammatory acne is best treated with isotretinoin, a synthetic vitamin A derivative. Given the restrictions surrounding its prescription and side effects, referral to a dermatologist is typically needed to pursue this therapy.

▮ SUMMARY AND RED FLAGS

While the time course of dermatosis often is variable, one should be vigilant to reevaluate skin lesions not following the typical course, to identify skin findings that represent manifestations of underlying chronic disorders or life-threatening disease processes. An ill-appearing child with acute skin findings and systemic symptoms should narrow the focus to specific subsets of disease processes. A careful history and physical examination can help differentiate between disease processes of hypersensitivity such as SJS and TEN, DRESS, and infections (SSSS, HSV, meningococcemia) to determine appropriate acute evaluation and management of these life-threatening entities.
